EAR. Many animals unquestionably enjoy the faculty of hearing to a limited extent, which are found, upon examination, to be unprovided with organs exclusively appropriated to the concentration and transmission of sound. In fact, the sense of hearing is, strictly speaking, only a refinement of the sense of touch. The impressions with which it is conversant arise wholly [ACOUSTICS, in ARTS AND SC. DIV.] from peculiar undulations of the particles of ordinary matter, propagated in obedience to its ordinary laws through the medium in which the animal lives, and impinging more or less immediately upon a sensitive part; they have no necessary dependence, like those of sight, upon the agency of the more subtle fluids; nor have they any connection, like those of smell and taste, with what may be called the chemical properties of matter. If to these considerations it be added that the vibratile substances which are commonly found to inclose the sensorium are not ill qualified to participate in the undulations of the surrounding medium, and carry them onwards to the internal seat of perception, the reader will be prepared to learn that tho only essential part of tho organ of hearing is a nerve, uot materially different from those of common sensation, lodged at a sufficient depth to be secured from external injury, and sufficiently sensitive to be affected by these delicate impulses. This is called the acoustic or auditory nerve.

It is probable that even the lowest animals provided with a nervous system are able to perceive the notices thus conveyed of external objects, and turn them to account in the degree necessary for their security and comfort. But to meet the increasing wauts and minister to the multiplied faculties of the more complete animals, various subsidiary parts are found to be added in something like a regular successiou as we advance upwards in the scale, each lower grade possessing the rudiments of some additional provision more fully developed in the next above, till the organ reaches its greatest amplification and final perfection in man and the other *Mammalia*. The particular use of many of these subsidiary parts has not yet been explained. We know in general that they must increase the force and vividness of the impression; that they afford indications of its direction, and the means of appreciating minute shades of difference in its kind and degree, and in the frequency of its repetition; that some of them add to the security of the organ without impairing its delicacy; and that others serve to adjust its position, and to adapt it to various changes in the state of the atmosphere.

The *Radiata* (Sponges, Polyps, &c.), which constitute the lowest, and in point of variety and number by far the most comprehensive division of Cuvier, appear to be universally unprovided with an organ of hearing; many of them have no nervous system, and are therefore probably altogether devoid of the sense. In some of the *Acalephæ* are bodies very like the otolithes found in the higher animals, but whether these are the commencement of an ear or not is doubtful.

The *Articulata*, which form the next division, are all furnished with a nervous system, and it is likely that they all enjoy the sense of hearing. Indeed, some of them are able to express their feelings and wants to their fellows by means of peculiar sounds, of which the cricket and queen-bee are well-known examples. We find accordingly, that in many of the more perfect species the extremity of the acoustic nerve is expanded upon a simple kind of auditory instrument consisting of a whitish membranous bag of fluid, placed within the head in a somewhat larger cavity, the space between them being also occupied by fluid. This cavity is situated near the outer feelers, or antennæ. When the animal lives in water, it is commonly complete; if in air, there is a round external opening closed by a thin tense and transparent membrane, showing the white colour within, to which the bag adheres, and which receives, concentrates, and transmits the sonorous vibrations of the surrounding medium. This kind of arrangement seems to be necessary, among other reasons, for tho purpose of indicating the direction of the sound, which is probably made known in part by the clearer vibration of the membrane when turned in that direction, and in part by a comparison of the impressions ou the two sides; for this organ, like all others which bring the animal into relation with the outer world, is always double and symmetrical. It may be observed that the nerve distributed to the membranous bag just described is given on by that which supplies the antenna with its exquisite sense of touch: some have thought, but perhaps erroneously, that the faculty of hearing resides in the antennæ themselves.

The parts we have enumerated are all found, with others, in the higher animals, and may be considered as the most essential parts of an organ of distinct hearing. The cavity is called the vestibule; the soft membranous bag of fluid is the vestibular sac; the round external opening is called, from its shape in mau and most other animals, the fenestra ovalis; tho fluids within and without the sac are called respectively the endo-lymph and peri-lymph (ἔνδον, within, περί, around); the latter, being analogous to the fluid discovered by Cotugno in the internal ear of *Mammalia*, is sometimes called, after his name, the Liquor Cotunni.

The principal tribes of the *Articulata* ascertained to possess organs of this kind are tho air-breathing insects of tho orders *Hymenoptera* (Bees), *Orthoptera* (Grasshoppers), and *Coleoptera* (Beetles); the *Arachnida* (Spiders), and the *Decapodous Crustacea*, such as the Lobster and Crab. In the common black beetle they aro very conspicuous, appearing externally in the form of round white points on the head, a little nearer the middle line, and somewhat higher than the base of the long outer antennæ. In the lobster they are contained in a small nipple-like prominence or papilla upon the under part of the moveable base of the antennæ, looking downwards and forwards. This papilla consists of a substance harder and more brittle and probably more vibratile than the rest of the shell.

The *Mollusca*, though placed higher in the scale of animals by Cuvier, do not afford so many examples of animals possessing a distinct organ of hearing as the *Articulata*. Such as have been discovered all belong to the order of the Cephalopods with two branchiæ, or gills, which approach more nearly to the true fishes in their structure than the other mollusks.

In the *Sepia*, or Cuttle-Fish, which belongs to this order, and which may be taken as a type of the rest, there is a protuberance under the elastic gristly integument at the back part of the head which contains the ear. It consists of a pair of symmetrical vestibules, each containing an oval sac filled and surrounded with fluid. On the interior surface of this sac the acoustic nerve is expanded in the form of a white mucous pulp. The sac is supported in the perilymph not only by an adhesion to the inner side of the parietes of the vestibule at the entrance of the nerve, but also by a fine net-work of fibrils which pass from its outer surface to numerous prominent points on the inner surface of the vestibule. There is no fenestra ovalis, or membrane, as in the lobster and the air-breathing insects, but the sac contains a small loose bony or chalky concretion, called an otolithe (οὖς ὠτὸς, the ear, and λίθος, a stone), which answers the same purpose, namely, to indicate the degree and direction of sound; for just as we estimate a weight by poising it in the hand, or, if it be suspended, by gently pushing it from us—thus measuring in our minds the muscular tension necessary to support it, or the force required to overcome its inertia, and conscious of the direction in which we exert our muscles—so, conversely (the weight and inertia of the lapillus always remaining the same), the degree and direction of a vibratory force affecting it from without through the medium of the integuments, the parietes of the vestibule, and the fluids within, may be estimated by a consciousness on the part of the animal of the nature of the stress on the sensitive membranes and fibrils which support it, which by their elasticity restrain and redress the slight movements impressed upon it. This should be borne in mind; for, as we shall see further on, it is in some degree by the exertion of the muscular sense, as Sir Charles Bell has called that by which we judge of weight and tension, that the human ear is enabled to estimate the intensity of sound. Other curious particulars as to the function of otolithes might be enlarged upon; but we have said enough to explain, as we think, the most important of them; and to correct the misstatements of authors who tell us that they are intended to increase the intensity of the vibrations of sound: they appear to us rather calculated to diminish it, as the board floating in the bucket of the water-carrier tends to pevent the fluid from dashing over the side. They undoubtedly play an important part in the organ of hearing, especially in the larger fishes, where they are more numerous, and attain a considerable size; but it is difficult to conceive that they are possessed of any intensative power.

The vertebrated classes of the animal kingdom, comprising the true fishes, reptiles, birds, and the mammals, are all provided with acoustic organs, which are very various in their degrees of complexity, but much exceed in that respect the comparatively simple organs of the inferior divisions.

In the Cartilaginous Fishes, such as the ray and the shark, the vestibule is deeply imbedded in the elastic walls of the back part of the cranium, near its junction with the spine. The fenestra ovalis, closed by a tense transparent membrane, faces upwards, backwards, and towards the middle line. The membrane is placed obliquely at the bottom of a more superficial flattened tubular cavity, which terminates beneath the integument in a kind of forked extremity, and may be considered as a rudiment of the tympanum, or middle ear, of the higher *Vertebrata*, with its Eustachian tube. The inner surface of the membrane is turned towards three sacculi, one of which is much larger than the rest, arranged at the opposite side of the cavity of the vestibule, and containing each an otolithe. The sacs are filled with a thick gelatinous endolymph, which adheres to the lapilli, and serves, with minute filaments, such as those in the *Sepia*, to steady them. The vestibule is filled with a limpid aqueous perilymph, traversed in all directions by a fine cellular network, by means of which its contents are supported in their relative situations. Besides the fenestra ovalis, other perforations lead out of the vestibule into three arched cylindrical canals of considerable diameter and dimensions, the diverging curves of which take a wide circuit within the cranial cartilage, and terminate at both ends in this central cavity. These passages, from their situation and form, are called the anterior, posterior, and horizontal semicircular canals. Within the canals, in which the vestibular perilymph freely circulates, there are three similarly curved but more slender membranous elastic tubes: they are nowhere in contact with the sides of the canals, but are suspended in the midst of them by means of the cellular net-work above mentioned. They all swell out at one end like a flask (ampulla) as they enter the vestibule, after which the anterior and horizontal tubes separately enter a common pouch or sinus; into this their other ends likewise open by a conduit common to both. The posterior tube, which is the largest and longest, after forming its ampulla resumes its former calibre, and passing along the floor of the vestibule under the largest sac, to which it is connected by the network, returns into itself, thus completing a separate circuit.

The fluid contents of the several membranous cavities do not communicate with each other or with the vestibular perilymph; though, as they lie in close apposition, their vibrations are mutually interchangeable.

The acoustic nerve is distributed in two principal branches only to the sacs and the ampullæ; chiefly to the latter, to which it gives a white colour. The filaments form a fine network on the outside of the ampullæ, and then, piercing their parietes, are raised up within into a kind of crescentic screen, in order probably that they may be more exposed to the impulse of the vibrations descending along the aqueous endolymph of the semicircular tubes. All the parts we have described are transparent except the opaque ampullæ and the solid cretaceous otolithes. We have been particular in our account of these membranous parts, which are found with little essential variation in all the superior animals, man included, because in the cartilaginous fishes they admit of more easy examination from their great size and firmer texture, and from the softness of the cartilage that incloses them. In man and the mammals they are not only much smaller and more delicate, but incased in the hardest bone in the body, from which it is almost impossible to separate them with sufficient accuracy to be certain that the description is correct.

In some cartilaginous fishes, as the sturgeon, the fenestra ovalis is not closed by a membrane, but by a round button-like piece of semi-transparent cartilage called an operculum, or lid.

The parts are similar in the osseous fishes, except that they have generally no fenestra ovalis.

In Serpents there is but one sacculus containing chalky matter, and all the semicircular tubes communicate with a central membranous sinus, which the anterior and posterior tubes enter by a common trunk. The fenestra ovalis is closed, not as in fishes by a membrane, but by the expanded trumpet-shaped extremity of a slender bone (ossiculum or columella) attached at the other extremity by a ligament to the outer end of the intermaxillary bone.

Nearly the same arrangement of the internal ear prevails in the Four-Footed Reptiles (turtle, crocodile, frog, lizard); but a new and important step is here made towards the ultimate perfection of the organ by the development of an air-cavity, called the tympanum or ear-drum, between the vestibule and the surface of the head. This addition, which as we said first becomes more than a mere rudiment in the four-footed reptiles, permits the vestibule to be placed with equal advantage at a comparatively greater depth, and therefore in greater security; but it has more important uses in rendering the sound more clear, and facilitating in several ways (to be presently explained) its communication to the auditory nerve. Like the musical instrument from which it takes its name, the tympanum is provided with a membrane tightly stretched upon the margin of a round opening in the outer part of its bony or cartilaginous wall; and has an open vent or passage called after the anatomist who discovered it the Eustachian Tube, leading forwards from the cavity to the throat or back part of the nostrils, by means of which the air within it is adjusted to the variable state of the atmospheric pressure without. If the animal be amphibious, as many of the four-footed reptiles are, the membrana tympani is still covered entirely by integument; sometimes, as in the crocodile, by a moveable flap of the scaly hard skin, which can be raised up when the animal is out of the water. More frequently however the membrane lies entirely beneath the skin, here thinner than elsewhere on the head, as in the tortoise. The *Lacerta agilis*, or Basking Lizard, alone, which lives entirely on the land, has the membrane naked to the air. In this class of animals the columella is not directed forwards to the angle of the jaw as in serpents, but is attached by a cartilaginous extremity to the centre of the membrana tympani, and thus conveys the collected effect of its vibrations directly to the fenestra ovalis: the effect of this arrangement in rendering the impression of sound more definite must be obvious. In some species the cartilaginous portion of the columella is joined to the bony portion at an acute angle, like the letter V, which adds an elasticity to the mechanism very serviceable as a protection to the delicate parts within the fenestra ovalis from the injury they might otherwise sustain by a blow or undue pressure upon the membrana tympani. This is the case with the lizard mentioned above, in which there is also a rudiment of the muscle which serves in the higher animals to tighten the membrane; a circumstance which makes this elbow in the columella a still more essential provision against sudden changes in the distance between the centre of the membrane and the fenestra ovalis. It is worthy of remark that in one class of serpents, the *Cæcilia* (Blind-Worms), the ear is as complete as in any of the four-footed terrestrial reptiles; possessing a tympanum with its membranes, a Eustachian tube, and a columella bent to an angle. This departure from the usual rule in serpents appears to be one of those compensations so frequently met with in the animal kingdom, the organ of sight in the *Cæcilia* being imperfectly developed.

In Birds, besides a greater nicety and tenuity in the conformation of the parts hitherto described, the ear is furnished with two additional provisions, both probably of great consequence to the perfection of the organ. The first is a short meatus auditorius externus, or outer passage, which removes the delicate membrane of the tympanum to some depth from the surface of the head, and thus places it more securely, and at the same time to greater advantage, for observing the direction of sound. The other additional provision in birds is an appendage to the mechanism of the internal ear. This is a small conical cavity in the bone, somewhat curved, with a double spiral ridge winding round the interior, and inclosing a cartilaginous structure so corresponding in form with the ridge as to divide the cavity into two partitions. These communicate with another at the apex, and with the vestibule and tympanum respectively, at their other ends. The cavity is termed the Cochlea, from its resemblance to a spiral shell; the partition communicating with the internal ear is the Scala (winding stair) of the vestibule; the other is the Scala Tympani. The opening from the latter into the tympanum is called the Foramen Rotundum; it is closed by a membrane to exclude the air of that cavity while it permits the transit of vibration to or from the vestibular perilymph within; for that fluid, passing up the cochlea by the scala vestibuli, descends the scala tympani, and bathes the inner surface of the membrane of the fenestra rotunda. The cartilaginous Newel is kept in its place like the semicircular tubes by retiform filaments, and is supplied with a separate branch of the acoustic nerve, which ramifies and expands on its surface. The lapilli, which seem to be chiefly a provision for hearing under water, and are therefore large and solid in aquatic and amphibious animals, appear in birds only as fine crystallised grains of chalk in the utricle or sinus of the vestibule, rendering the endolymph somewhat turbid. The columella is straight, and the membrana tympani pressed outwards by it is consequently convex. There is a crescentic fold of skin extending upwards from the superior margin of the meatus externus, sometimes furnished, as in the horned owl, with a fringe of feathers which can be spread at pleasure like a fan to catch the sound. This fold of skin is a rudiment of the concha, or outer ear, of the *Mammalia*.

As we have already said, it is only in this last-mentioned class of animals that the ear reaches its complete development. It is nearly the same in all of them; the difference being only in the comparative size and shape of the component parts of the organ, and not in their essential structure, number, or arrangement.

We shall therefore describe the organ in one species only.

There is every reason to suppose that in hearing, as in seeing, man has no superiority over many of the lower animals except what arises from that intellectual supremacy which enables him to discriminate and compare his sensations more justly than they can do. Indeed it is certain that in the mere perception of sounds he is inferior to most of the *Mammalia*, and probably to birds; and if the musical faculty should seem to imply a greater perfection of the organ, the error, for such we believe it to be, may perhaps disappear upon reflection. We therefore select the human ear as the type of the organ in *Mammalia*, not because it is in any respect more complete than the rest, but as the most interesting. The same description, of the more important parts at least, might be applied nearly word for word to all.

The parts now to be described fall naturally under a three-fold division into the internal, middle, and external ear.

1. The Internal Ear, comprising the Acoustic Nerve, Vestibule, and Labyrinth, is deeply placed in the interior of the head, within the most compact and hardest of the bones, denominated from that circumstance the petrous or rocky portion of the temporal bone. This wedge-like or triangular projection passes obliquely inward and forward in the direction of the outer tube of the ear, forming a strongly-marked knobby ridge within the cranium, in the basis or floor of that cavity. Near the inner point, which nearly meets its fellow on the other side, and upon its posterior declivity, there is a large trumpet-like hole (meatus auditorius internus) into which the seventh cerebral nerve enters from the medulla oblongata. [BRAIN; NERVE.] The meatus passes in a direction outwards, and therefore obliquely, into the petrous portion for half an inch, and then terminates abruptly in two foveæ, or pits: from the upper of these there goes a winding canal through the substance of the bone, which is the course of the motor nerve of the face (the portio dura of the seventh pair), which, here separating from the auditory nerve, or portio mollis, we need not follow. The latter, splitting into several sets of filaments, finds its way through small sieve-like openings at the bottom of the lower fovea into the internal ear, and is here distributed in three separate portions to the cochlea, the ampullæ of the semicircular tubes, and the utricle or vestibular sac. The cochlea is more complicated than in birds; it consists of a spiral canal in the bone, gradually diminishing as it ascends to a point, wound round a central hollow pillar of bone called the Modiolus, or Newel. From its inner surface, that namely which may be considered as a groove in the modiolus, a thin and spongy lamella of bone projects rather more than half across the canal, ascending in a similar spiral. From the edge of this lamella (called the Lamina Spiralis) a membrane passes to the outer surface of the canal, where it is attached; thus completing the separation of the canal into two scalæ, or winding partitions, which unite at the summit, and open (as before), the lower and narrower into the vestibule, the superior and larger into the tympanum; each scala taking two turns and a half round the modiolus in ascending from the base of the cochlea to the Cupola, or inverted cup-shaped cavity at the summit, placed over the funnel (Infundibulum) into which the top of the modiolus expands. The cochlea is on a level with the vestibule and anterior to it, the base being turned towards the meatus internus; the summit looking outwards and a little downwards, is turned towards the sudden bend of the wide canal in the petrous portion of the temporal bone by which the internal carotid artery enters the cavity of the head. It is the close neighbourhood of this artery as it passes through the compact bone that occasions the rushing sound of the pulse to be heard when the ear is placed upon a pillow, or the attention is led to dwell upon what passes within, by deafness arising from some cause not affecting the parts essential to hearing. The modiolus is hollow to some distance from the base. Up this tubular cavity rises the large cochlear branch of the acoustic nerve, giving off lateral filaments through minute openings arranged spirally, which pass through the light spongy bone, and emerge from different points on the spiral floors and sides of the scalæ, where they ramify in a delicate pulpy expansion upon the membranous tubes which line the spiral osseous canals: the rest of the cochlear nerve passes through capillary perforations in the cul-de-sac of the tubular cavity; and ascending in the substance of the central pillar of the modiolus, is distributed through the bone in a similar way to the upper turns of the cochlea and the infundibulum. The two other branches of the acoustic nerve are distributed to the vestibular sac, which lies in a round depression or pit in the barrel-shaped cavity of the vestibule, and to the ampullæ of the semicircular tubes. The latter all meet in a membranous sinus, or utricle, which occupies another distinct pit of the vestibule, called from its shape the Elliptic Fovea, much according to the arrangement already described in other animals. The principal opening from the vestibule is the fenestra ovalis, situated on the outer side towards the tympanum, which is closed by a membrane. At the lower and front part there is another opening into the scala vestibuli of the cochlea. There are five at its posterior and outer side, which lead into the semicircular canals, of which the superior and posterior enter the vestibule by a common foramen. The sac and utricle each contain a cretaceous deposit called Otoconia, or ear-sand, which in some of the lower *Mammalia* has the consistence of soft chalk. The cochlea and semicircular canals, from their complexity, are termed the Labyrinth. With respect to the object of their peculiar arrangement, not even a probable conjecture has been hazarded. Yet they appear with surprising uniformity in all the *Mammalia*, and some of them, as we have seen, in the more numerous tribes of birds, reptiles, and fishes. The bony canals of the labyrinth and vestibule are stated to be invested within by a delicate periosteum, the surface of which towards the perilymph is thought to be of the nature of a serous membrane, and to secrete that fluid.

Fig. 1.

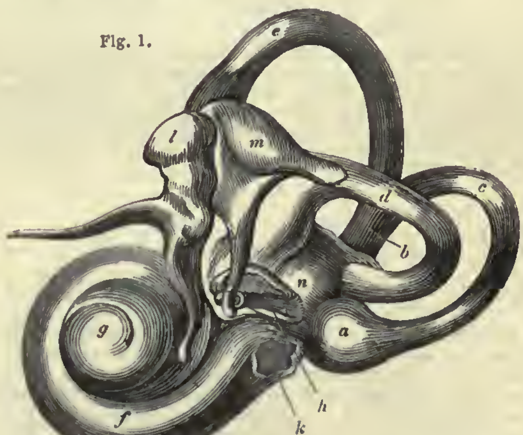

Fig. 1. Magnified view of the osseous labyrinth and vestibule as they would appear if the solid bone in which they are imbedded were removed, with the ossicula auditus in situ: *a*, ampulla of the posterior semicircular canal; *b*, common tube by which this and the superior canal enter the vestibule; *c*, posterior canal; *d*, external canal; *e*, superior canal; *f*, cochlea; *g*, its cupola; *h*, fenestra ovalis covered by the stapes; *k*, fenestra rotunda; *l*, malleus; *m*, incus; *n*, vestibule.

The deafness which arises from causes which affect the fenestra ovalis, or the nerves and canals within the vestibule and labyrinth, is seldom or never cured; and it is unfortunately very common. There is a very easy way by which the nature of the case may be often sufficiently tested. If the internal ear be affected, especially the nerves of it, the ticking of a watch pressed against the teeth or the outer part of the head on that side, will be very obscurely distinguished. If not, the sound can be easily heard, as the solid bones interposed between the sonorous body and the nerve are excellent conductors of vibration.

2. The Middle Ear comprises the cavity of the Tympanum, with its contents; the cells in the bony prominence behind the ear, called the Mastoid Process, with which the tympanum communicates; and the Eustachian Tube, or passage leading from the tympanum into the upper and back part of the throat, where it opens in the form of an expanded slit on each side behind the posterior nares.

The Tympanum is an irregular cavity scooped in the petrous portion of the temporal bone between the vestibule and the external meatus. The principal entrances to it are the fenestra ovalis and the round or somewhat oval opening at the bottom of the external passage upon which the membrana tympana is stretched. Between these there is extended a chain of three small bones, obliquely articulated to each other with perfect joints, so placed that the chain somewhat resembles in figure the letter Z.

These bones are called respectively the Stapes (stirrup), the Incus, (anvil), and Malleus (hammer), from some similarity in form to those implements. The base of the stapes is applied to the fenestra ovalis, exactly fitting it, and is attached firmly to its membrane. The extremity of the longer leg of the incus is articulated to the head of the stapes, and there is a minute bone between them of the size of a small shot, which is generally considered to be only a process of the incus. It is however called from its spherical shape the Os Orbiculare, and is sometimes reckoned as a fourth bone. (*Fig.* 3, o.) The shorter leg of the incus (*fig.* 2, *c*,) rests against the bony parietes of the tympanum at the back part, near the mastoid cells. Upon the hollowed cavity in the head of the incus (*fig.* 2, *a*) the lateral depression of the head of the malleus (*fig.* 2, *k*) is articulated, and moves easily; the long handle of the latter is attached by its extremity (*fig.* 2, *h*) to the middle of the membrana tympani, as well as by a portion of the side of the handle, which lies close to and parallel with the membrane. The long slender process of the malleus called the Processus Gracilis (*fig.* 2, *g*) lies in a slit passing to the articulation of the jaw called the glenoid fissure.

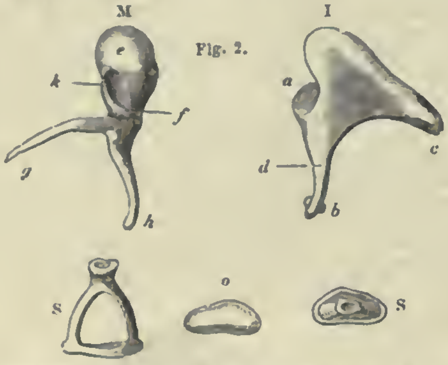

Fig. 2. Magnified view of the ossicula auditus: M, malleus; I, incus; S, stapes; *o*, shape of the fenestra ovalis; *a*, cavity of the incus, which is articulated to the malleus; *d*, longer process of the incus with the os orbiculare attached at *b*; *c*, its shorter process; *e*, head of the malleus; *f*, its short process, or prominent point for the attachment of the tensor tympani; *k*, the depression which articulates with the incus; *g*, processes gracilis of the malleus; *h*, its handle, or manubrium.

Fig. 3.

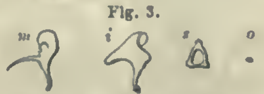

Fig. 3. The same bones of their natural size: *m*, malleus; *i*, incus; *s*, stapes; *o*, orbiculare.

At first sight the use of these bones would appear to be to transmit the vibrations of the membrana tympani to the membrane of the fenestra ovalis, and thence to the internal ear, but when it is found that sounds can be heard with distinctness even when the membrana tympani and the ossicula have been removed by disease, it is evident that this function can be performed independent of them. They have evidently another use which would be incompatible with a single bone passing between those membranes, as in birds and most reptiles; this is to permit the membrana tympani to be drawn into a conical shape so as to tighten it, and adapt it either to resist the impulse of too loud a sound, or favour a more acute or gentle one. The muscle which chiefly effects this object, called the tensor tympani (*fig.* 4, *a*), is attached near the head of the malleus to a point projecting from it. (*Fig.* 2, *f*.) Other muscles, to steady and antagonise its action, called the laxator major and minor tympani are also attached to the malleus, the former (*fig.* 4, *b*) to the processus gracilis, the latter (*fig.* 4, *c*) to the handle of the bone. A further description of the directions and outer attachments of these minute muscles would be tedious and unintelligible to the general reader. No muscle is attached to the incus, but a small one of great importance is inserted into the neck of the stapes, called the stapideus; the effect of this is to counteract the obliquity of traction or tilting of the stapes, which would otherwise ensue from the movements of the other bones; by this means the motion of the stapes is directed either immediately to or from the fenestra ovalis, the membrane of which is also further preserved from injury by the oblique arrangement of the joints of these minute bones, by means of which, although the membrane of the tympanum oscillates through a considerable space in passing from tension to relaxation, that of the fenestra is moved to a much smaller extent. It is to be observed that the same action which draws the membrana tympani into a cone thrusts the base of the stapes farther into the fenestra ovalis.

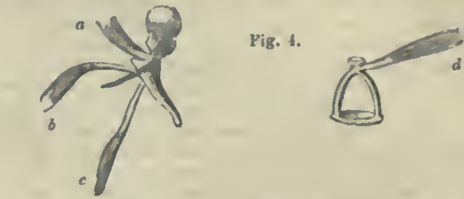

Fig. 4. Muscles attached to the ossicula auditus: *a*, tensor tympani; *b*, laxator major; *c*, laxator minor; *d*, stapideus.

These small muscles are not under the dominion of the will, being supplied with nerves in a way peculiarly interesting to a physiologist, and acting automatically in correspondence with the impressions on the auditory nerve. Yet the instinctive consciousness we have of the degree of their contractions in adjusting the tension of the membrana tympani to circumstances, is probably one of our chief means of estimating the intensity of sounds.

The fenestra ovalis is situated nearly opposite the membrana tympani, on the upper edge of a prominence called the Promontory; it faces outwards and a little downwards; and beneath it, concealed by the promontory, is the foramen rotundum, closed by a membrane, and leading into the cochlea by the scala tympani. The object of this last opening is disputed: some think it conveys in part the vibrations of the air of the tympanum to the internal ear; but it seems more reasonable to suppose, with Sir C. Bell, that the end it chiefly serves is to give vent and freedom to those of the fluids pent up in the unyielding bony canals of the labyrinth. Besides these openings from the tympanum, there are others which lead into the mastoid cells behind it; these are also filled with air, and are supposed to contribute to the distinctness of the tympanic vibrations. There is also an opening from the tympanum forwards into the Eustachian tube. This canal is nearly two inches long; the first part of its course from the tympanum is bony: it then becomes cartilaginous, and widens as it approaches the throat, the mucous membrane of which lines it, and thence passing into the tympanum, spreads over the surface of the whole cavity, investing the ossicula and its other contents, as well as the mastoid cells. From this circumstance arises the tendency of the inflammation of cold or sore throat to extend into the tympanum, producing temporary deafness, ear-ache, and sometimes mischief of a more permanent kind. From the deafness which accompanies the closure of the Eustachian tube by that or other causes, the importance of its functions in renewing and giving vent to the air within the tympanum may be appreciated. Besides the foramina already mentioned, there are others through which nerves and vessels enter the tympanum. We have not space to describe them: we shall only mention that one of the nerves, called the chorda tympani, originally connected with the portio dura of the seventh nerve, after traversing the petrous bone in a circuitous course, enters the cavity of the tympanum, and passing quite across it, is transmitted through the glenoid fissure to a salivary gland under the lower jaw. The object of this singular but uniform course of the chorda tympani is not well understood.

Deafness arising from the closure of the Eustachian tube has been sometimes cured by dilating that canal by instruments passed for that purpose into its outer expanded extremity through the nostrils, or from the back of the throat; or by injecting fluids into it by means of a syringe with a small curved pipe. This latter plan has also been successful in curing deafness arising from chronic inflammation or morbid secretion within the tympanum. Suppuration within that cavity or in the mastoid cells sometimes results from high inflammation, and has been attended with fatal consequences by spreading to the bones of the cranium, or along the nerves to the brain or its membranes. Cases of this kind generally originate, as we have already stated, in cold with sore throat, and are found to occur chiefly in scrofulous habits.

3. The External Ear consists of the Meatus Auditorius Externus (*fig.* 5, *m*), and Concha. The former, commencing from the membrana tympani, is an osseous canal in the first part of its course in the adult, and then becomes nothing more than a tubular continuation of the expanded cartilage of the concha, or outer appendage of the ear. It is lined throughout with a delicate skin, covered by a thin cuticle, which also covers the outer surface of the membrane. Beneath the skin, and opening through it on the surface, are numerous glandular follicles which secrete the ear-wax or cerumen. In the fœtus and new-born infant there is hardly any appearance of this tube; the membrane of the tympanum being close to the surface of the head, stretched upon the inner margin of a bony ring (annulus auditorius)

which afterwards increases in length and becomes a tube. In the adult the length of the whole tubo may be nearly an inch; but from the obliquity of the membrane, which faces a little downwards, it is longer below than above. Its direction from the membrane is outwards and a little backwards, and it is slightly convex upwards, and rather narrower in the middle than elsewhere. The last-mentioned peculiarity is the reason why it is so much easier to introduce beads and other round bodies (as children are apt to do) than to get them out. This however must always be done as soon as possible when such an accident happens; for the presence of the foreign body sometimes excites great inflammation and swelling, and may lead to very

Fig. 5.

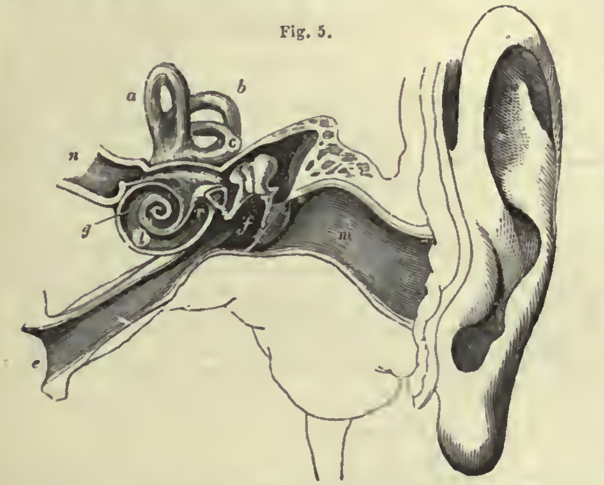

Fig. 5. This is not to be considered as a correct delineation of the organ, being intended only as a diagram, to give a general idea of the relative situations of the several parts: *a*, superior semi-circular canal; *b*, posterior ditto; *c*, external ditto; *d*, scala tympani of the cochlea opened, to show *r*, the fenestra rotunda, entering the tympanum under the promontory; *e*, Eustachian tube; *f*, membrana tympani; *g*, vestibule, not laid open; *m*, meatus auditorius externus; *n*, meatus internus, terminating in two foveæ.

serious consequences. The most easy method and the least painful is to direct a strong stream of warm water into the tube with a syringe, which commonly succeeds immediately if resorted to before there is much swelling. Other means will readily suggest themselves; but if resorted to, they should be very tenderly used, for the part is extremely sensitive, especially the membrane itself, to rough contact. The wax, which is very bitter, serves to prevent the entrance of insects and to keep the skin soft. When secreted too abundantly, it is often a cause of deafness, and should be removed as a foreign body by means of a syringe and a solution of soap in warm water. The commonest kind of ear-ache is that caused by inflammation of this passage, and is generally followed by a copious and fœtid secretion poured out by

Fig. 6.

Fig. 6. View of the pinna, or auricle. The cartilaginous prominences are, *a*, helix; *b*, anti-helix; *d*, tragus; *e*, anti-tragus; the lobe or lobulus, *g*, contains no cartilage, being composed only of skin and a fatty cellular tissue. The depressions are *c*, the scapha or scaphoid (boat-like) fossa; and *f*, the concha, a term often used to denote the whole appendage of which it is the most important part.

the ceruminous follicles. If this last long, deafness is sometimes the result from thickening of the membrane, and has been removed, as well as that arising from closure of the Eustachian tube, by puncturing the membrane. This part is sometimes ruptured by the spasmodic action of the tensor muscle caused by loud sounds, or by driving air up the Eustachian tube in a forcible expiration, as in blowing the nose violently. This accident is not followed by the degree of deafness that might be expected, unless the stapes becomes displaced from the fenestra ovalis: the other ossicula may be lost with comparative impunity for obvious reasons.

The concha, or pinna, or auricle (for by all these names the outer appendage of the ear is known), consists of several pieces of elastic cartilage expanded in a form more or less resembling an ear-trumpet in different animals. In man it serves the purpose of collecting the sonorous vibrations and directing them into the meatus externus much less perfectly than in many other animals, which are also provided with muscles for directing it to the source of sound, which in man are but rudimentary. It is marked with various prominences and hollows, of which the names are given in the figure. It does not seem necessary to describe them more particularly. The cartilages are bound by ligaments to the neighbouring prominences of bone, and are covered by a smooth and closely adherent skin.

It may be observed that the Aquatic *Mammalia* (Whales, Porpoises, &c.) are unprovided with this part of the organ; and have a very narrow but long and curved meatus externus, passing obliquely into the surface of the head, and in some instances capable of being closed by a flap of moveable skin to exclude the water. In these animals also the cochlea is imperfect, the scalæ making but one turn and a half round the modiolus. For an account of diseases of the ear, see DEAFNESS, in ARTS AND SC. DIV.

EAR-SHELL. [HALIOTIDÆ.]

EARTH-NUT. [BUNIUM.]

EARTH-NUTS are either the fruit of certain plants which bury it below the ground after the flowering is past, as the *Arachis hypogæa*, *Lathyrus amphicarpos*, and others, or else the subterranean tubercles of fleshy-rooted plants, such as *Bulbocastanum*, *Cyclamen*, *Lathyrus tuberosus*, *Apios tuberosa*, and the like.

EARTH-WORM. [ANNELIDA.]

EARWIG. [FORFICULIDÆ.]

EBENA'CEÆ, *Ebenads*, a natural order of Monopetalous Exogenous Plants with the following essential characters:—Flowers either with separate sexes, or occasionally hermaphrodite. Calyx permanent, with from three to six divisions. Corolla monopetalous, regular, of a thick leathery texture, usually downy on the outside, with the same number of divisions as the calyx. Stamens twice or four times as numerous as the lobes of the corolla, adhering to its tube, and usually in two rows; sometimes adhering in pairs. Styles several. Fruit fleshy, superior, with only one pendulous seed in each cell. Embryo lying in much albumen, with large leafy cotyledons and a long taper radicle. The species consist entirely of bushes or trees, some of which are of large size; their leaves are alternate, with no stipules, and generally leathery and shining. They are chiefly Indian and tropical species. A few occur at the Cape of Good Hope and in Australia. This order is related to *Aquifoliaceæ*, *Oleaceæ*, and *Sapotaceæ*. There are 9 genera and 160 species. *Diospyrus Ebenus*, and some others, yield the valuable timber called ebony. The fruit of *D. Kaki* is about as large as an apricot, and is dried as a sweetmeat by the Chinese. Most of the plants of this order are tropical; of the few found beyond the tropics, *D. Lotus* inhabits Africa and Switzerland, and *D. Virginiana* the United States. [DIOSPYRUS.]

A branch of *Diospyrus Lotus* in fruit: 1, a flower; 2, a corolla, cut open; 3, the calyx and ovary; 4, a section of a ripe fruit, showing the seeds.

EBONY. [DIOSPYROS.]

EBURNA. [ENTOMOSTOMATA.]

ECCREMO'CARPUS, a genus of Plants belonging to the natural order *Bignoniaceæ*. *E. scaber* is a climbing plant, inhabiting thickets and hedges in Peru and Chili, and scrambling among the branches of bushes and small trees. It has an angular cinnamon-brown stem, with pale-green succulent branches; opposite pinnated trifoliolate leaves, with obliquely cordate serrated leaflets, and a terminal tendril; horizontal racemes of tubular orange-scarlet obliquely ventricose flowers, the limb of whose corolla is narrow and 5-lobed; and remarkable oval compressed pods covered all over with short tubercles, and opening into two thin convex valves, within which is placed a number of thin winged netted seeds. It is a handsome half-shrubby plant, which will live in the open air in the milder parts of England. By some it is called *Calampelis scabra*.

ECCULIO'MPHALUS, a genus of Fossil *Gasteropoda*, from the Mountain Limestone chiefly. (Portlock.)

ECHENEI'S, a genus of Fishes belonging to the section of Subbrachial *Malacopterygii* and the family *Echeneidæ*. The body is elongated, covered with very small scales; a single dorsal fin placed opposite the anal; the head very flat, covered with an oval disc formed by numerous transverse cartilaginous plates, the edges of which are directed backward; the mouth wide, with numerous small recurved teeth on both jaws, the tongue, and the vomer. (Yarrell.)

The species of this genus are not numerous. Cuvier enumerates four, and another has been described from the West Indies. They are all easily recognised by the peculiar adhesive disc on the top of the head, by means of which they attach themselves to other fishes, the bottoms of vessels, or other objects floating in the sea. The object of this contrivance is not very well ascertained.

E. remora, the Common Remora, or Sucking-Fish, is found in the Mediterranean Sea, and was known to the Greeks and Romans. Dr. Turton once took a specimen of this species riding on a codfish in Swansea Bay. The following is Mr. Yarrell's description of the sucking apparatus:—

"The disc of the adhesive apparatus in the specimen now described, with seventeen transverse laminæ, was one-third of the whole length of the fish, not including the caudal rays; the breadth one inch and one quarter. The margin is free, flexible, and of considerable breadth, to secure perfect contact with the surface to which it is opposed; the parallel laminæ are represented as only slightly elevated: the degree of adhesion is in proportion to the power used to raise the inner surface of the disc in a direction perpendicular to the plane of contact. The figure on the right side represents the inner surface of the posterior half of the disc. The vertical direction of the moveable laminæ is effected by sets of muscles going off obliquely right and left from two elongated bony processes, one on each half of each of these moveable divisions. The contraction of these muscles acting upon these levers, raises the external edges of the parallel divisions, increasing the area of the vacuum; and it will be observed that the points of the moveable transverse divisions to which the muscles are attached, are nearer the middle line than the outer edge, by which the chance of interfering with the perfect continuity of the free margin, and thereby destroying the vacuum, is diminished. All the bony laminæ, the outer edges of which are furnished with rows of minute tooth-like projections, are moved simultaneously, like the thin vertical divisions of our common window-blinds, by means of the mechanical contrivance on the framework. The longer muscles placed nearer the outer oval edge are probably instrumental in preserving the contact of the more flexible margin, and the serrated external edges of the parallel laminæ help to preserve the degree of elevation obtained: the adhesive power as before observed, is in proportion to the area of the vacuum."

ECHEVERIA, a genus of Plants named after M. Echeveri, author of the drawings in the 'Flora Mexicana.' It belongs to the order *Crassulaceæ*. It has a 5-parted calyx, the sepals erect, united at the base. Petals united at the base, erect, thick, stiffish, thickest at the middle nerve, and nearly trigonal at the base, acute. Stamens 10, shorter than the petals, and adnate to them at the base. Scales 5, short, obtuse. Carpels 5, ending each in a subulate style. The species are succulent shrubs, natives of Mexico. None of the species are used in the arts or medicine, but their handsome leaves and showy flowers give them a place in every collection of plants. The genus is closely allied to *Sedum*, and many of the species resemble that genus.

ECHIDNA (Cuvier), *Tachyglossus* (Illiger), a genus of Monotremes, *Monotremata* (Geoffroy), the third tribe of the order *Edentata* (Cuvier's sixth order of Mammifers) none of which have any incisor teeth in either jaw.

Dental formula 0.

The following are the characters of this genus:—Muzzle elongated, slender, terminated by a small mouth furnished with an extensible tongue, similar to that of the ant-eaters and pangolins. No teeth, but the palate armed with many rows of small spines directed backwards. Feet short, very robust, and formed for digging, each armed with five long claws. Tail very short. Body covered with spines like that of the hedge-hog. Stomach ample and nearly globular; cæcum moderate. Leur verge se termine par quatre tubercules.

Of this curious genus, zoologists are agreed that only one species has been yet discovered, though two have been recorded, namely, *Echidna Hystrix* and *Echidna setosa*, the so-called two species being the same animal in the clothing of different seasons, or of different periods of age. This species is the *Myrmecophaga aculeata* and Porcupine Ant-Eater of Shaw, *Ornithorhynchus aculeatus* of Home, *Echidna Hystrix* and *Echidna setosa* of G. Cuvier, *Echidna Australiensis* of Lesson, Hedge-Hog of the colonists at Sydney.

Skull of *Echidna*.

The size is about that of the common hedge-hog. The spines are dirty-white for the greatest part of their length, and black at their extremity. Hair of a chestnut colour, soft and silky, in such abundance, at a certain season, as to half cover the spines, whilst, at another, the hair entirely disappears.

This animal lives on ants, which it captures with its extensile tongue.

The habits of the *Echidna* in a state of nature are but little known. It digs for itself burrows, wherein it remains during the dry season, coming out of the earth only during the rains. It is supposed to be capable of supporting a long abstinence, and has intervals of suspended animation (engourdissemens), which continue for eighty hours at a time, and recur frequently when the animal is kept in confinement. For protection the animal is said to be able to roll itself up like a common hedge-hog.

Porcupine Ant-Eater (*Echidna Hystrix*).

Lieut. Breton had an *Echidna* which lived with him for some time in Australia, and survived a part of the voyage to England. The animal was captured by him on the Blue Mountains: it is now very uncommon in the colony of New South Wales. It burrows readily, but he does not know to what depth. Its strength he considers as exceeding, in proportion to its size, that of any other quadruped in existence.

Previous to embarkation, Lieutenant Breton fed his *Echidna* on ant eggs (pupæ) and milk, and when on board its diet consisted of egg chopped small, with liver and meat. It drank much water. Its mode of eating was very curious, the tongue being used sometimes in the manner of that of the chameleon, and at others in that in which a mower uses his scythe, the tongue being curved laterally, and the food, as it were, swept into the mouth: there seemed to be an adhesive substance on the tongue, by which the food was drawn in. The animal died suddenly off Cape Horn, while the vessel was amidst the ice; perhaps in consequence of the cold, but not improbably on account of the eggs with which it was fed being extremely bad.

Lieutenant Breton concurs with Messieurs Quoy and Gaimard in thinking that there would be little difficulty in bringing the *Echidna* to Europe, and the following plan is suggested by him for effecting its importation:—

Previously to embarkation the animal should be gradually weaned from its natural food (ants). This may be done by giving it occasionally ants and ant-eggs, but more generally milk, with eggs chopped very small, or egg alone. It should be kept on shipboard in a deep box, with strong bars over the top, and a door. The box or cage must be deep, because the animal constantly tries its utmost to escape; and, as it possesses very great strength, it is liable to injure itself in its exertions to force its way through the bars. Its excrements are so extremely fetid, that it cannot be kept altogether in a cabin, unless the cage be frequently cleaned. While this is being done, the *Echidna* may be allowed its liberty, but must be narrowly watched, or it will certainly go overboard. It is absolutely necessary that the eggs on which it is fed during the voyage should be as fresh as possible: they can be preserved in lime-water. If milk is not to be procured, water must be supplied daily; and egg and liver, or fresh meat, cut small, should be given at least every alternate day. When the weather will permit, it should be fed once a day. Half an egg, boiled hard, and the liver of a fowl or other bird, will suffice for a meal. The animal should be kept warm, and should be well supplied with clean straw. It will be as well to nail two or three pieces of wood (battens) across the floor of the cage, to prevent the animal from slipping about when the ship is unsteady. ('Zool. Proc.,' 1834, Part 2.)

It inhabits the Blue Mountains, &c., the environs of Port Jackson, and Van Diemen's Land.

ECHINARACHARIAS. [ECHINIDÆ.]

ECHINASTRÆA. [MNADREPHYLLIŒA.]

ECHI'NIDÆ, a family of Radiated Animals, comprehending those marine animals popularly known by the name of Sea-Eggs, or Sea-Urchins (Oursins of the French).

De Blainville makes the *Echinidea*, the second order of the class *Echinodermata*, and he thus defines the order:—

Body oval or circular, regular, sustained by a solid shell, which is calcareous and composed of polygonal plates, disposed in radiated order in 20 rows, which are either equal, or alternately and regularly unequal. The shell supports upon proportionable mamillary projections stiff spines which are extremely variable in form, and is pierced by a series of pores, forming by their assemblage a kind of ambulacra. It radiates more or less regularly from the summit to the base, and gives exit to tentaculiform cirrhi. Mouth armed or unarmed, pierced in a notch of the shell invariably on the lower side. Vent always distinct, but offering many variations in its position. Generative orifices four or five in number, disposed round the dorsal summit.

The Sea-Urchins are a family of considerable interest both to the zoologist and geologist. To the first they offer the most perfect examples of the type of radiate animals, whilst their hard covering and habits of living in the sand, have preserved them in many rocks of the strata of the earth for the study of the geologist. They are distinguished from the other *Echinodermata* by their form, which is more or less rounded without arms of any kind. Calcareous matter is deposited within their integument so as to form a series of regular plates, which are studded with tubercles, bearing jointed on them spines of various forms and sizes according to the genus or family. These spines are sometimes small in proportion to the size of the body, but in others they are singularly large, and excite wonder as to how they can be employed by the animal. These spines have a beautiful microscopic structure, being composed of cells which are arranged around a common centre, almost in the same manner as the zones of wood in a tree. (Carpenter 'On the Structure of Shells.') As in other *Echinodermata*, the Sea-Eggs have ambulacra variously arranged, perforated with pores for the exsertion of suckers, or feet. The ovarian holes are seated on the apex, whence the eggs are extruded. There are two openings for the digestive apparatus—a mouth, always placed below and sometimes connected with an internal dental apparatus, and a vent, which is very variable in its position. The intestine is winding, and is attached to the inner surface of the shell by a mesentery, the surface of which, as well as of the membrane, lining the shell, is covered with vibratile cilia, and undoubtedly serves for respiratory purposes. The ovaries are placed in the spaces between the ambulacra. The vascular system is more or less complicated, having a portion with muscular parietes, and exhibiting pulsations. Van Beneden has asserted the existence of a nervous system in the *Echinidæ*, but no one has yet confirmed his observation.

The Sea-Urchins progress by means of the joint action of their suckers and spines. Many of them moor themselves also by means of suckers, and thus adhere firmly to the rocks. Professor Agassiz denies that they adhere by means of their suckers, or that these organs serve the purposes of progression. This is however opposed to the observations of the majority of naturalists, and Professor E. Forbes refers especially to this point for the purpose of giving his unqualified opposition to the assertion of Professor Agassiz. As to what uses these organs are applied to, if not for progression, Professor Agassiz states that "we are yet unable to solve."

The Sea-Urchins are free throughout their existence, unlike the *Asteriadæ*, in which we find a fixed condition in the earliest periods of their development. [ECHINODERMATA.]

With regard to the classification of the *Echinidæ*, Professor E. Forbes remarks that there has been "a tendency to an extreme multiplication of genera."

Breyn, Klein, Linnæus, Leske, Lamarck, Cuvier, Gray, Desmarest, Goldfuss, Von Buch, Desmoulins, Agassiz, and E. Forbes, are the principal zoologists who have undertaken the classification of the *Echinidæ*. De Blainville observes that the relative position of the mouth and the vent, and above all, of the ambulacra, are the principal points on which most of these writers have rested; and as he considers that this mode of viewing the subject has led to approximations not very natural, he proposes a system based on the following grounds:—

1st. On the general form of the body of the animal, which, at first subradiated, becomes by little and little completely radiated in all the parts which constitute it.

2nd. Upon the position of the mouth, which, nearly terminal and transverse, or bilabiated, in the first species, becomes completely central and circular in the last.

3rd. On the arming of this mouth, which, completely null in a great proportion of the *Echinidæ*, is, on the contrary, very powerful in the rest.

4th. Finally, on the position of the vent, on the number of ovaries and their orifices, on the nature of the spines and the tubercles which support them, as well as on the disposition of the ambulacra.

Synoptical Table of the Genera, according to De Blainville:—

Mouth	Subterminal		*Spatangus.* *Ananchites.*
	Subcentral	Without teeth	*Nucleolites.* *Echinoclypeus.* *Echinolampas.* *Cassidula.* *Fibularia.* *Echinoneus.*
		Armed with teeth	*Echinocyamus* *Laganus.* *Clypeaster.* *Echinodiscus.* *Scutella.*
	Central; Vent	Infra-lateral	*Galerites.*
		Central	*Echinometra.* *Echinus.* *Cidaris.*

Sub-Family 1. *Excentrostomata.*

Spatangus.—Body oval, more or less elongated, heart-shaped, wider before than behind, with a furrow more or less profound at the anterior extremity. Shell delicate, of little solidity, composed of large polygonal plates, not many in number. Spines short, flat, sessile, and scattered. Ambulacra incomplete, only four in number. Buccal notch more or less anterior, transverse, bilabiated, circumscribing a mouth without teeth. Vent terminal, and rather above than below the border. Genital pores four in number, disposed in two pairs. The species are very numerous, and are subdivided by De Blainville and others into sections according to their shape, &c. The following is De Blainville's method:—

a. Species whose ambulacra are not petaloid, and form scarcely but two lines, a little broken or bent at their internal side, and which have a rather deep anterior furrow, and the mouth not much in front.

S. arcuarius of Lamarck, the Common Heart-Urchin, may be taken as an example of this section. It is the *S. pusillus* of Leske; *S. cordatus*, Fleming; *S. flavescens*, Müller; *Echinus spatangus*, Linnæus; *E. pusillus*, Gmelin; *E. cordatus*, Pennant; *Amphidotus pusillus*, Agassiz. It is the commonest form of *Spatangus* in the European seas. It abounds in all the bays of Great Britain, and after storms is cast on shore. Popularly it is called in England the Mermaid's-Head, the Child's-Head Urchin, the Hairy Sea-Egg.

β. Heart-shaped species, with five deep and straight dorsal furrows, in which the ambulacra are hidden. Ex. *S. Atropos.*

γ. Species whose ambulacra are petaloid, going from a centre, and which have an antero-dorsal furrow more or less deep, occupying the place of the fifth ambulacrum; the posterior pair shorter than the anterior. This section is divided into sub-sections, according to the depth of the ambulacra.

S. purpureus, the Purple Heart-Urchin, is an example of this section. It is found in the seas of Great Britain, and is one of the handsomest species of the whole family. It grows to the length of 4 inches by 3¼ inches broad. It is of a deep purple colour, with pale spines; some of the spines are very long and curved.

δ. Species whose anterior furrow is much less deep, or nearly null, and whose ambulacra, more or less petaloid, to the number of four, occupy the greatest part of a sort of dorsal plate, circumscribed by a sinuous line without tubercles or spines. This section includes the genus *Brissus* of Klein.

B. lyrifer (Forbes), the Fiddle Heart-Urchin, is a British species, and may be taken as an example of the section. This species has been taken by Professor E. Forbes in various localities in the æstuary of the Clyde, off the island of Cumbury in Rothsay Bay and the Kyles of Bute. It is a handsome and remarkable species. It has a red body with pale yellowish-white spines, and the dorsal and post-anal impressions of a rich brownish-purple. It inhabits mud at the depth of from 10 to 15 fathoms.

ε. Heart-shaped species, rather strongly widened and notched in front, with five distinct and truncated ambulacra. Ex. *S. gibbus.*

ζ. Species whose anterior furrow is still distinct; whose ambulacra, to the number of four, are marginal, and sometimes complete, or reaching up to the mouth; and whose genital pores are five. This section is subdivided into two, according to the extent of the ambulacra, the first (ex. *S. subglobosus*), with ambulacra only reaching the circumference; the second (ex. *S. cordatus, Ananchites cordatus*, Lam.), with ambulacra reaching to the border.

De Blainville supposes that the *Spatangi* are nourished with the animal matters which are mingled with the sand; for their intestinal canal, which is thin as a spider's web, was always found by him full of fine sand.

Ananchites (fossil only).—Body oval in its longer diameter (from before backwards), rounded and a little wider, but without a furrow, anteriorly, subcarinated posteriorly, conical, elevated at its summit, which is mesial, entirely flat below, covered with a very few small scattered tubercles. Ambulacra, to the number of five, rather large, divergent, comprised between double lines of pores but little approximated, and scarcely overpassing the borders. Mouth and vent subterminal and inferior. De Blainville subdivides this genus into two sections; the first, with the ambulacra prolonged up to the borders (*Ananchites*. Lam.), ex. *A. ovatus;* the second, with the ambulacra prolonged up to the mouth (*Echinocorys*, Leske, Gray; *Galea, Galeola*, Klein), ex. *A. pustulosus, Echinocorytes pustulosus*, Leske.

Sub-Family 2.—*Paracentrostomata Edentata.*

Nucleolites (fossil only).—*Echinobrissus* of Breyn and Gray, adding the *Cassidulæ.*—Body oval or heart-shaped, wider and with a large furrow behind, rather convex, the summit sub-central and moderately elevated above, somewhat concave below; covered with small equal and scattered tubercles. Ambulacra, to the number of five, subpetaloid, open at the extremity, dorsal and marginal, and continued by as many furrows up to the mouth, which is inferior, subcentral, and anterior. Vent sub-central, above, in the furrow. Genital pores to the number of four. Ex. *N. depressus, Spatangus depressus*, Leske, Klein; *Clypeus lobatus*, Fleming.

The species are tolerably numerous and are frequent in the Chalk, but are also found in the beds anterior and posterior to it.

Echinoclypeus (fossil only).—Body depressed or conical, circular or inclining to oval, with a furrow behind, convex and with a sub-central summit above, rather excavated below, formed of distinct plates and covered with very small equal tubercles. Ambulacra to the number of five, dorso-marginal, sub-petaloid; the double rows of pores united by a transverse furrow. Mouth sub-central, a little more anterior, pentagonal, with five converging ambulacriform furrows. Vent entirely above, behind the summit, and at the origin of the posterior furrow. Genital pores to the number of four.

Echinolampas, Gray. (*Echinanthus?* Leske).—Body oval or circular, depressed, sub-convex above, rather concave below, rounded and widened forward, rather narrowed towards the anal extremity, composed of great polygonal plates and covered with spines, probably very small. Ambulacra, to the number of five, sub-petaliform, not closed at their extremity, and nearly approaching the border. Mouth round, sub-central, and nevertheless a little anterior. Vent entirely marginal, terminal. Genital pores four only in number. Ex. *E. orientalis* (recent).

Cassidula. — Body oval, more or less depressed, composed of indistinct plates and covered with small spines. Ambulacra five, dorsal, rarely marginal. Mouth below, submedian, in a stelliform notch. Vent postero-dorsal, or above the border. Genital pores four.

De Blainville subdivides this genus into the following sections:—

α. Species whose ambulacra form a dorsal star, and whose mouth is at the bottom of a stelliform impression. Ex. *C. Lapis Cancri.*

β, Species whose ambulacra are prolonged to the border and not closed. Ex. *C. Australis.*

γ. Species whose ambulacra are not known to De Blainville. Ex. *C. scutella.*

De Blainville observes that this genus (Lamarck's) is evidently artificial. Goldfuss unites the genus with *Nucleolites.*

Fibularia.—Body globular, but rather higher than it is wide, ribbed, as it were, with about 20 ribs, formed probably by so many ranks of polygonal scales, and covered with very fine spines. Ambulacra five, very short, and not shut at the extremity. Mouth round, sub-central. Vent inferior, and much approximated to the mouth. Genital pores unknown. Ex. *F. craniolaris.*

This genus was established by Van Phelsum and by Leske, under the denomination of *Echinocyamus*, adopted by Dr. Gray. *E. pusillus* is a British species, and Professor E. Forbes says it is one of the connecting links between the true *Echini* and the *Spatangaceæ*. It has the teeth of the former and the spines of the latter. It is the least of all the British species, and one of the smallest of the family. Mr. Forbes says, "I believe the *Fibularia ovulum* and *F. tarentina* of Lamarck, and the *F. angulosa* of Deslongchamps, will all prove to be identical with this species."

Echinoneus.—Body rounded or oval, generally excavated below, composed of plates often distinct and covered with small spines. Ambulacra five, large, complete, radiating from the dorsal centre to the mouth, and formed by ambulacral lines, which are very close and impressed. Mouth central or sub-central, without teeth, and pierced in a sub-triangular hole of the shell. Vent towards the border below or even above, in a longitudinal and sub-symmetrical hole of the shell. Genital pores four.

De Blainville subdivides the genus into the following sections:—

α. Oval species, with the anal hole longitudinal and below. Ex. *E. minor.*

β. Circular species, with the vent below and round. (*Discoidea*, Gray). Ex. *E. subuculus.*

γ. Oval species, with the vent entirely marginal, and the genital pores to the number of seven (?) Ex. *E. ovalis.*

δ. Circular species, which are depressed and have a margino-dorsal, non-symmetrical anal opening. Ex. *E. cassidularis.*

Sub-Family 3.—*Paracentrostomata Dentata.*

Mouth subcentral, in a regular notch of the shell, and provided with teeth.

Echinocyamus.—Body depressed, oval, wider behind than before, a little excavated below, covered with rounded tubercles pierced at the summit and rather large in proportion, supported internally by five double inferior ribs, terminating round the buccal notch by as many simple apophyses. Ambulacra dorsal, not marginal, completely open at the extremity, a little enlarged, and forming a sort of cross with dilated branches. Buccal opening sub-central, regular, armed with five teeth as in *Clypeaster.* Vent below, between the mouth and the border. Genital pores four. Ex. *E. minutus.*

De Blainville states that he characterised this genus from a considerable number of individuals of a very small species found in the intestines of a turbot, and which occurs in great quantity in the sand of the coasts of the English Channel, according to Pallas, both on the French and English shores. He adds that, very probably, it is the *Fibularia ovulum* of Lamarck; and that, without doubt, *Fibularia tarentina* belongs to this genus, as well as *Echinoneus placenta* of Goldfuss.

Lagana, Gray (*Echinodiscus*, Van Phelsum, Leske).—Body depressed, circular or oval lengthwise, a little convex above, concave below, with an entire disc and borders, composed of plates, but little distinct and covered with scattered spines. Ambulacra five, regular, petaloid, shut, or nearly so at the extremity, with the pores of each side united by a furrow. Mouth median in the middle of a hole, with converging furrows and furnished with teeth. Vent inferior, pierced in a regular hole, situated between the mouth and the border. Genital pores five. The genus is thus subdivided by De Blainville:—

α. Circular species. Ex. *L. orbicularis.*

β. Oval species. Ex. *L. ovalis.*

γ. Polygonal species. Ex. *L. decagona.*

The genus approximates to *Clypeaster*, under which Lamarck arranges the species.

Clypeaster.—Body much depressed, rounded and rather thick on the borders, sometimes incompletely orbicular or radiated, enlarged towards the anal extremity, composed of large and unequal plates, covered with very small, equal, scattered spines supported on very small tubercles pierced with a pore. Ambulacra constantly five in number, dorsal, petaloid, the two rows of pores of each branch united by a furrow. Mouth central or sub-central, at the bottom of a sort of tunnel, formed by five grooves and armed with five teeth. Vent terminal and marginal. Genital pores to the number of five.

The living species are but few. They inhabit the seas of warm countries—in Asia and America. Ex. *C. rosaceus.*

The fossil species are more numerous and are generally from the Tertiary Beds.

Echinodiscus.—Body rounded, depressed, sub-quinquelobated (the posterior lobe a little notched in the median line), rather conical above, concave below, composed of plates in 20 rows, placed two and two. The ambulacraires narrower and covered with very small, fine, close-set spines. Ambulacra to the number of five, diverging by the complete separation of each double line of pores. Mouth median, round, towards which converge five straight and stelliform furrows. Vent marginal. Genital pores to the number of four. Ex. *Echinus Parma.*

Echinorachnius placenta, Gmelin, the Cake-Urchin of Forbes, is the *Echinodiscus placenta* of Blainville, *Scutella placenta* of Lamarck. It is described by Forbes as a British species. It has however been seldom taken on our coasts.

Scutella (*Mellita*, Klein; *Echinodiscus*, Leske).—Body irregularly circular, wider behind, extremely depressed, borders nearly sharp-edged, sub-convex above, a little concave below, composed of large polygonal scales, and covered with very small uniform and scattered spines. Ambulacra 5, more or less petaliform, the two rows of pores of each branch united by transverse furrows, which makes them appear striated. Mouth median, round, furnished with teeth, and towards which converge five vasculiform furrows more or less ramified, and sometimes bifid from the base. Vent always inferior and at some distance from the border. Genital pores 4.

The recent species of *Scutella* are arranged as follows:—

α. Species whose disc alone is perforated. Ex. *S. hexapora.*

β. Species whose disc and borders are perforated. Ex. *S. tetrapora.*

γ. Species whose border only is notched. Ex. *S. aurita.*

δ. Species whose disc and border are entire. Ex. *S. integra.*

ε. Species whose disc is perforated and their border multidigitated. Ex. *S. octodactyla.*

ζ. Species whose disc is imperforate and the border multiradiated (Demi-Soleils.) Ex. *S. dentata.*

The living species whose habitat is known are foreign, and the South Seas appear to be their principal locality.

The fossil species are tolerably numerous, and occur generally in the Calcaire Grossier of Paris, Grignon, and the environs of Nice.

Sub-Family 4. *Centrostomata.*

Mouth quite central. Summit median. Body regularly oval or circular, covered with tubercles and mamillæ, and consequently with spines of two sorts. Vent variable, ordinarily medio-dorsal.

Galerites (fossil only); *Conulus*, Klein; *Echinoconus*, De Blainville.—Body nearly regularly circular or polygonal, entirely flat below, convex and often conical, with the summit median above, formed of very dissimilar plates, and covered with tubercles of two kinds. Ambulacra complete, narrow, to the number of 4 or 5, dorso-buccal. Mouth central, and probably armed. Vent infero-marginal. Genital pores to the number of 5. The species may be placed in two sections.

α. Species with 4 ambulacra, and consequently with 6 series of plates. Ex. *G. quadrifasciatus.*

β. Species with 5 ambulacra. Ex. *G. vulgaris.*

γ. Species with 6 ambulacra. Ex. *G. sexfasciatus.*

The genus is often found silicified and in casts. The greater portion belong to the Chalk, and a small number to the beds anterior to the Chalk. None have as yet been found iu the more recent strata.

Echinometra (Gray).—Body thick, solid, transversely oval, a little depressed, convex, with the summit (which is median) flat above and arched below, covered with mamillated tubercles of two sorts, and bearing diversiform but always strong and large spines. Ambulacra 5, enlarging themselves below. Buccal opening of the shell large, transverse, with very powerful auricles on its internal circumference. Five sharp teeth at the mouth, with a complicated apparatus, as in *Echinus.* Vent medio-superal, or opposed to the mouth. Genital pores to the number of 5. Ex. *E. atrata.*

The species are found in tho seas of warm climates. They are unknown in those of England and France.

Echinus.—Body in general very regularly circular or sub-polygonal, sometimes slightly transverse, composed of 20 radiated rows, alternately unequal, of polygonal plates bristled with diversiform spines of two kinds, and supported on imperforate mamillated tubercles. Ambulacra constantly to the number of 5, and complete. Mouth central, armed with 5 pointed teeth, supported upon a very complicated internal apparatus. Vent median, superior, or exactly opposite to the mouth. Genital pores to the number of 5.

The food of the species of *Echinus* is generally believed to consist of mollusks and crustaceans. Tiedemann found in *E. saxatilis* small univalve and bivalve shells entire among the excrements, as well as fragments of larger ones. Boso is said to have witnessed an *Echinus* in the act of seizing and devouring a small crustacean. Dr. Sharpey usually found in the intestine of *E. esculentus* small morsels of seaweed for the most part encrusted with *Flustra;* and he says that the excrements, which are in the form of small round pellets about the size of peppercorns, consist chiefly of sandy matter with fragments of shells. But he adds that it would be difficult to say whether these are the remains of digested *Mollusca* or merely a portion of the usual testaceous debris so abundant in sand and mud.

The species of this genus are most abundant in all the seas of Enrope. Several very fine species are natives of the Mediterranean. The following are British species:—

E. sphæra, the Common Egg-Urchin, Sea-Egg, 'Sca'ad Manshead.' It is the *E. marinus* of Lister; *E. esculentus*, Pennant; *E. globiformis*, Lamarck. It has the following characters:—Rows of pores obliquely parallel, three pairs of pores in each row; spines thick, conic, longitudinally striate; striæ broader than the ridges, and transversely striated; primaries scarcely longer than secondaries. (Forbes.) The Common Sea-Urchin is usually of a reddish or purplish colour with white spines. These are in some specimens tipped with purple. It lives in various depths of water, extending its range from the littoral zone to that of the corallines. It is found in greatest numbers on a clean sea-bottom, but inhabits all the shores of Great Britain and Ireland. It is eaten abroad in the same manner as *Echinus esculentus.* Pennant says it is also eaten amongst the poor in England. The ancients deemed it a dainty dish, and ate it both raw and cooked in various ways. They are best when full of eggs, which is in the autumn.

E. miliaris (Leske), the Purple-Tipped Egg-Urchin, has the following characters:—It is depressed, the rows of pores not parallel, three pairs of pores in each row; spines longitudinally striated, shining, smooth; striæ narrower than ridges; primaries long. (Forbes.) This is a small species, and is found in company with tho last, from which it may at once be distinguished by its long purple spines. It is abundant in the Irish Sea, as also on the west coast of Scotland.

E. Flemingii, Fleming's Egg-Urchin. It is the *E. miliaris* of Fleming, but is undoubtedly a distinct species. It is the largest of the British species, measuring from 10 to 14 inches in circumference. It has the following characters:—Rows of pores sub-parallel, three pairs in each row; primary spines thick, much fewer than the secondary, and nearly thrice as long; spines longitudinally striate; striæ somewhat narrower than tho very narrow ridges. (Forbes.)

E. lividus (Lamarck), Purple Egg-Urchin. It is the *E. saxatilis* of Linnæus; *E. lithophagus* of Leach. It has the rows of pores bent, five pair in each row above and centrally, but diminishing in number near the mouth; spines striated; ridges broad, smooth; primary spines longer than secondaries. (Forbes.) In the British Isles this species is peculiar to Ireland, where it is chiefly found in the south. It is always stationary, never quitting the cup-like hole which it appears to form with its spines.

E neglectus (Lamarck), Silky-Spined Egg-Urchin; *E. subangularis*, Fleming. Rows of pores bent, five pairs in each row throughout; spines thick, conic, glistening, longitudinally striate; striæ and ridges equal, transversely striated; primary spines scarcely longer than secondaries. This species has been taken on the coasts of Scotland.

All the species of *Echinus* present upon their integument a number of bodies called *Pedicellariæ.* Whether they are parts of the animal or parasitic animals has not been decided by naturalists. They are however curiously characteristic of many forms of *Echinus* as of other species of *Echinodermata.* [PEDICELLARIA.]

For further remarks ou the *Echinidæ*, and their fossil forms, in connection with the other species of Star-Fishes, see ECHINODERMATA.

ECHINOBRISSUS. [ECHINIDÆ.]

ECHINOCACTUS, a genus of Plants belonging to the natural order *Cactaceæ.* The stem is of an ovate or spheroidal form, the sides being divided into many ribs, upou whose projecting angles are stationed at short intervals little spiny stars, which are the rudiments of leaves, and from whose centre the flowers appear. The latter consist of numerous sepals collected into a tube, an equally large number of petals, numerous stameus, and a filiform style divided into many lobes at the point. The species are very remarkable for the singular forms of their stems, and for the curious manner in which their spines are arranged. They are often moreover conspicuous for the beauty of their large flowers. The genus is extremely near *Cereus*, from which, according to De Candolle, it only differs in having the sepals and petals distinct from each other, not united into a tube. But as *C. triangularis* has its sepals distinct, and all the *Echinocacti* have more or less of a tube, we consider it better to limit the latter to such species as have a depressed or spheroidal form. With such a limitation the *Cereus Eyresii*, one of the most beautiful of plants, will really beloug to the genus *Echinocactus*, of which it has all the habit; otherwise it would be a *Cereus*, to which its stems bear but little resemblance. There are above 30 species enumerated. Most of them are natives of Mexico and the West Indies. A few are found in Brazil. They are known by the name of Hedgehog Thistles.

Echinocactus Eyresii.

ECHINO'CHLOA (from ἐχῖνος, a hedgehog, and χλόη, grass), a genus of Grasses belonging to the tribe *Paniceæ.* It has compound spikes secund in the whole and in each part; spikelets on one side of a flattened rachis, 2-flowered, the inferior flower rudimeutary; 2 glumes, the lower small, 3-nerved, the upper as long as the flower, 5-nerved mucrouate; the outer palea of the sterile flower resembling and equalling tho upper glume. This is a genus of coarse grasses, of which only one species, the *E. Crus-Galli*, grows in Great Britain. It is a strong coarse grass, bearing any climate better than most others, and is found in the vicinity of London. (Babington, *Manual.*)

ECHINOCIDARIS. [ECHINIDÆ.]

ECHINOCLYPEUS. [ECHINIDÆ.]

ECHINOCOCCUS. [ENTOZOA.]

ECHINOCONUS. [ECHINIDÆ.]

ECHINOCORYS. [ECHINIDÆ.]

ECHINOCYAMUS. [ECHINIDÆ.]

ECHINODE'RMATA. Lamarck made his Radiaires Echinodermes consist of three sections:—1st, the Stellirideans (Star-Fishes), including *Comatula*, *Euryale*, *Ophiura*, and *Asterias*; 2nd, the *Echinidæ*; and 3rd, the *Fistulidæ*, comprehending *Actinia*, *Holothuria*, *Fistularia*, *Priapulus*, and *Sipunculus*.

Cuvier's Echinodermes form his first class of Zoophytes, and this class is divided into two orders:—1st, the Pedicillated Echinoderms, containing the great genus *Asterias* and its sub-genera the *Encrinites*, the *Echinidæ*, and *Holothuria*; and 2nd, the Footless Echinoderms, consisting of *Molpadia*, *Minyas*, *Priapulus*, the Lithoderms, *Sipunculus*, *Bonellia*, and *Thalassema*, with its sub-genera *Echiurus* and *Sternaspis*.

De Blanville's *Echinodermata* are placed as his first class of *Actinozoa*, and are divided into three orders:—1st *Holothuriadea* [HOLOTHURIADÆ]; 2nd, *Echinidea* [ECHINIDÆ]; 3rd, *Stelleridea* [ASTERIADÆ]; embracing the *Encrinites* [ENCRINITES]; as well as the Free Star-Fishes, &c.

The *Echinodermata* belong to the Cycloneurose sub-kingdom.

They are characterised by possessing a well-organised skin, under which or attached to it are frequently found plates of solid matter, constituting a kind of skeleton. They have a digestive and a vascular system, and a circular nervous system has been detected in many of the species. A muscular system is constantly present.

Before speaking of the classification of the *Echinodermata*, we shall refer generally to their organisation and structure.

The nutritive apparatus of the *Echinodermata* is very simple; presenting in most of the family a single orifice destitute of teeth in the centre of the lower surface of the body, performing the functions both of the mouth and the anus; but in some presenting a digestive cavity with an orifice for the evacuation of its contents, distinct from that by which the food is taken in. In the 'Catalogue of the Physiological Series in the Museum of the Royal College of Surgeons in London' there are examples of both these modifications.

Illustrative of the first section, consisting of those Star-Fishes which have the digestive cavity simple, or without distinction of stomach and intestine, receiving and expelling its contents by the same orifice, we find No. 432, a preparation of a Star-Fish (*Asterias papposa*, Linn.; *Stella dodecactis*, Link; *Asterias helianthoides*, Pennant; *Stellonia papposa*, Agassiz; and *Solaster papposa*, Forbes). It exhibits the central orifice of the digestive cavity, and a portion of the integument has been reflected on the opposite side of the body, to show the numerous cæca continued from the degestive cavity. No. 433 presents a vertical section of the same species, showing the interior of the same cavity. In No. 434 the integument has been removed from the whole of the anterior part of the body of an *Asterias rubens*, Linn. (*A. glacialis* and *A. clathrata*, Penn.; *Stellonia rubens*, Ag.; *Uraster rubens*, Ag.), showing the membranous digestive cavity, containing some small bivalves. No. 435 is a specimen of *Asterias discoidea*, Lam., from which two rays have been removed, showing the singular and beautifully ramified form of the digestive cavity. The membranous pouches appear to be given off in two series, are sacculated, and strung, as it were, upon a mesentery.

The second modification is shown in No. 435 A, which presents the body of a Star-Fish (*Alecto glacialis*, Leach). Here the alimentary canal is continued in a spiral direction from the cental orifice or mouth, and terminates by a second direct orifice or anus, situated at the extremity of a fleshy tube, which projects forward by the side of the mouth.

De Blainville states that the liver is apparent and rather considerable in the Star-Fishes; it occupies the circumference of the stomach, forming bunches or racemi (des espèces de grappes), which are prolonged more or less into the cavity of the appendages when there are any; at least, he observes, such is the opinion of Cuvier, who is followed by Spix and Meckel. Delle Chiaje, on the contrary, regards these organs as a kind of stomachal cæca (and such an opinion seems to be strengthened by the preparations above noticed), and thinks that the liver is an irregular organ, situated on the upper part or dome of the stomach, of which no other author, according to De Blainville, makes mention, and which he himself had not observed. This organ is a racemose little bag of a yellowish-green or yellow colour, and its contents present a similarity to bile both to the sight and taste.

The very dilatable mouth and gullet of the Star-Fishes is admirably adapted for securing the testaceous mollusks and other animal substances on which the family feed. When the prey is apparently disproportioned to the parts into which it is to be conveyed, the œsophagus or gullet, together with part of the stomach itself, can be protruded and everted so as to draw the desired food into the cavity by the application of the everted surface to it. Thus, the shell-fish is swallowed whole, and specimens still living have been taken from the cavity. At other times the juices of the prey are sucked out, and the exhausted bivalve is left dead with its shell gaping. Not that the old supposition that the Star-Fish succeeded, in this last mode of feeding, by inserting a ray or finger into the gaping shell, and if it found the bivalve too strong for it, got rid of the difficulty and the ray at once, conscious of its power of reproducing another, seems to be at all founded in fact. Star-Fishes have been detected in the act of sucking the juices of *Conchifera* through perforations, and also with their mouths applied to the edges of the valves. From the apparently paralysed state of the bivalves found in such situations, it has been conjectured that the Star-Fish introduces some deleterious secretion within the valves, and thus leaves the mollusk torpid and deprived of the power of closing its valves against the attacks of its destroyer. Star-Fishes are considered, and not without reason, as great enemies to oyster-beds. But it is not on living prey alone that the Star-Fishes feed. They seem to assist materially in cleansing the sea from dead and decomposing animal matter. A human tooth has been found in the stomach of a Star-Fish.

Although there does not appear to be any special organ for respiration in the *Echinodermata*, the oxygenisation of the circulating fluid is extensively provided for by the exposure of the peritoneal cavity, and all the viscera, to the sea-water, which is freely admitted through membranous pipes, which have thence obtained the name of respiratory tubes. "These," says Dr. Sharpey, "communicate at their base with the interior of the body, and are perforated at the summit by an orifice which can be very accurately closed. Most of them are placed in groups or patches, and opposite each group the fibrous membrane, forming the wall of the body, presents on its inside a shallow pit perforated with holes, through which the tubes communicate with the internal cavity. The tubes are formed externally of the superficial layer of the skin, and are lined in the inside by a prolongation of the peritoneal membrane. This membrane lines the parietes of the body, and is reflected over the contained parts; at least it covers the stomach and cæca, and probably also the ovaries and vesicles of the feet; opposite the perforated pits it sends prolongations through the holes into the tubes, as may be easily seen on stripping off a portion of it. There can be no doubt that sea-water enters the peritoneal cavity. The animal slowly distends itself with that fluid, and again, but at no stated interval, gives out a portion of it. This is obvious from the fact that the same animal may be seen distended at one time and flaccid at another. Naturalists are generally of opinion that the water enters and issues by the respiratory tubes, and indeed no other orifices have been discovered. We must however freely own that we have never been able actually to observe its passage through these tubes. The peritoneal membrane seems to be the principal seat of respiration; spread over the viscera and the parietes of their containing cavity, and lining the respiratory tubes, it presents a great extent of surface continually in contact with the surrounding medium; and we have found that a beautiful provision exists for maintaining currents of water along the membrane, and thus effecting that constant renovation of the fluid in contact with its surface, which is required in the respiratory process. These currents are produced by means of cilia. Ciliary currents take place also on the external surface of the body, which probably partakes in the process of respiration. We have moreover observed them within the tubular feet, and on the internal surface of the stomach and cæca. In this last situation they are probably subservient to digestion." ('Cyclopædia of Anatomy and Physiology.')

Tiedemann and Delle Chiaje are the authorities from whom a knowledge of the circulating system of these animals is principally derived; but this part of their organisation is so obscure, that we need not be surprised at the difference which exists in the views of those observers. Thus, the true sanguiferous system is, according to Tiedemann, restricted in a great measure to the alimentary organs and ovaries, and he consequently supposes that the ducts which convey the fluid supplied to the feet afford nutrition to other parts of the body. In other words, he recognises two distinct systems of nutrient vessels; one a true sanguiferous system, consisting of vessels which carry blood, and the other a set of vessels (those of the feet) conveying a nutritious fluid secreted from the blood.

Delle Chiaje contends that the two orders of vessels above alluded to intercommunicate, and so form but one system.

Dr. Sharpey is disposed to conclude, from his own observations, that the vessels of the feet form a system apart from the blood-vessels, as Tiedemann maintained; but he observes that there is considerable reason to doubt whether, as that author supposes, they serve as the nutritious vessels of the parts in which they run; for, according to Tiedemann's description, it does not appear that they ramify in the tissues. Moreover, Dr. Sharpey adds, their contained liquid does not present the usual characters of blood, or of a fluid adapted to nourish the textures. He admits it to be true that there are floating particles suspended in it, but he states that the clear fluid, when filtered, yields no trace of animal matter, but agrees almost entirely in composition with sea-water. Such, at least, was the result of Dr. Sharpey's examination of it in the *Asterias*; and he proceeds to give an account of the proper sanguiferous system, following Tiedemann as his leading authority, but, at the same time, stating the more material points in which Chiaje differs from him, thus—

"In *Asterias*, a delicate vessel runs along the upper surface of each of the cæca. There are, of course, ten such vessels in *A. aurantiaca* (from which the description is taken), corresponding in number with the cæca. They commence near the extremity of the rays, and, receiving branches from the branches and lobes of the cæca, proceed to the central part of the animal, where they terminate in a circular vessel which runs round the upper part of the body on the internal surface. The circular vessel also receives ten branches from the ovaries, and five from the stomach, which, before joining it, unite into two. The vessels described seem to constitute the venous system, and Tiedemann further supposes that the cæcal and gastric veins convey the chyle or nutritious part of the food from the alimentary organs. The circular vein opens into a vertical canal, which descends along the prominent angle between the two rays, inclosed in the same membranous sheath with the sand-canal, and terminates in an inferior circular vessel. The descending canal is dilated in the middle; its comparatively thick brown-coloured parietes are smooth externally, but reticulated on the inside, and composed of interlaced fibres, which Tiedemann found to possess muscular irritability. He accordingly considers this canal as the heart. The inferior circular vessel (which must not be confounded with the circular canal connected with the feet) surrounds the month on the outside or inferior surface; it sends out five branches, which pass into the interior of the body, and are distributed to the stomach, cæca, and ovaries. Tiedemann regards these branches, with the circular vessel from which they proceed, as arteries, and he thinks it probable that their minute ramifications open into the radicles of the veins, though from their delicacy he has not been able to ascertain the fact by injection. Tiedemann's view of the function of the respective vessels is derived solely from a consideration of their anatomical disposition; and while in the same way it may be inferred that the blood circulates in a direction conformable with this view, it must nevertheless be kept in mind that no direct physiological proof of such a course of the blood has been yet obtained. Besides the vessels described, Tiedemann found yet another circular vessel surrounding the mouth on the under surface, and placed more superficially than the last mentioned; it is of an orange colour, and sends a branch along each of the rays in the groove which is on the middle of their inferior surface. He could trace no connection between this vessel or its branches and the rest of the vascular system, and he professes himself at a loss to conjecture what may be its function.

"According to Delle Chiaje, the circular vessel into which the canals of the feet open receives also the veins from the upper surface of the cæca and stomach. The same vessel, which he names the venous sinus, gives out—1, twenty short dental arteries; 2, the mesaraics to the under surface of the cæca; 3, five vertebral arteries which open into the vesicles of the feet; 4, the radial to the under part of each ray; 5, the dorsal arteries to the upper part of the ray, which extend their ramifications to the external surface of the body." ('Cyclopædia of Anatomy and Physiology.')

Professor Owen, in his Preface to the third volume of the 'Descriptive and Illustrated Catalogue of the Physiological Series of Comparative Anatomy contained in the Museum of the Royal College of Surgeons in London,' remarks, that when the nervous system begins to be distinctly eliminated in the form of fibres, it is accompanied by a distinct development of the muscular system; and the digestive canal is provided with a proper contractile tunic, and floats freely in an abdominal cavity. He observes that the nervous fibres in the classes of animals in which they are first discernible proceed from a ganglion or ganglions in the neighbourhood of the mouth, and extend in a radiated or longitudinal direction according to the form of the body, but are not afterwards brought into communication by ganglionic masses.

"The Echinoderms, as the Star-Fish and Sea-Urchins," writes the Professor, "first present these conditions of the nervous, muscular, and digestive systems. A very gradual transition from the radiated to the elongated form is traceable from this class through the *Holothuriæ* and *Sipunculi* to the cavitary *Entozoa* or *Cœlelmintha* (intestinal worms having an abdominal cavity), and thence to the *Epizoa* and *Rotifera*, which make a near approach to the annulose division of the animal kingdom; but at the same time do not possess that structure of the nervous system which is its true characteristic. The four classes of animals, thus distinguished by a common character of the nervous system from the *Acrita* on the one hand, and the *Articulata* on the other, constitute a second division of the animal kingdom, which may be termed *Protoneura*."

The preparation No. 1292 A, in the series illustrative of the nervous system of the *Nematoneura* is a Star-Fish (*Asterias papposa*, Lam.) with the membrane removed from the oral surface of the central disc, to show the simple nervous chord surrounding the mouth and distributing filaments to each ray. These filaments run in the interspace of the tubular feet, extending from between the spines which protect the ambulacral grooves. ('Catalogue.')

Tiedemann, who discovered the nervous system in these animals, describes it in *Asterias aurantiaca* as composed of a delicate white chord surrounding the mouth, in form of a ring immediately on the external side of the circular vessel into which the heart opens, and of filaments arising and diverging from the annular chord opposite to the rays—three filaments for each ray—one running along the under surface in the median line, and appearing to send small branches to the feet; the other two, shorter, passing between the first and second segment of the ray into the interior of the body, and probably distributed over the stomach. No ganglia were discovered by Tiedemann, but minute ganglia have been described by others as existing at the points whence the diverging filaments spring. (Grant's 'Comp. Anat.')

All of course agree in assigning the sense of touch to the Star-Fishes, but many would confine their endowment to that sense. Professor Ehrenberg however, who is a keen and accurate observer, is disposed to think that some of them at least are gifted with visual organs under the form of a single red speck at the termination of each ray. These specks had been long noticed, but without any determinate conjecture as to their use in the animal economy, till he, struck by their outward resemblance to the eyes of the *Entomostraca* and *Infusoria*, thought that they might be organs of sight, and he traced the long nerve of the ray up to the extremity, where it enlarges into a sort of ganglion connected with the red speck.

Professor Rymer Jones, after noticing the nervous system of these animals, thus expresses his dissent from Professor Ehrenberg's views: "Such an arrangement can only be looked upon as serving to associate the movements performed by the various parts of the animal, for no portion of these simple nervous threads can be regarded as being peculiarly the seat of sensation or perception. But this inference is not merely deducible from an inspection of the anatomical character of the nerves: it is based upon actual experiment. We have frequently, when examining these animals in a living state—that is, when, with their feet duly developed, they were crawling upon the sides of the vessel in which they were confined—cut off with scissors successive portions of the body so as to expose the visceral cavity; but so far from the rest of the animal appearing to be conscious of the mutilation, not the slightest evidence of suffering was visible: the suckers placed immediately beneath the injured part were invariably retracted; but all the rest, even in the same ray, still continued their action, as though perfectly devoid of participation in any suffering caused by the injury inflicted. Such apathy would indeed seem to be a necessary consequence resulting from the deficiency of any central seat of perception whereunto sensations could be communicated; nevertheless Ehrenberg insists upon the existence of eyes in some species of the star-fish, attributing the function of visual organs to some minute red spots visible at the extremity of each ray, behind each of which he describes the end of the long nerve which runs along the ambulacral groove as expanding into a minute bulb. We must however confess that the proofs adduced in support of such a view of the nature of these spots appears to us to be anything but satisfactory; and as we have already stated in the first chapter the physiological objections which may be urged against the possibility of any localised organ of sense being co-existent with a strictly nematoneurose condition of the nervous system, they need not be repeated here. The general sense of touch in the *Asteridæ* is extremely delicate, serving not only to enable them to seize and secure prey, but to recognise its presence at some little distance, and thus direct these animals to their food. A person who has been in the habit of fishing with a line in the shallow bays frequented by star-fishes, and observed how frequently a bait is taken and devoured by them, will be disposed to admit this; yet to what are we to attribute this power of perceiving external objects? It would seem most probably due to some modification of the general sensibility of the body, allowing of the perception of impressions in some degree allied to the sense of smell in higher animals, and related in character to the kind of sensation by which we have already seen the *Actiniæ* and other polyps able to appreciate the presence of light, although absolutely devoid of visual organs." ('General Outline of the Animal Kingdom and Manual of Comparative Anatomy.')

Professor Edward Forbes, although he admits that the existence of ganglions in the nervous system of these animals is generally regarded as doubtful, seems, from the frequent recurrence of the terms 'eye' and 'eyelid,' to be of opinion that the specks above alluded to are visual organs. ('History of British Star-fishes and other Animals of the Class Echinodermata.')

Our own opinion and observation are in favour of the views of Ehrenberg; and we think that those who have accurately watched the Star-Fishes which are furnished with these specks on the sea-coast will in general be irresistibly led to the conclusion that the organs, though not eyes in the strict sense of the term, serve the purposes of vision modified to the exigencies of the animal, enabling it to seek or avoid objects according to its will. Nor does analogy, in our view of the case, present any difficulty. We have only to consider that the centre is a head as well as a stomach, a condition that will hardly be denied to it, and the rays proceeding from it may be viewed as so many antennæ—(take those of the snail for example, with their terminal ocular points, as in some degree analogous)—with visual dots at their extremities. This, at all events, may solve the problem of the destructive visitation of these animals to the baited line, more in unison with the analogies than the supposed existence of a general olfactory sense, of whose presence not the slightest trace has been observed.

The muscular system is generally present in the *Echinodermata*, but the organs of motion in them are various. The rays themselves are moveable, and in the free forms aid in the removal of the animals from place to place. Thus the common Star-Fish can bend its rays towards the upper or towards the lower surface of the centre or disc, and can approximate some while it extends others; so that they are widely divaricated laterally, and thus facilitate its advance in the water, or its passage through small spaces. In the common Star-Fish these motions are slow, but in *Ophiocoma* they are comparatively rapid, and manifested in active contortions on some occasions. According to M. Sars, the young of *Asterias sanguinolenta*, which have four short club-shaped appendages or arms at their anterior extremity, move slowly but uniformly in a straight line with their fore arms foremost. Vibratile cilia are supposed to form the moving power in this case: the arms also enable the little animal to creep at a slow pace along the rocks. When the animal is more fully developed the power of swimming ceases.

Tiedemann considers that the power of moving the rays resides in the contractile skin. Meckel states that there are distinct muscles leading between the calcareous plates which form the floor of the rays. Dr. Sharpey has no doubt that the motions are partly effected by the skin, but he had himself observed a distinct band of muscular fibres running along the roof of each ray, between the coriaceous skin and peritoneal membrane when it is stripped off.

But the principal locomotive organs of the *Echinodermata* are the membranous tubes which can be protruded at will through the ambulacral apertures, and which have been termed the feet. The clearest description of this complicated and in some degree obscure apparatus known to us is that by Dr. Sharpey; and we therefore give it in his own words.

"These," writes Dr. Sharpey, treating of the membranous tubes or feet, "are very numerous, and are usually disposed in regular rows: they contain a clear fluid, which is conveyed to them by a peculiar system of vessels. Each foot consists of two parts, an internal and generally vesicular portion placed within the body, and a tubular part on the outside projecting from the surface, and continues with the first through an aperture in the skin or shell. The tube is closed at the extremity, and terminates there in a sucker, which has usually the form of a disc slightly depressed in the centre. Both parts of the foot are evidently muscular, the fibres of the tubular portion being disposed in a circular and longitudinal layer; the cavity is lined with a transparent membrane, and the tubular part moreover receives an external covering from the epidermis. The foot is extended by the contraction of its internal vesicle, which forces the fluid into the tube; or when a vesicle is wanting, by the projection of a fluid into the tube from a communicating vessel. The tubular part is thus distended and elongated; it retracts itself of course by its muscular fibres; and when this takes place the fluid is forced back again into the vesicular or internal part. In progression the animal extends a few of its feet in the direction in which it desires to go, attaches the suckers to rocks, stones, or other fixed objects immediately in advance; then shortening its feet it draws its body in the wished-for direction. In the star-fish the feet are disposed in rows along the under surface of the rays, diminishing in size as they approach the extremity. There are usually two simple rows in each ray, and the vesicular part is for the most part deeply cleft into two lobes, as in *A. aurantiaca*. In other cases, as *A. rubens*, there are two double rows in every ray, and each foot has a round undivided vesicle. The canals or vessels which convey the fluid to and from the feet are all connected with a circular vessel situated in the vicinity of the mouth. This vessel lies immediately within the calcareous ring already described as connecting the rays at the commencement; from it a straight canal proceeds along the floor of each ray in the median line, and in its progress gives off lateral branches, which open into the vesicles of the feet. There are moreover connected with the circular vessel—First, a certain number of bodies (ten in five-rayed species) which Tiedemann compares to glands; they are very small, brown, sacculated organs, each opening by a small orifice into the circular vessel: Tiedemann supposes them to be the source from which the fluid filling the feet is derived. Secondly, pyriform sacs: in *A. aurantiaca* there are four groups of these; and each group consists of three or four sacs, which open by a common tubular pedicle into the circular vessel. In some other species there are five simple sacs. They are muscular, and Tiedemann conceives them to be the chief agents by which the fluid is forced into the vesicles of the feet, to which they are placed in a sort of antagonism. It would seem however that this purpose may be accomplished by other means; for according to Meckel's statement, and we may add our own observation, they are not present in all species. Lastly, the circular vessel receives the singular organ named the stone-canal or sand-canal by Tiedemann, who describes it as a membranous canal containing a friable mass of sandy or earthy matter, which commences by a wide origin on the inferior or internal surface of the calcareous disc already described as situate on the upper part of the body, descends in a duplicature of fibrous membrane, and opens by a narrow orifice into the circular vessel, the upper or wide end being closed by the disc. Ehrenberg has correctly remarked that this organ is not filled with an amorphous mass of earthy or cretaceous matter: he describes it as exhibiting a dense net-work of calcareous fibres, with hexagonal and pentagonal meshes, resembling in some respects the cavernous structure of the penis. The result of our own examination, in more than one species, is different still. We have always found the earthy matter forming a jointed calcareous tube. This tube, which is about the thickness of a surgeon's probe, is composed of rings of calcareous substance connected by membrane, so that viewed externally it is not unlike the windpipe of a small animal. On cutting it across however it is found to be more complex in structure than appears externally; for it contains within two convoluted laminæ of the same nature as its calcareous parietes. These laminæ are rolled longitudinally: they rise conjointly, or as one, from the internal surface of the tube, pass inwardly a certain way, then separating, are rolled in opposite directions, something after the same manner as the inferior turbinated bone of the ox. These internal laminæ become more convoluted towards the upper end, where at last they, as well as the more external part of the tube, join the dorsal disc, appearing gradually to become continuous with its substance. The disc is perforated with numerous pores, which open into the tube. Tiedeman conceives the function of the sand-canal to be that of secreting the earthy matter required for the growth of the calcareous skeleton. Meckel considered this view as very improbable, and the description we have given does not tend to corroborate it. We must confess ourselves unable to offer more than mere conjecture as to the use of this singular structure. If the fluid contained in the feet and their vessels be sea-water (either pure or with an admixture of organic particles), which is probable from its chemical composition, may it not be introduced, and perhaps again discharged, through the pores of the disc and the calcareous tube, the porous disc serving as a sort of filter to exclude impurities?" ('Cyclopædia of Anat. and Physiol.')

The reproduction of the *Echinodermata* appears to be monœcious, of that nature which Professor Owen terms cryptandrous hermaphroditism. Ovaries are, as far as we are aware, the only organs relating to the generative functions hitherto discovered; but Fabricius, in his 'Fauna Grœnlandica,' would seem to affirm that two individuals are necessary for the propagation of the species, and states that union takes place in the month of May—"congreditur oribus arctè connexis, altera supina." The ovaries, which appear to vary in number in different species, form in general an oblong cluster of tubes branching from a single stem, by which the whole is attached, and ending in circular dilated vesicles. In some species, *Asterias aurantiaca* for instance, the tubes form numerous bundles (about twenty), each of which is distinctly attached, so that they are not all connected by a single stem. In the Museum of the College of Surgeons, London, No. 2236 is a portion of a Star-Fish (*A. rubens*, Lam.) prepared to show the ovaria, ten in number, attached on each side of the base of each ray, near the angle of divergence; the ova are not developed in this specimen. No. 2237 exhibits an *A. papposa*, Lam., with the anterior parietes of one ray and the posterior parietes of another ray, dissected off, showing the ovaria with the ova at the commencement of their development. The ovaria are two in number in each ray, as in the preceding species, and are similarly attached on each side of the base of the ray, where they may be distinguished from the digestive and locomotive cæca by their greater opacity and granular structure. No. 2238 is the same species with the posterior parietes of the central disc removed, showing the commencement of the digestive cæca and the ovaries. No. 2239 is a portion of one of the rays of *Comatula solaris*, Lam., showing the ovarian receptacles occupying the inner side of each of the pinnæ, or articulate processes sent off from the rays. Three of the receptacles are laid open to expose the contained ova. ('Catalogue Physiol. Series.')

M. Sars states that the young of *A. sanguinolenta* immediately after birth have a depressed and rounded body, with four very short club-shaped appendages or arms at their anterior extremity, as above stated. When they are a little more developed papillæ disposed in five radiating rows on the upper surface may be distinguished. At the expiration of twelve days the five rays of the body, which up to that time had been rounded, begin to increase; and at the conclusion of eight days more the two ranges of feet or tentacula are developed under each ray, and assist in the locomotion of the animal by alternate elongation and contraction and performing the office of suckers.

The integuments of a Star-Fish are—1, a leather-like tough membrane in which portions of calcareous matter, which may be termed the skeleton of the animal, are imbedded; 2, an external membrane of a softer texture; 3, certain appendages. "The calcareous pieces," writes Dr. Sharpey, 'Cyclo. of Anat. and Physiol.,' "form inferiorly a ring round the mouth and a series of transverse segments placed in succession along the floor of each ray. The first of these segments is connected with the ring; they decrease in size as they approach the point or distal end of the ray, and openings are left between them for the passage of the feet. In the *Asterias rubens*, which has five rays, the central ring consists of ten larger and five smaller pieces, the former disposed in pairs opposite the commencement of the rays, the latter corresponding to the angles between the rays. The segments of the rays are symmetrical; in the species mentioned they consist of two oblong pieces united in the median line, and two smaller ones placed laterally. On the sides of the ray the calcareous substance is disposed as it were in ribs; these rise from the floor at first nearly parallel with each other, and are connected by cross bars, but on approaching the upper part or roof of the ray they cross in all directions and form an irregular net-work, the intervals of which are occupied by softer integument. The ribs and bars are made up of small pieces joined by plane but oblique surfaces, a mode of construction calculated to admit of their being lengthened and shortened upon one another, and thus to allow the cavity they surround being dilated and contracted. A broad calcareous disc is situated on the upper surface of the body in the angle between two of the rays, which is connected internally with the sand-canal. The calcareous pieces are of a homogeneous structure without cells or fibres; they consist, according to Hatchett's analysis, of carbonate of lime, with a smaller proportion of phosphate of lime. The coriaceous membrane which connects the pieces of the skeleton is made up of white glistening fibres. It is contractile and irritable, for it slowly shrinks on being scratched with tho point of a knife, or when it is cut through. The external membrane is much thinner and softer than that just described; iu various parts it is coloured, or in these parts there is a coloured layer underneath it. The appendages or processes on the surface of the body are of three kinds. First, calcareous spines; these are found over the whole surface, except the grooves for the feet. They are attached by a moveable joint at their base to the calcareous pieces of the skin, and are invested by the external soft membrano nearly as far as their point. Those on the upper surface are solitary, short, and for the most part club-shaped, their broader summit being marked with radiating points; whence thoy were named stelliform processes by Tiedemann. On each side of the groove for the feet the spines are thickly set; these in *A. rubens* have three rows, in the middle and innermost of which they are placed three deep. On this part of the surface they are also longer and pointed. The spines are slowly moved at the will of the animal. The appendages of the second kind are of a very singular nature; they have the appearance of pincers of crab's claws in miniature, and were described by Müller as parasitical animals under the name of *Pedicellaria*. Monro gave the name of antennæ to analogous organs which are found on the Sea-Urchin. They probably do not exist in all species, for Tiedemann makes no mention of them in his description of *A. aurantiaca*. In *A. rubens* they cover the surface generally, and form dense groups round the spines. Each consists of a soft stem, bearing on its summit, or (when branched) at the point of each branch, a sort of forceps of calcareous matter not uulike a crab's claw, except that the two blades are equal and similar. When the point of a fine needle is introduced between the blades, which are for the most part open in a fresh and vigorous specimen, they instantly close and grasp it with considerable force. The particular use of these prehensile organs is not apparent; their stem, it may be remarked is quite impervious. The third sort of appendage consists of thoso which are named the respiratory tubes." In the other *Echinodermata* the same general construction of the skeleton may bo observed; but the modifications differ with the forms. In some it consists of hundreds of pieces disposed in various patterns, and fitting with the most minute accuracy. In some these pieces are soldered together, as in the calcareous central purse from which the arms of the *Ophiuræ* radiate; and in others they are united by ligaments, as in the rays of these *Ophiuræ*, the *Gorgonocephali*, and the *Encrinites*.

The sudden and voluntary act of dismemberment by which many of the *Echinodermata* will save their central disc at the expense of their rays or arms, must have struck those who have observed these animals in their uative seas, as well as the length of time during which the sovered parts still continue to be endowed with motion. This power of dismemberment seems to bo carried to its fullest extent in *Ophiocoma* and *Luidia*. The following account by Professor E. Forbes of an attempt to capture a species of tho last genus is a good illustration of this property:—

"It is the wonderful power which the *Luidia* possesses, not merely of casting away its arms entire, but of breakiug them voluntarily into little pieces with great rapidity, which approximates it to the *Ophiuræ*. This faculty renders the preservation of a perfect specimen a very difficult matter. Tho first time I ever took one of these creatures I succeeded in getting it into the boat entire. Never having seen one before, and quite unconscious of its suicidal powers, I spread it out on a rowing bench, the better to admire its form and colours. On attempting to remove it for presorvation to my horror and disappointment I fonnd only an assemblage of rejected members. My conservative endeavours were all neutralised by its destructive exertions, and it is now badly represeuted in my cabinet by a discless arm and an armless disc.

"Next time I went to dredge on the same spot, determined not to be cheated out of a specimen a second time, I brought with me a bucket of cold fresh water, to which article star-fishes have a great antipathy. As I expected, a *Luidia* came up in the dredge, a most gorgeous specimen. As it does not generally break up before it is raised above the surface of the sea, cautiously and anxiously I sunk my bucket to a level with the dredgo's mouth, and proceeded in the most gentlo manner to introduce *Luidia* to tho purer clement. Whother the cold air was too much for him or the sight of the bucket too terrifio I know not, but in a moment he proceeded to dissolve his corporation, and at every mesh of the dredge his fragments were seen escaping. In despair I grasped at the largest, and brought up the extremity of an arm with its terminating eye, the spinous eyelid of which opened and closed with something exceedingly liko a wink of derision. Young specimons are by no means so fragile as those full grown, and tho five-armod varicty secins less brittle than that with seven arms. Like other star-fishes it has the power of re-producing its arms."

With regard to the power of restoration, few collectors have not come into possession of a specimen with a budding or growing ray occupying the place of a lost one. [ENCRINITES.] Jussieu, Guettard, and Gerard de Villars brought to Reaumur specimens of Star-Fish with four large rays and a small one still growing; they found others, he tells us, with only three large rays and two very small ones; and others with two largo rays and threo very small, and, as it seemed, very young ones. Moro than once they met with a large ray from which four young rays had begun to sprout. Reaumur speaks of the fact as being well known to the fishermen, and in allusion to certain experiments which Jussieu and Guettard had been carrying on he remarks that the portious into which they had divided the animals appeared to go on well, the wounds healed and consolidated; but he adds that those who made the experiment were obliged to limit their stay on the coast to about fifteeu days—too short a period, he observes, to trace the progress of a reproduction which apparently requires several months, or perhaps even more than a year for its completion.

Although the *Echinodermata* have so great a power of reproducing lost parts, they present no indications of any power of increasing separate individuals by gemmation as witnessed in the *Acalephæ* and lower animals. As in the *Acalephæ*, the embryo of the *Echinodermata* pass through several forms before arriving at maturity. The following is an outline of the process in the *Asteriadæ*:—"From the accounts of the development given by different trust-worthy observers, there can be little doubt that the process takes place after at least two very diverse plans. The first and simplest of these has been witnessed by Sars in the *Echinaster rubens*; and the observations of Agassiz are on the whole in accordance with those of that industrious naturalist. In the early stages the segmentation of the yoke takes place as in other animals; and the embryo comes forth from the egg soon after it has attained the state of the 'mulberry mass,' and swims freely about, by means of the cilia with which it is covered, in a sort of marsupial chamber which is formed by the drawing together of the rays of the parent around its mouth. Soon after its emersion, the embryo begins to put forth an organ of attachment, resembling the stem of a Crinoid; this at first possesses two tubercles, then three, then four, with a fifth smaller one between them. At tho same time, the principal mass becomes flatteued, and shapes itself into five lobes surrounding a central disc; thus sketching out the body and rays. When in this state it attaches itself to fixed objocts by its organ of adhesion; but if detached, it swims through the water by the action of the cilia with which the body and arms are clothed; so that it bears a strong analogy to the *Pentacrinus* in process of conversion into a free moving *Comatula*. At the same time, five double rows of small tubercles may be perceived radiating from the centre of what is to become the ventral surface of the body; these gradually elongate themselves, and become cirrhi, each furnished with a sucker at its extremity. A peculiar tubercle is also seen at the edge of each of the five lobes of the body; and this is the rudiment of the ocellus, which is afterwards found at the extremity of each ray. As development proceeds, the primitive organ of adhesion gradually decreases iu size, and the animal creeps by means of its cirrhi; and at last tho pedicle is drawn (as it were) into the body, the lobes of the body lengthen into rays, the animal loses its ciliograde progression, and the ordinary characters of the Star-Fish become apparent. The progress of the internal organisation is thus described by Agassiz:—'The earliest deposit of calcareous matter takes place around tho prominent tubercles of the lower surface; at first in the condition of little isolated crystals, which are formed as nuclei in tho cells; and then as a network formed by the coalescence of several of these. Of these networks there are at first ten, symmetrically disposed on the ventral surface, in a manner corresponding to the arrangement of the solid plates in Crinoids; but they gradually increase in number, and more distinctly mark out the rays; new ones being interposed in pairs between those already existing, and small spines projecting from the older ones. The calcareous deposit in the dorsal surface, on the other haud, seems to proceed from a central nucleus above tho yolk-mass. The progress of development is obviously from without inwards; the cells ou the surface of the yolk-mass being the first to undergo metamorphosis into the permaneut structure. Those occupying the central part of the body and pedicle undergo liquefaction, and a kind of circulation is seen in the latter. Gradually what remains of the yolk-mass is more distinctly circumscribed in the interior of the animal, and forms a central cavity with prolongations extending into the rays; but it is not until the pedicle has contracted itself iuto a mere vesicle that the mouth is formed, by the thinning-away of tho envelope of the yolk-mass on the lower surface, a little to one side of the base of the pedicle; and it is not until after the formation of the mouth, that tho nervous ring can be traced, with its prolongations extending to the ocelli at the extremities of the rays.'

"The second plan of development seems much more conformable to what will be presently described as taking place in the *Ophiuridæ* and *Echinidæ*; for the body first developed from the embryonic mass is a larva, of which little remains in the pormanent structure, and the Star-Fish is budded off, as it were, from the anterior extremity of this. This larva, which has received the name of *Bipinnaria* from the symmetrical wing-like arrangemeut of its natatory organs, presouts much more resemblance to an Articulated, or to a Vertebrated, than to a Radiated animal. Its body is elongated, and carries at its antorior extremity the portion of the yolk-mass not yet metamorphosed, from which the Star-Fish is afterwards to be developed; and into the cavity of this a passage is formed, through what may be termed the mouth of the larva, which opens in the middle of a transverse furrow, whilst another tube passing forth from it seems to answer to an intestine. On either side of the anterior portion of the body are six or more narrow fin-like appendages, which are fringed with cilia; and the posterior part of the body is prolonged into a sort of podicle, bilobed towards its extremity, which also is covered with cilia. The organisation of this larva seems completed, and its movements through the water are very active, before the mass at its anterior extremity presents anything of the aspect of the Star-Fish; in this respect corresponding with the movements of the Pluteus of the *Echinidæ*. The temporary mouth of the larva does not remain as the permanent mouth of the Star-Fish; for it is on what is to become the dorsal side of the body; and the true mouth is subsequently formed by the thinning away of the integument (which has completely inclosed the yolk-mass) on the ventral surface. The young Star-Fish is separated from the bipinnarian larva, by the forcible contractions of the connecting pedicle, as soon as the calcareous consolidation of its integument has taken place, and its true mouth has been formed, but long before it has attained the adult condition; and as its ulterior development has not hitherto been observed in any instance, it is not yet known what are the species in which this mode of evolution prevails. The larva continues active for several days after its detachment; but there is no reason to believe that its existence is prolonged for any considerable time; and as the Star-Fish is not formed by gemmation from it, but from a portion of the yolk-mass which remained unconsolidated after its completion, it is obvious that the larva does not stand in the same relation to the Star-Fish, as the hydraform polype to its medusa-bud." (Carpenter, 'Principles of Physiology.')

Müller ('Ueber die Larven und die Metamorphose der Echinodermen,' 1848) has also described the process of embryonic development in the *Ophiuridæ* and *Echinidæ*. In these the embryo issues forth from the ovum as soon as it has attained by the repeated segmentation of the yolk the condition of the 'mulberry mass,' and the superficial cells of this are covered with cilia, by whose agency it swims freely through the water. So rapid are the processes that not more than 24 hours elapse between fecundation and the exit of the embryo. Shortly after its emersion the embryo changes from the spherical into a sub-pyramidal form with a flattened base; and in the centre of this base is a depression, which gradually deepens so as to form a mouth that communicates with a cavity in the inside of the mass. The pyramid is at first triangular, but it afterwards becomes quadrangular, and the angles are greatly prolonged round the mouth (or base), whilst the apex of the pyramid is sometimes greatly prolonged in the opposite direction, but is sometimes rounded off into a kind of dome. This body is strengthened by a frame-work of thread-like calcareous rods. In this condition the embryo swims freely through the water propelled by the cilia which clothe the angles, and the projecting arms. The creature has at this stage received the name of Pluteus. The Pluteus of the *Ophiura* and *Echinus* differ but little at first in their general form and structure. Each species however has its distinctive characters. In this stage the Pluteus resembles the *Acalephæ*; its probosciform mouth resembling the *Medusæ* and its cilia the *Beröe*. [ACALEPHÆ.] The Pluteus gradually loses its Acalephoid characters, the jaws and teeth and calcareous plates slowly developing; and it thus passes into its true Echinodermatous form.

Systematic Arrangement.—Most systematists have given classifications of the *Echinodermata*.

Link, in his volume 'De Stellis Marinis' (fol., Leipzig), arranges and figures a considerable number of species, in the method of which the outline is here given.

Section I. *De Stellis Fissis.*

Class 1. *Oligactis* (Star-Fishes with fewer than five rays).
Genera, *Trisactis*, *Tetractis*.
Class 2. *Pentactinodos* (Quinquefid Star-Fishes).
Genera, *Pentagonaster*, *Pentaceros*, *Astropecten*, *Palmipes*, *Stella coriacea*, *Sol marinus*, *Pentacdylosaster*.
Class 3. *Polyactinodos* (Multifid Star-Fishes).
Genera, *Hexactis*, *Heptactis*, *Octactis*, *Enneactis*, *Decactis*, *Dodecactis*, *Triscaidecactis*.

Section II. *De Stellis Integris.*

Class 1. *Stellarum Vermifermium.*
Genera, *Stella lumbricalis*, *Stella scolopendroides*.
Class 2. *Stellarum Criniterum.*
Genera, *Decacnemos*, *Triscaidecacnemos*, *Caput-Medusæ*.
Class 3. *Astrophyton.*
Genera, *Arachneides*, *Astrophyton costosum*, *Astrophyton scutatum*.

Linnæus divided his genus *Asterias* into the following sections:—

1. *Integra.*—Example, *Asterias Luna*, the only species.
2. *Stellatæ.*—This section contained nine species. Example, *Asterias papposa*.
3. *Radiatæ*—Containing six species. Examples, *Asterias Ophiura*, *A. Caput-Medusæ*.

Position of the genus between *Medusa* and *Echinus*.

Gmelin arranged the genus in three sections also, retaining the names of Linnæus for the last two; but altering that of the first, under which he includes four species, to *Lunatæ*.

Position of the genus, between *Physsophora* and *Echinus*.

Lamarck, who, according to De Blainville, "a suivi à peu près les erremens de Link dans la distribution systematique des Stellérides," arranged them as the first section or family of the Echinodermatous *Radiata*, and separated them into the genera *Comatula*, *Euryale*, *Ophiura*, and *Asterias*.

Ophiura is divided by Lamarck into two distinct sections; 1st, Those species which have the rays rounded or convex on the back, 2nd, Those species which have the rays flattened on the back, that is, above as well as below. Then comes a crowd of species under the title of "Espèces que je n'ai point vues."

Agassiz divides the *Ophiuræ* into five sections:—

1. *Ophiura.*—Those species which have the disc very much depressed, the rays simple, scaly, and furnished with very short spines, and embracing or close down upon the rays. Examples, *Ophiura texturata*, *O. lacertosa*, Lam.
2. *Ophiocoma.*—Those species which differ from the preceding by having very long and moveable spines upon the rays. Examples, *Ophiura squamata*, *O. echinata*, Lam.
3. *Ophiurella* (Fossil only).—Those species whose disc is hardly distinct. Examples, *Ophiura carinata*, Münst.; *O. Egertoni*, Brod.
4. *Acroura* (Fossil only).—Differing only from *Ophiura* in having spines on the sides of the rays instead of scales; while the rays themselves are very slender. Examples, *Ophiura prisca*, Münst.; *Acroura Agassiz*, Münst.
5. *Aspidura* (Fossil only).—Having the upper surface of the disc covered by a star of ten plates, whilst the rays, which are proportionally stout, are surrounded by imbricated scales. Example, *Ophiura loricata*, Goldf.

Asterias is arranged by Lamarck under the following divisions:—

1. Those species which have the body scutellated. These are numerous, and comprise the genera *Scutaster*, *Plataster*, *Palmaster*, and *Solaster* of De Blainville.
2. Those which have the body radiated, consisting of numerous species also, and comprising the genera *Solaster* and *Pentaster* of De Blainville.

The *Stelleridæ*, in Lamarck's arrangement, are immediately followed by the *Echinidæ*.

Cuvier makes the Echinodermes the first class of Zoophytes, and the Pédicellés the first order of that class, observing that Linnæus established three genera of them (meaning apparently the three divisions above stated), which are very natural, but numerous enough, and comprise species sufficiently varied to be considered as three families.

Cuvier divides the species into:—

Les Astéries (*Asterias*, Linn.), commonly called Sea-Stars. He recognises some of the genera of Leach and Lamarck, and observes that the *Encrinites* (*Encrinus*, Guettard) ought to be placed near the *Comatulæ*.

The Oursins (*Echinus*, Linn.) immediately follow the Sea-Stars.

De Blainville divides the Stelliridians into three families:—1. Those with a stelliform body; 2, those with a disciform body; 3, those with a cupuliform body.

I. Asteridians.

Genus *Asterias*, comprising the following divisions or sub-genera:—

A. Species whose body is pentagonal, and but little or not at all lobated on its circumference; the angles being fissured (Les Oreillers). Example, *Asterias Luna*.

B. Pentagonal species: delicate, and, as it were, membranous (Les Palmastéries—*Palmipes* of Link).

C. Quinquelobated species, which are not articulated on the circumference. Example, *Asterias minuta*, Linn. (*Pentaceros*, Link; *Asterina*, Nardo.)

D. Pentagonal species more or less lobated and articulated at their circumference (Les Scutastéries, ou Platastéries). Example, *Asterias tessellata*. [ASTERIAS.]

De Blainville remarks that the species of this section, many of which exist in the European seas, do not appear to him to have been examined by zoologists with sufficient accuracy; and he thinks that many species have been confounded under the same name.

E. Species deeply divided into five rays (Pentastéries).

*

Triangular, depressed, and articulated on the edges (*Astropecten*, Link.; *Crenaster*, Llhuyd). Example, *Asterias aranciaca*, Linn.

* *

Triangular, rather short, and rounded above. Example, *Asterias rubens* Linn. (*Uraster*. Ag.)

* * *

Rays long, strait, and often narrowed at their origin. Examples, *Asterias variolata*; *A. granifera*, Lam.

De Blainville remarks that the species which enter into this section are numerous, but that their distinction is not yet sufficiently established. He is certain, for example, that four species have been confounded under the name of the Fringed Star (Astérie Frangée). On the other hand, he thinks that those of the last section may have been too greatly multiplied.

F. Species which are divided into a greater number of rays than five or six (Solastéries). Examples, *Asterias tenuispina; A. endeca; A. papposa.*

II. Asterophidians.

Genera, *Ophiura*, *Euryale.*

Ophiura.

A. Species the spines of whose rays are very short, and applied upon the latter. Example, *Ophiura texturata*, Lam.

B. Species the spines of whose rays are long, and not applied upon the latter. Example, *Ophiura squamata*, Lam. [OPHIURA.]

Euryale.

A. Species whose rays dichotomise but little, and far from the root. Example, *Euryale palmifera*, Lam.

B. Species whose rays divide and dichotomise from the base. Example, *Euryale scutata.* [OPHIURA.]

III. Asterencrinidians.

1. Free Asterencrinidians. Example, *Comatula.* [COMATULA.]
2. Fixed Asterencrinidians.

Genera, *Encrinus; Phatocrinus; Pentacrinus; Apiocrinites; Poteriocrinites; Agathocrinites; Actinocrinites; Rhodocrinites; Platycrinites; Caryocrinites; Marsupites; Pentremites.* [ENCRINITES.]

Agassiz also divides the Stellirideans into three families or principal sections, but he gives them different names.

1st. Asterians, consisting of those species which have for their digestive organ a single orifice surrounded by suckers, but deprived of teeth; a madreporiform tubercle on the back between the two posterior rays, and deep furrows occupied by many rows of pedicles, going from the mouth to the extremity of the arms.

2nd. Ophiurians, comprising those whose body forms a flattened and distinct disc, to which are annexed more or less elongated or even ramified rays, deprived of furrows on their lower surface.

3rd. The Crinoidians, having two separate, but closely approximated orifices to the intestinal canal; and being for the most part fixed by the dorsal surface, by means of an articulated pedicle.

Before we enumerate the genera into which this zoologist divides *Asterias*, we must notice the division of M. Nardo, who had previously proposed the following:—*Stellaria* (*A. aranciaca*—*A. calcitrapa*); *Stellonia* (*A. rubens*—*A. glacialis*); *Asterina* (*A. exigua*—*A. minuta*); *Anseropoda* (*A. membranacea*—*A. rosacea*); *Linkia* (*A. lævigata*—*A. variolosa*).

The following is the division of Agassiz.

1. *Asterias* (*Astropecten*, Link; *Crenaster*, Llhuyd.; *Pentaster*, Bl.; *Stellaria*, Nardo).
2. *Cœlaster*, Ag., differing from the preceding in having the interior cavity circumscribed by plates disposed like those of the *Echini*, at the summit of which may be perceived a star with ambulacra. A genus approaching the Crinoidians in its organisation, whilst its general form is that of the true Star-Fishes. Example, only one species, and that fossil, *C. Couloni*, Ag.
3. *Goniaster*, Ag. (*Scutaster* or *Plataster*, Bl.). Examples, *Asterias tessellata*, Lam., *A. equestris*, Linn.
4. *Ophidiaster*, Ag. Example, *A. ophidiana*, Lam.
5. *Linkia*, Nardo. Example, *A. variolata*, Lam.
6. *Stellonia*, Nardo, (*Pentaster* in part and *Solaster* in part, Bl.). Examples, *A. rubens; A. glacialis; A. endeca; A. papposa; A. Helianthus*, &c.
7. *Asterina*, Nardo (*Asterias*, sect. C., Bl.; *Pentaceros*, Link). Example, *A. minuta.*
8. *Palmipes*, Link (*Palmaster*, Bl.; *Anseropoda*, Nardo). Example, *A. membranacea.*
9. *Culcita*, Ag. (*Oreiller*, Bl.). Example, *A. discoidea.*

In 1840 Müller of Berlin read his paper on the genera of Star-Fishes to the Berlin Academy, in which the anus or anal pore is employed as characteristic of family distinction. This aperture is described as present in all Star-Fishes, excepting *Asterias* proper and *Hemichemis*, which, according to Mr. Forbes, seems to be identical with his previously established *Luidia.* "His genus *Crossaster* also," says Mr. Forbes, "is my *Solaster*, published a year before. Several generic names, previously adopted by Agassiz and Nardo, are wantonly changed; thus *Uraster* is turned into *Asterocanthium*, and *Palmipes* into *Asteriscus*, with which he unites *Asterina.* In this paper Müller maintains that one of the five intermediate inferior plates of the *Ophiuridæ* bears a madreporiform tubercle, or rather corresponds to that body, a view which I am not inclined to adopt."

With regard to *Solaster*, we have seen how long ago Solastérie was used by De Blainville; but the practice of wantonly changing names is productive of so much confusion that it cannot be too strongly reprobated. Mr. Forbes admits, as all indeed must, that the generic characters in Müller's papers are excellently drawn up; and no difference of opinion can exist as to the great general value of the memoir.

The following arrangement is that of Dr. J. E. Gray, in the 'List of the Specimens of British Animals in the Collection of the British Museum.'

Centroniæ.

1. *Echinodermata.*

Class I. *Ditremata.*

Order I. *Echinida.*

Family 1. *Cidaridæ.*

I. *Cidaris.*

1. *C. papillata.* North Sea.

Family 2. *Echinidæ.*

I. *Echinus.*

1. *E. Flemingii.* Falmouth.
2. *E. esculentus* (*E. sphæra*, Forbes). Isle of Arran.
3. *E. miliaris.* Isle of Man.
4. *E. lividus.* Cork.

II. *Echinometra.*

1. *E. Drabachensis* (*E. neglectus*, Forbes). Shetland.

Family 3. *Scutellidæ.*

I. *Echinorachnius.*

1. *E. placenta.* Zetland.

II. *Echinocyamus.*

1. *E. pusillus.* Berwick-on-Tweed, and Arran.

Family 4. *Spatangidæ.*

I. *Spatangus.*

1. *S. purpureus.* Irish Sea.

II. *Echinocardium.*

1. *E. cordatus* (*Amphidotus cordatus*, Forbes). Coast of England.
2. *E. ovatum* (*Amphidotus roseus*, Forbes). Coast of Northumberland.

III. *Brissiopsis.*

1. *B. lyrifera* (*Brissus lyrifer*, Forbes). Shetland.

Order II. *Holothurida.*

Family 1. *Holothuridæ.*

I. *Thyone.*

1. *T. fusus* (*T. papillosa*, Forbes). Berwick Bay, Ireland.
2. *T. Raphanus.* Ireland.

II. *Holothuria.*

1. *H. nigra.* Cornwall.

Family 2. *Cuvieriadæ.*

I. *Psolus.*

1. *P. phantopus.* North Sea.

II. *Psolinus.*

1. *P. brevis.* Shetland.

Family 3. *Pentactidæ.*

I. *Pentacta.*

1. *P. frondosa* (*Cucumaria frondosa*, Forbes). Shetland.
2. *P. fusiformis* (*Cucumaria fusiformis*, Forbes). Shetland.
3. *P. Hyndmanni* (*Cucumaria Hyndmanni*, Forbes).
4. *P. lactea* (*Ocnus lacteus*, Forbes).
5. *P. pentactes* (*Cucumaria pentactes*, Forbes). South Coast of Devon.
6. *P. Montagui* (*Holothuria pentactes*, Forbes). South Devon.
7. *P. Neillii* (*Holothuria pentactes*, Forbes). Frith of Forth.
8. *P. dissimilis* (*Holothuria pentactes*, Forbes). Leith.

II. *Thyronidium.*

1. *T. pellucidum* (*Cucumaria hyalina*, Forbes). Shetland.
2. *T. Drummondi* (*Cucumaria Drummondii*, Forbes). South Devon, and Falmouth.

Family 4. *Synaptidæ.*

I. *Synapta.*

1. *S. inherens* (*Chirodota digitata*, Forbes). South Devon.
2. *S. Hensloviana.* May be the young of the preceding.

Family 5. *Sipunculidæ.*

I. *Sipunculus.*

1. *S. nudus* (*Syrinx nudus*, Forbes).
2. *S. papillosus* (*Syrinx papillosus*, Forbes). Clare, Ireland.
3. *S. macrorhynchopterus.*
4. *S. Harveii* (*Syrinx Harveii*, Forbes). Devonshire.
5. *S. Strombi* (*S. Bernhardus*, Forbes). Devonshire.
6. *S. Johnstoni* (*Sipunculus Johnstoni*, Forbes). Berwick.
7. *S. saccatus.* Teignmouth.
8. *S. tenuicinctus.* Ireland.
9. *S. Forbesii.* Ireland.
10. *S. granulosa.* Roundstone Bay.

II. *Phascolosoma.*

1. *P. Pallasii* (*Sipunculus Pallas*, Forbes). Coast of Sussex.

III. *Priapulus.*

1. *P. caudatus.*

IV. *Thalassema.*
 1. *T. rupium* (*T. Neptuni*, Forbes). South Coast of Devon.
V. *Echiurus.*
 1. *E. oxyurus* (*E. vulgaris*, Forbes). St. Andrews.
Class II. *Hypostoma.*
Order I. *Asteroida.*
Family 1. *Asteriadæ.*
I. *Asterias.*
 1. *A. rubens* (*Uraster rubens*, Forbes). Frith of Forth.
 2. *A. violaceus* (*Uraster violaceus*, Forbes). Frith of Forth, Plymouth Sound, Berwick-on-Tweed.
 3. *A. glacialis* (*Uraster glacialis*, Forbes). Plymouth Sound.
 4. *A. hispida* (*Uraster hispida*). Isle of Man.
Family 2. *Astropectenidæ.*
I. *Astropecten.*
 1. *A. irregularis* (*Asterias aurantiaca*, Forbes). South Coast of England.
II. *Luidia.*
 1. *L. Savignii* (*L. fragilissima*, Forbes). Isles of Man and Arran.
III. *Solaster.*
 1. *S. endeca.* Scotland.
 2. *S. papposa.* Frith of Forth.
IV. *Henricia.*
 1. *H. oculatus* (*Cribella oculata*, Forbes). Plymouth Sound, Coast of Northumberland, Frith of Forth.
 2. *H. rosea* (*Cribella rosea*, Forbes). Ayrshire.
Family 3. *Pentacerotidæ.*
I. *Hippasteria.*
 1. *H. equestris* (*Goniaster equestris*, Forbes). North of England.
 2. *H. abbensis* (*Goniaster abbensis*, Forbes). St. Abb's Head.
Family 4. *Asterinidæ.*
I. *Palmipes.*
 1. *P. membranaceus.* Isle of Man.
II. *Porania.*
 1. *P. pulvillus* (*Goniaster Templetoni*, Forbes). Plymouth Sound, Arran, Isle of Man.
III. *Asterina.*
 1. *A. gibbosa.* Plymouth Sound.
Order II. *Ophiurida.*
Family 1. *Ophiuridæ.*
I. *Ophiolepis.*
 1. *O. ciliata* (*Ophiura texturata*, Forbes). Dover, Frith of Forth.
 2. *O. albida* (*Ophiura albida*, Forbes). Frith of Forth.
 3. *O. elegans* (*Ophiocoma neglecta*, Forbes). Shetland.
 4. *O. punctata* (*Ophiocoma punctata*, Forbes). Scotland.
 5. *O. filiformis* (*Ophiocoma filiformis*, Forbes). Frith of Clyde, Frith of Forth.
II. *Ophiopholis.*
 1. *O. aculeata* (*Ophiocoma bellis*, Forbes). Isle of Man, Shetland, and Orkney.
 2. *O. brachiata* (*Ophiocoma brachiata*, Forbes). Devonshire.
 3. *O. Ballii* (*Ophiocoma Ballii*, Forbes). Ireland.
 4. *O. Goodsiri* (*Ophiocoma Goodsiri*, Forbes). North Britain.
III. *Ophiocoma.*
 1. *O. nigra* (*O. granulata*, Forbes). Devon, Plymouth Sound.
IV. *Ophiothrex.*
 1. *O. fragilis* (*Ophiocoma rosula*, Forbes). Torbay.
 2. *O. minuta.* Isle of Man.
Family 2. *Astrophytonidæ.*
I. *Astrophyton.*
 1. *A. arborescens* (*A. scutatum*, Forbes). North Sea.
Order III. *Crinoidea.*
Family 1. *Pentacrinidæ.*
I. *Antedon.*
 1. *A. decameros* (*Comatula rosacea*, Forbes). British Ocean, Cork, Plymouth Sound.
II. *Gynameda.*
 1. *G. pulchella.* Kent.

Of this arrangement Mr. Forbes says:—"The other memoir to which I must allude is one by Mr. Gray on the Star-Fishes, which he calls the class *Hypostoma*, and defines somewhat ambiguously, published simultaneously with my two first numbers, in the 'Annals of Natural History.' I am afraid I must censure Mr. Gray for changing names still more than Müller, and with less reason. It is a pity zoologists do not take a lesson from their fellow-labourers in the field of nature, the botanists, in this respect. Mr. Gray has increased the confusion by giving fragments of descriptions instead of genuine and specific characters, probably from carrying too far a laudable desire for brevity. His essay deserves praise however for recording many new foreign habitats of the beautiful animals he catalogues." Dr. Gray's arrangement was first published in the 'Annals of Natural History' in 1840.

The following is Professor E. Forbes's arrangement of the *Echinodermata*, to which we have added his table of the distribution of the British species:—

Order I. *Pinnigrada.*

Crinoideæ.—First appearance of cirrhi springing from brachial membranes, which with the true arms form the organs of motion.

II. *Spinigrada.*

Ophiuridæ.—Disappearance of brachial membranes; cirrhi as before; true arms clothed with spines for motion.

III. *Cirrhigrada.*

Asteriadæ.—Arms disappear; body more or less lobed, and lobes channeled beneath for cirrhi, which act as suckers, and are the organs of motion.

IV. *Cirrhi-Spinigrada.*

Echinidæ.—Gradual disappearance of lobes; cirrhiferous canals appearing as avenues where cirrhi act as in Order III., but are assisted by mobile spines clothing the integument.

V. *Cirrhi-Vermigrada.*

Holothuriadæ.—Lobes disappear; motions effected by avenues of cirrhi, assisted by contraction and extension of the soft body.

VI. *Vermigrada.*

Sipunculidæ.—Cirrhi become obsolete and disappear; motion effected by the contraction and extension of the animal's body.

"A glance," says Mr. Forbes, "at this arrangement will at once show that it is most natural. There is nothing novel in it as regards the constitution of the groups, saving the recognition of the *Ophiuridæ* as an order equivalent to the other orders; but as an explanation of the true nature and relation of the Echinodermatous tribes I prefer it to any arrangement at present used, and have accordingly followed it throughout this work. All the *Radiata* are greatly influenced in the arrangement of their parts by some definite number. In the *Echinodermata* the reigning number is five. The name of 'Five-Fingers' commonly applied by mariners to the Star-Fishes is founded on a popular recognition of the number regnant. It has long been noticed. Among the problems proposed by that true spirited but eccentric philosopher Sir Thomas Browne is one—'Why among the Sea-Stars nature chiefly delighteth in five points?' and in his 'Garden of Cyrus' he observes, 'By the same number (five) doth nature divide the circle of the Sea-Star, and in that order and number disposeth those elegant semicircles or dental sockets and eggs in the Sea-Hedgehog.' Among the lower and the typical orders we find this number regulating the number of parts. Every plate of the Sea-Urchin is built up of pentagonal particles. The skeletons of the digestive, the aquiferous, and the tegumentary systems equally present the quinary arrangement; and even the cartilaginous framework of the disc of every sucker is regulated by this mystic number. When the parts of Echinoderms deviate from it, it is always either in consequence of the abortion of certain organs, or it is a variation by representation; that is to say, by the assumption of the regnant number of another class. Thus do monstrous Star-Fishes and Urchins often appear quadrate and have their parts four-fold, assuming the reigning number of the *Actinodermata* consistent with a law in which I put firm trust, that when parallel groups vary numerically by representation, they vary by interchange of their respective numbers.

"In this short introduction I have rather given the generalities of the subject than details of structure, for which I would refer the reader to the excellent account of the anatomy of *Echinodermata* given by Professor Jones in his 'Outlines of the Animal Kingdom.' I shall conclude by presenting a tabular view of the distribution of our native species. In the first of the two following tables the numbers of species of each family known to inhabit the several zones of the sea is given; in the second a view of their distribution in the various provinces of the British seas with such foreign localities as are recorded. I have divided the marine provinces thus:—

"I. Thulean, including the Orkney and Shetland Islands. II. Hebridean. III. Scottish Eastern Coast. IV. English Eastern Coast. V. English Channel. VI. St. George's Channel. VII. Southern, the District between Land's End and Cape Clear. VIII. South-west, Irish. IX. North-west, Irish. X. The Clyde Province and North Channel. XI. Irish Sea.

"*Table of Zonal Distribution.*

Fossil Echinodermata.

Till within a comparatively recent period but little attention was paid to the study of the fossil *Echinodermata.* Various forms of *Encrinites* [ENCRINITES] had been described, and the forms of *Echinidæ,* especially those presented by the Chalk, had been studied and described; but through the labours of Wahlenberg, Von Buch, E. Forbes, and others, a new family of animals, the *Cystideæ,* have been added to the group of *Echinodermata,* and large additions have been made to our knowledge of other forms. Previous to referring to more recent researches, we present a list of the fossil *Echinodermata,* as given in Professor Tennant's List of British Fossils.

TERTIARY SERIES.

Crag Formation.

Echinocyamus Suffolciensis, Ag.
Echinus ——(?).
Spatangus ——(?).
Asterias ——(?).
Amphidetus ——(?).
Temnopleurus ——(?).

London Clay.

Glypticus ——(?), *Ophiura Wetherellii,* Morr. M.S.S.
Pentacrinus Sowerbii, Sow.
Spatangus ——(?).

Remains of this family belonging to two or three genera have been found at Sheppey, but are not yet described.

Cretaceous Group.

Ananchytes conoideus, Godf.
A. hemisphæricus, Brong.
A. ovatus, Lam.
A. striatus, Lam.
Apiocrinus ellipticus, Mill.
Arbacia granulosa, Goldf.
Caratomus hemisphæricus, Des.
C. rostratus, Ag.
Cidaris claviger, König.
C. cretosa, Park.
C. marginata, Goldf.
Cassidulus lapis-cancri, Lam.
Catopygus carinatus, Ag.
Cidaris saxatilis, Park.
C. vesiculosa, Goldf.
Comptonia elegans, Gray.
Diadema granulosum, Ag.
D. variolare, Ag.
Discoidea cylindrica, Ag.
D. hemisphærica, Ag.
D. subuculus, Bronn.
Galerites abbreviatus, Goldf.
G. albogalerus, Lam.
G. conicus, Ag.
G. vulgaris, Lam.
G. subrotundus, Ag.
Goniophorus lunulatus, Ag.
Glenotremites paradoxus, Goldf.
Holaster complanatus, Ag.
H. granulosus, Goldf.
H. nodulosus, Goldf.
H. subglobosus, Goldf.
Marsupites Milleri, Mant.
Micraster Bufo, Ag.
M. cor-anguinum, Brong.
M. cor-testudinarium, Goldf.
M. lacunosus, Park.
M. Murchisonii, König.
M. prunella, Lam.
M. rostratus, Mant.
Nucleolites lacunosus, Goldf.
Ophiura serrata, Römer.
Pyrina depressa, Desm.
Salenia petalifera, Ag.
S. geometrica, Ag.
S. scutigera, Gray.
S. stellulata, Ag.
Spatangus ornatus, Defr.
Tosia lunata, Woodw.
T. regularis, Park.

Oolitic Group.

Amphiura Prattii, Forbes.
Apiocrinus Prattii, Gray.
A. rotundus, Mill.
Aspidura loricata, Ag.
Asterias Cotteswoldiæ, Buckm.
Cidaris Blumenbachii, Goldf.
C. coronata, Goldf.
C. crenularis, Lam.
C. elegans, Goldf.
C. glandifera, Goldf.

Oolitic Group. *Continued.*

C. gracilis, Benson.	*E. perlatus*, Desm.

But few of the species here recorded belong to the group of the true Star-Fishes, or *Asteriadæ*. To Professor E. Forbes we are indebted for having collected together all the information possessed on this subject. In his paper in the 'Memoirs of the Geological Survey of Great Britain, on the British Fossil Asteriadæ,' he says—

"The traces of the first appearance of *Asteriadæ* occur in rocks of the Bala series, or even lower in the geological scale. They were first noticed by Professor Sedgwick, who found them in beds of corresponding age in Cumberland, where they were also observed by Mr. Daniel Sharpe. The researches of the Geological Survey have brought to light similar fossils in the Bala Rocks, near Bala, and in the ashy slates at Drumcannon, near Waterford, where they were found by Captain James. These latter beds probably correspond with the former. It is very remarkable that forms of Star-Fishes, strikingly similar, have been found in the Lower Silurian Strata of the United States.

"The Cumberland, Welsh, and Irish Star-Fishes all belong to one genus. After a very careful examination of all the specimens I have been able to procure (and through the kindness of Professor Sedgwick and Mr. Sharpe every facility has been afforded), I am induced to refer them to the existing genus *Uraster* (*Asteracanthion* of Müller and Troschel), members of which are at the present day the most abundant Star-Fishes in the British seas and throughout North America.

"The general aspect of the Palæozoic Star-Fishes must have been strikingly similar to that of the *Urasteriæ*, now living.

"Indeed, impressions taken from the latter in clay would so closely resemble those which we find in ancient rocks, that the critical eye of a naturalist would be required for the definition of their specific distinctness. Nor does this arise through the obscurity of imperfections of such impressions, for the external characters, so far as colour and sculpture of surface, and even many points of structure, are very completely indicated in them, rude as they may seem.

"As yet, with the exception of the instances already referred to, only one other instance of the discovery of a Palæozoic Asteriad has come to my knowledge, namely, that of a well-preserved species, apparently also belonging to the genus *Uraster*, by M. Thorent, in the 'Terrains Anthraxifères' of the department of l'Aisne. It is probable, however, that the progress of research will bring many more to light. In the older secondary strata not a few have been found, both in Britain and abroad. A doubtful form (*Asterias obtusa*) has been figured by Goldfuss from the Muschelkalk, who has also made known a true *Asterias* or *Astropecten*, from the Lias of Wurtemberg. Several species of *Astropecten* have been observed in the Oolites of Yorkshire, and similar forms in corresponding beds in Germany. Where *Urasteriæ* have also been found, a single example of fossil *Luidia* has been made known from the marlstone of Yorkshire, and a *Goniaster* from Oolitic Beds in Germany. In the Upper Secondary (Cretaceous Rocks) numerous fossil Star-Fishes have occurred, especially of the genus *Goniaster*. Representatives of *Oreaster*, *Astropecten*, *Asterina*, and *Arthraster* (n. g.), are also present in the Cretaceous series. The few older Tertiary Star-Fishes with which we are acquainted belong to the genus *Astropecten*. Arguing from the analogy of their associates, there can be no question that Star-Fishes were abundant in the Tertiary seas.

"Yet how very rare are the traces of their existence. In the later Tertiary Strata, the only evidence as yet procured of their presence during the deposition of those beds consists in a few minute fragmentary ossicula of *Urasteria*. Yet when we consider the gregarious habits of those Star-Fishes, especially of the species to which the ossicula preserved in all probability belonged, it is very wonderful to remark the almost total disappearance of their exuviæ, and the fact should serve as a caution to those who would unhesitatingly infer the absence of a tribe of organised beings, especially of such as present few facilities for preservation, from the absence of their fossil remains. Even now, when dredging, we very rarely bring up any remains of dead Star-Fishes, whilst the living animals are not only present in the locality explored, but often so abundant as to fill the bag of the dredge, to the exclusion of all other creatures.

"Instead of confining this paper to an account of the Palæozoic Star-Fishes only, I have thought it desirable to embody in it a synopsis of all our British fossil species, and a notice of all foreign ones with which I am acquainted. This is the more necessary as no connected account of the fossil *Asteriadæ* exists, and as the geologist has no text at present by which he may determine the species in his collection." (See Table in column 485.)

One of the most interesting groups of Fossil *Echinodermata*, is undoubtedly that to which the name *Cystideæ* has been given. Remains of these creatures were known to occur in the strata of the north of Europe, as long ago as the time of Linnæus. The true nature and relations of these fossils were entirely misunderstood, till the appearance of Von Buch's illustrated Essay 'Über Cystideen,' published in 1845. Since the publication of Von Buch's Essay numerous researches have been made in this country and on the continent of Europe on this subject. One of the most valuable contributions is the Monograph of Professor E. Forbes, 'On the Cystideæ of the Silurian Rocks of the British Islands,' in the 'Memoirs of the Geological Survey of Great Britain.' The general characters of this group of animals are as follows:—They are more or less spherical bodies covered with polygonal plates, varying in number according to the genus, closely fitting together, so as to invest the entire surface with a coat of mail, except at four points, namely, inferiorly where the body unites with a stem; centrally or above the centre; on one side, where there is an opening closed by valves, supposed with good reason to be the orifice of the reproductive system; and superiorly where the mouth is found, usually if not always with a small perforation, supposed to be a vent, alongside of it. These parts, namely, the plates investing the body, the three orifices (for the fourth perforation, that of the base, is continuous with the canal of the stem where the latter is well developed), and probably the stem, are common to all *Cystideæ*.

There are other parts, apparently of great consequence in the organisation of the animal, which are common only to certain members of the order. These are the brachial appendages (arms and tentacula) and certain curious organs connected with the plates, to which the name of 'pectinated rhombs' may he appropriately given. (Forbes.)

The result of Professor E. Forbes's lahours are given in the following Tahle of Fossil *Asteridæ* :—

	Genus.	Species.	Formation.	Locality.	Reference.

The following is an arrangement of the genera of British *Cystideæ* found in the Silurian Rocks :—

A. Bodies composed of definite numbers of plates.

a. With arms and pectinated rhombs. (Upper Silurian.)

Pseudocrinites.

Apiocystites.

b. Armless, with oval tentaculated and pectinated rhombs. (Upper Silurian.)

Prunocystites.)

c. Armless, with oral tentacula wanted; pectinated rhomb present. (Upper Silurian.)

Echino-Encrinus.

d. Armless, no rhombs; bodies composed of four series of plates, exclusive of the oral plates. (Lower Silurian.)

Hemicosmites.

e. Armless, no rhombs; bodies composed of more than four series of plates, exclusive of the oral plates. (Lower Silurian.)

Caryocystites.

B. Bodies composed of an indefinite number of plates.

a. With arms, no rhombs. (Lower Silurian.)

Agelocrinites.

b. Without arms, no rhombs. (Lower Silurian.)

Various views have been entertained hy naturalists as to the nature of these bodies. Linnæus, from the polygonal forms of the plates with which they are covered, regarded them as minerals. From the time however that their animal nature was admitted, they have heen regarded hy most writers as helonging to various groups of the *Echinodermata*. Mr. M'Coy has suggested their resemhlance to certain forms of *Ascidia*, hut Professor E. Forhes regards this resemhlance as one of analogy only. In the Monograph above referred to, Professor Forhes thus arranges the *Cystideæ* amongst the *Echinodermata* :—

ECHINIDÆ. ASTERIADÆ. OPHIURIDÆ.

	CYSTIDEÆ	
Archæocidaris.		
Palæchinus.		*Pentacrinites.*
Agelocrinites.		Apiocystites.
		Pseudocriuites.
Sphœronites.		Pruuocystites.
		Echinoencrinites.
Caryocystites.		Cryptocrinites.

Hæmicosmites.

Caryocrinus.

CRINOIDEÆ.

"In this diagram," says Professor Forhes, "the word CYSTIDEÆ occupies the centre, and around it are the names of the several geuera of undouhted Cystideans printed in small Roman letters, and arranged in the order of their affinities. Between them, however, and the names in small Roman capitals indicating the great groups of equal value with the CYSTIDEÆ, are other names of genera printed in italics. These are the genera which seem to me to link the Cystideans with the members of the other great sectious of *Echinodermata.* The lowest of these is the remarkable fossil *Caryocrinus*, admitted on all hands to afford a distinct passage from the Crinoids to the Cystideans, as far as there can be a distinct passage hetween two great orders." He then proceeds to point out in detail the relations of the various genera referred to with each other and with the families at the top of the diagram.

ECHINODI'SCUS. [ECHINIDÆ.]

ECHINOLA'MPAS, a genus of fossil *Echinida*, from the Oolitic and Chalk Strata. [ECHINODERMATA.]

ECHINOME'TRA. [ECHINIDÆ.]

ECHINONE'US. [ECHINIDÆ.]

ECHINO'PHORA (from ἐχῖνος, a hedgehog, and φορος, in composition signifying 'hearing'), a genus of Plants helonging to the natural order *Umbelliferæ*, and to the tribe *Smyrneæ*. It has a calyx of fivo teeth, the petals obcordate with an inflexed point, the exterior largo and hifid; the flowers of the ray sterile on loug stalks, the central fertile and solitary; the fruit ovate terete, emhedded in the enlarged receptacle; the carpels with five depressed equal striated wavy ridges; interstices with single vitta, covered by a cobweh-like memhrane. The *E. spinosa*, the Sea-Parsnip, has heen admitted into the British Flora, but it must he considered a douhtful native. It has heen found in Lancashire and Kent. It is mostly an inhahitant of sandy sea-shores, and has pinnate spinose leaves, and resembles in hahit and external character the *Eryngium*. Three other species are described. When cultivated they require a warm situation and a dry soil. They must he propagated hy cuttings of the roots or stems. (Don, *Dichlamydeous Plants.*)

ECHINORHI'NUS. [SQUALIDÆ.]

ECHINORO'DON. [ECHINIDÆ.]

ECHINO'STACHYS, a genus of Fossil Plants, from the Bunter Sandsteiu. (Brongniart.)

ECHINUS. [ECHINIDÆ.]

ECHIODON, a genus of Apodal Malacopterygious Fishes belonging to the family *Murænidæ*. The head is oval; jaws furnished with large cylindrical teeth in frout; other smaller teeth on the palatal hones and on the vomer. Gill-apertures large; branchiostegous memhrane with seven rays. Body smooth, without scales, elongated, compressed. Dorsal and anal fins nearly as long as the body; all the rays soft; no ventral fins; anal aperture near the head.

This genus was constituted to receive a very remarkable fish found by Dr. J. L. Drummond on the beach at Camclough, near Glenarm, in the county of Antrim, Ireland. It was described by the late Mr. W. Thompson in part iii. vol. ii. of the 'Transactions of the Zoological Society.' This fish has anomalous characters, and Mr. Thompson had some difficulty in assigning it its proper position. The total length of the fish was 11 inches. As Dr. Drummond's specimen is the only one on record, nothing is known of the habits of the fish.

(Yarrell, *British Fishes*.)

ECHI'TES, a genus of twining Plants, inhabiting tropical countries, and belonging to the natural order *Apocynaceæ*. They have handsome yellow or white corollas, and are moreover remarkable for the singular fruit, which consists of two divaricating woody pod-like follicles containing a large number of silky seeds. There are above 60 species of this genus. They are dangerous lactescent plants, of no known use.

E'CHIUM (from ἔχις, a viper), a genus of Plants belonging to the natural order *Boraginaceæ*. It has a calyx with five deep segments; the corolla sub-bell-shaped, throat dilated, naked, limb irregular; the stamens exserted, filaments very long, unequal, style bifid; the nuts wrinkled, attached by a flat triangular base. The species are rough shrubby or herbaceous plants, with lanceolate or oblong-lanceolate leaves, and blue or white flowers.

E. vulgare, Viper's Bugloss, is covered with hispid tubercles, has an erect simple stem, the leaves lanceolate, 1-ribbed, the stem-leaves narrowed below, sessile, the flowers in short lateral spikes, the stamens longer than the corolla. It is a native of dry places in Great Britain and throughout Europe. It is a remarkably handsome plant. The flowers are at first reddish, and afterwards become blue.

E. violaceum is a pilose-hispid plant, with an erect branched diffuse stem, the lower branches prostrate, the radical leaves oblong-ovate, stalked, the stem-leaves oblong, narrowed from a cordate half-clasping base with lateral ribs, the spike panicled, elongate, simple, the stamens scarcely longer than the corolla. The root of this plant is red, and when kept in an herbarium stains the paper of a violet colour. It is a native of Jersey, also of the south of Germany, Spain, France, Italy, and the south of Taurida.

E. giganteum has a branched stem, hoary at the top, with petiolate-lanceolate leaves attenuated at the base; the panicles thyrsoid; the spikelets bifid. This plant is a shrub, with whitish-blue flowers, and attains a height of eight or ten feet, and is one of the largest species of the genus. It is a native of Teneriffe.

E. plantigineum, naturalised in Brazil, is used in that country as a pickle. The roots of *E. rubrum* yield a red dye, which is used in the arts.

Above 80 species of this genus have been described; they inhabit the temperate parts of all quarters of the globle, but are more especially European. A large number of the shrubby species are natives of the Canary Islands, and another entirely different group are inhabitants of the Cape of Good Hope. The great bulk of the European species are herbaceous, as well as those which inhabit South and North America. All the species are worthy of cultivation, and the European species are amongst the handsomest of the indigenous plants of Europe. The shrubby species are all greenhouse plants, and will grow in a mixture of sand, loam, and peat; and cuttings will strike under a hand-glass in this mixture. They may be also propagated by layering and by seed, which sometimes come to perfection in this country. The hardy species will grow very well in any common garden soil, and may be propagated by seeds sown in an open border, in the spring; their general treatment must be the same as other perennial, biennial, and annual plants. They are well adapted for flower-borders, and afford a pleasing variety by the different shades of blue which they exhibit.

(Don, *Dichlamydeous Plants*; Babington, *Manual*.)

ECHIURUS. [SIPUNCULIDÆ.]

ECPHYMO'TES (Fitzinger), a genus of Saurians belonging to the family of the *Iguanidæ*. It possesses the teeth and pores of the genus *Polychrus*, but with small scales on the body only. The tail, which is large, has great scales, which are rhombic and carinated. The head is 4-sided, and covered with small plates. The form is a little short and flattened, like that of some of the *Agamæ*, rather than like the slender shape of *Polychrus*. There are four species—*E. Fitzingerii* and *E. undulatus*, natives of Brazil; *E. obtusirostris*, native of Mexico; and *E. acutirostris*, a native of Brazil.

ECTOCARPACEÆ. [ALGÆ.]

ECTOPISTES. [COLUMBIDÆ.]

ECTOZOA (from ἐκτός, without, and ζωός, living), animals found living upon the external parts of other animals. This term is applied to distinguish the forms of animal life which are parasitic upon the surface of other animals from those which inhabit their interior. [ENTOZOA.] Whilst those which inhabit the interior of animals have so much resemblance to each other that naturalists place them together in an order which is called *Entozoa*, those which are found on the surface are very dissimilar, and belong to distant and dissimilar families. The term *Ectozoa* is therefore not one expressing any affinity between the animals included in it, but simply refers to their habitation.

The *Ectozoa* as well as *Entozoa* are found frequently associated with the diseased states of the animal bodies on which they are found, and much discussion has arisen as to whether they are the true causes of the diseases which they accompany. Thus much is certain, that whether they originate or not the diseased state of the body on which they are found, when allowed to increase they become themselves a source of diseased conditions, which disappear as soon as they are destroyed.

This is a general law equally applicable to parasitic plants as well as animals. So that it would appear that, although their first attacks may be invited by a diseased condition of the plant or animal on which they are found, they may be productive of destructive effects by an unnatural and unhealthy increase. Every species of plant and animal appears to be subject to the attacks of special forms of parasitic plants and animals; and with regard to the latter they may be either inside or outside, so that we have not only *Ectozoa* and *Entozoa*, but *Ectophyta* and *Entophyta*. [ENTOPHYTA.]

Under the term *Epizoa* a number of animals have been placed together whose claims to be regarded as a section of the great family *Crustacea* are now generally recognised. These are found more especially on the bodies of fish, infesting their skin, eyes, and gills. They are very numerous, and the larger number of them belong to the family *Lerneadæ*. [LERNEADÆ.] They must be regarded as the *Ectozoa* of aquatic animals. The bodies of the *Cetacea* are frequently the chosen residence of many species of *Cirripedia*. [CIRRIPEDIA.] These ecto-parasitic habits seem to be partaken of by some of the Vertebrate Animals, as we find the *Remora* [ECHENEIS] and other fish attaching themselves to the bodies of animals by an apparatus adapted for the purpose.

Land animals are subject to the attacks of various forms of *Ectozoa*, more especially those belonging to the Articulate tribes of animals. The following is a list of the creatures to which man is subject in various parts of the world:—

Phthirus inguinalis (Leach), the Crab-Louse; *Pediculus Capitis* (Nitzsch), Head-Louse; *Pediculus Vestimenti* (Nitzsch), Body-Louse; *Pediculus Tabescentium*, Burmeister [ANOPLURA]; *Sarcoptes Scabiei* (Latreille), Itch-Insect [ACARIDÆ]; *Dermanyssus Boryi* (Gervais); *Ixodes Americanus* (De Geer), Tick [IXODES]; *Argas Persicus* (Fischer); *Pulex penetrans* (Gmelin), Chigoe; *Pulex irritans* (Linn.), Common Flea [PULEX]; *Cimex lectularius* (Linn.), Bed-Bug [BUG]; *Œstrus Hominis* (Say), Gad-Fly [BOTS].

Other creatures are occasionally found taking possession of the surface of the human body. In diseased conditions the common fly has been known to deposit its ova in various parts of the body, and many of the insects which are parasitic upon the lower animals will take up their abode on the human body. This is the case with the various forms of the *Anoplura*, which are a peculiar species on almost every species of animal on which they are found, so also with the species of the genera *Pulex* and *Cimex*.

(Leidy, in *Flora and Fauna within Living Animals*.)

EDA'PHODON, a genus of Fossil Placoid Fishes, from the London Clay and Bagshot Sand. Three species. (Agassiz.)

EDDOES, the name by which the esculent *Caladium* is known by the blacks of the Gold Coast. [CALADIUM.]

EDELSFORSITE, a Mineral consisting of silicate of lime, &c. It occurs fibrous or feathery and massive. Its colour is white or grayish. Its hardness 6 (?). Its lustre shining. Transparent. The specific gravity 2·58. It is found at Aedelfors in Smaland, Cziklowa in the Banate, and in Norway. The following is its analysis:—Silica, 61·85; lime, 38·15, with small quantities of magnesia, alumina, and iron. Another compound under this name has also been called the Aedelfors Red Zoolite. It agrees in composition with *Stilbite*, except that it contains 2 per cent. less of water.

EDENTATA, a group of Mammiferous Animals brought together on account of their agreement in the comparatively unimportant character of the absence of incisive teeth in their jaws, and the length of their claws. Cuvier divided his *Edentata* into three tribes:—1. *Tardigrades*, including the Sloths. [BRADYPUS]. 2. The *Edentata* proper, including the Armadilloes (*Dasypus*) [ARMADILLO]; the Aard-Vark (*Orycteropus*) [ARD-VARK]; the Chlamyphore [CHLAMYPHORUS]; the Ant-Eaters (*Myrmecophaga*) [ANT-EATER]; and the Pangolins (*Manis*) [MANIS]. 3. The third tribe embraces the *Monotremes*, *Echidna*, and *Ornithorhynchus*. These last are mostly regarded as a group of at least equal value with the *Edentata*. [ECHIDNA; ORNITHORHYNCHUS.] The *Edentata* also include the gigantic toothless *Herbivora* of a former period in the world's history, and of which the *Megatherium* may be taken as a type. [MEGATHERIDÆ.]

In the list of the specimens of the *Mammalia* in the 'Collection of the British Museum,' the species of this group are distributed as follows:—

Order V. UNGULATA.

Family 4. DASYPIDÆ.

a. Manina.

Manis tetradactyla, the Phatagin.
M. multiscutata, Many-Shielded Phatagin.
M. pentadactyla, the Badgareit.
M. Javanica, the Tangiliu.

b. Dasypina.

Dasypus sexcinctus, the Armadillo.
Tatusia tricincta, the Apara.

T. septemcinctus, the Peba.
T. minuta, the Pichey.
Xenurus unicinctus, the Tatouay.
Priodonta gigas, the Tatou.

c. *Myrmecophagina.*

Orycteropus Capensis, the Aard-Vark.
Myrmecophaga jubata, the Tamanoir.
Tamandua tetradactyla, the Tamandua.
Cyclothurus didactylus, the Ant-Eater.

d. *Ornithorhynchina.*

Platypus anatinus, the Mullingong.
Echidna hystrix, the Echidna.
E. setosa, Brown Echidna.

Family BRADYPIDÆ.

Cholœpus didactylus, Unau.
Bradypus torquatus, the Gipakeiou.
B. gularis, the Yellow-Faced Sloth.
B. tridactylus, the Sloth or Ai.

EDINGTONITE, a Mineral, consisting of silicate of alumina, &c. It occurs in small right square prisms, with lateral cleavage. It is nearly colourless, and has a vitreous lustre. It has a hardness of 4 to 4·5, and a specific gravity from 2·7 to 2·75. It is found with Thomsonite, in Dumbartonshire.

EDRIOPHTHALMIA (Leach), a legion of Crustaceous Animals with sessile eyes, which are generally compound, but sometimes simple, situated on the sides of the head. Tho mandibles are often furnished with a palp, and the head is almost always distinct from the body.

Desmarest makes the *Edriophthalmia* comprehend the *Amphipoda* of Latreille, which, the former observes, Leach has not admitted, and which iucludes the two first sections of his legion of *Malacostraca Edriophthalmia*, and correspouds to the genus *Gammarus* of Fabricius.

The *Amphipoda* are characterised as having a head distinct from the trunk, aud formed of a single piece; mandibles provided with a palp; jaws to the number of three pairs, the external pair of which represent a lip with two palps or two small feet uuited uear its origin; a body laterally compressed, and divided into seven segmeuts; fourteen feet, of which the anterior are often terminated by a claw with a siuglo finger; vesiculous branchiæ situated at the internal base of the feet, with the exception of that of the anterior pair; tail composed of from six to seven articulations, and bearing underneath five pairs of false feet in form of filaments, with two very moveable branches. They are thus divided by Desmarest:—

The first section consists of those species whose antennæ are inserted one on each side of the front; whose tail is terminated by styliform filaments; and whose head is large and vertical. Example, *Phronima*, Latr., Leach, Lam., &c. &c.; *Cancer*, Herbst, Forsk.

The secoud (not admitted by Leach) comprises those with four antennæ; two flattened leaflets serving for fins, placed at the end of the tail, in place of the styles; and the head large and vertical. Example, *Hyperia*, Latr.

The third includes those which have four antennæ; the tail terminated by styliform filaments; the head moderately large and not vertical, aud contains six divisions, some of which are subdivided. *Talitrus*, Latr.; *Atylus*, Leach; *Dexamine*, Leach; *Melita*, Leach; *Gammarus*, Fabr.; *Podocerus*, Leach; *Corophium*, Latr.; *Cerapus*, Say, may be taken as examples of some of tho forms of these divisions and subdivisions.

The other orders arranged by Desmarest under the *Edriophthalmia* are the *Læmodipoda*, Latr., and the *Isopoda*, Latr.

M. Milne-Edwards makes the Edriophthalmians consist of the same orders, placing them as a legiou of the sub-class of Maxillated Crustaceans, next to tho legion of Podophthalmians. [CRUSTACEA.]

EDWARDSIA. [ACTINIADÆ.]

EDWARDSITE, a name for *Monazite*. [CERIUM.]

EEL. [MURÆNIDÆ.]

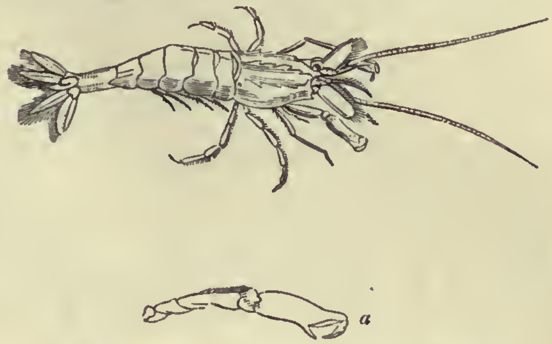
EEL, SAND. [AMMODYTES.]

EFT. The terms Eft and Newt are applied almost indiscriminately to all the species of Lizards which are found in the British Islands. The word lizard is evidently formed from *lacerta*, and is comparatively modern. Eft and Newt are the old Saxon words. Eft seems to be more usually applied to the land animals, one of the most common of which is the *Zootoca vivipara*, and another less common, the *Lacerta agilis*. Newt is more commonly applied to the animals which inhabit ponds, wet ditches, and other damp places, such as the *Triton cristatus* (the Great Water-Newt), *Lissotriton punctatus* (the Common Smooth Newt), and other species. [AMPHIBIA; SAURIA.]

EGEON, Risso's name for a genus of Macrourous Decapodous *Crustacea*, whose characters aro generally like those of the Shrimp [CRANGONIDÆ], but with the following differeuces. The fourth or last visible joint of the external jaw-feet is nearly twice as large as the preceding. The feet of the second pair are extremely short, slender, and didactylous; those of the third loug, very slender, and terminated by a single nail; those of tho fourth and fifth pairs larger, and ending by a compressed nail. The carapace elongated, cylindrical, spinous, and terminated anteriorly by a small rostrum.

The extreme brevity, observes Desmarest, of the second pair of feet, and the roughness of the carapace, are the most remarkable of theso differences; but they do not in his opinion present characters sufficient for the establishment of a genus.

E. loricatus, Risso; *Pontophilus spinosus*, Leach (see 'Trans. Soc. Linn.' t. xi., p. 346; and 'Malac. Brit.' tab. 37 A) has a carapace supporting three longitudinal dentelated carinæ above; rostrum very short; total length about an inch and a half. *Pontophilus spinosus* inhabits the coasts of England, those of Nice and the Adriatic Sea.



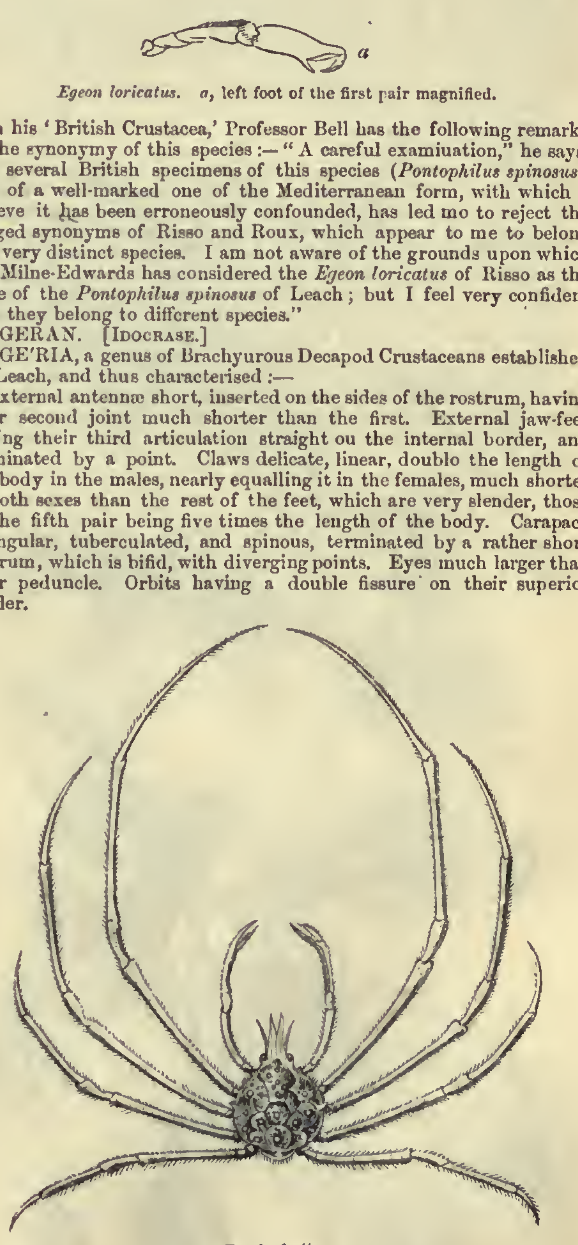
Egeon loricatus. *a*, left foot of the first pair magnified.

In his 'British Crustacea,' Professor Bell has the following remarks on the synonymy of this species:—"A careful examiuation," he says, "of several British specimens of this species (*Pontophilus spinosus*), and of a well-marked one of the Mediterranean form, with which I believe it has been erroneously confounded, has led mo to reject the alleged synonyms of Risso and Roux, which appear to me to belong to a very distinct species. I am not aware of the grounds upon which Dr. Milne-Edwards has considered the *Egeon loricatus* of Risso as the male of the *Pontophilus spinosus* of Leach; but I feel very confident that they belong to different species."

EGERAN. [IDOCRASE.]

EGE'RIA, a genus of Brachyurous Decapod Crustaceans established by Leach, and thus characterised:—

External antennæ short, inserted on the sides of the rostrum, having their second joint much shorter than the first. External jaw-feet having their third articulation straight ou the internal border, and terminated by a point. Claws delicate, linear, doublo the length of the body in the males, nearly equalling it in the females, much shorter in both sexes than the rest of the feet, which are very slender, those of the fifth pair being five times the length of the body. Carapace triangular, tuberculated, and spinous, terminated by a rather short rostrum, which is bifid, with diverging points. Eyes much larger than their peduncle. Orbits having a double fissure on their superior border.



Egeria Indica.

Desmarest observes that this genus, somewhat hastily established by Leach, if the uumber of articulations of the abdomen in the species which compose it were seven, would be nearly approximated to *Maia*, *Pisa*, *Mithrax*, and *Micippa*, in the form of the body; but the difference lies in the delicacy and disproportioned length of the feet. If the number of articulations composing it be six, as there is room for believing, although neither Latreille nor Leach say so positively, it would bear great relationship to the long-legged genera, *Macropodia*, *Leptopodia*, and *Doclea*, for example. But it has not the long, slender, divided rostrum, as well as the long claws larger than the feet, which characterise the first; nor does it present the very long, very slender, and entire rostrum, as well as the very elongated and linear claws, of the second; and finally, it has not the globular body and the very short and delicate claws of the last. It is removed from *Inachus* by the claws, which are proportionally shorter and less thick than those of the last-named crustaceans; by the other feet, which are relatively longer than theirs; by the antennæ, of which the first two joints of the base, and not the third, are longer than the others; and by the double fissure of the bottom of the orbits above.

E. Indica, in size, general form of the body, and length of the feet, bears a great resemblance to *Inachus Scorpio*; but besides the generic differences pointed out, it is still further removed from it in having a larger rostrum which is deeper incised in the middle, and in having the points with which the elevated and distinct regions of the carapace above are beset disposed in the following order: 3, 2, 1 and 1. A rather long sharp-post-ocular point is directed forwards. The arms are rather short and slender. It inhabits the Indian seas.

Egeria is also used by De Roissy for a genus of Conchifers, which M. Sander Rang considers identical with *Galathea*, Brug., and *Potamophilus*, Sow.

EGG. [REPRODUCTION IN ANIMALS.]

EGG-APPLES. [SOLANUM.]

EGG-PLANT. [SOLANUM.]

EGLANTINE. [ROSA.]

EGRET, the common name of several species of Heron. [ARDEA.]

EGYPTIAN BEAN, a name sometimes given to the bean-like fruits of *Nelumbium speciosum*, from the notion that they were the beans which the disciples of Pythagoras were forbidden to eat.

EHRETIA'CEÆ, *Ehretiads*, a small natural order of Exogenous Plants, consisting of shrubs or trees inhabiting the warmer countries of the world, and having rough leaves, monopetalous regular flowers, a definite number of stamens, a superior ovary, a 2-lobed style whose divisions are capitate, and a nucamentaceous undivided fruit. The flowers are more or less gyrate, and the order itself, which contains no species of economical value, is so near *Boraginaceæ* as to render it doubtful whether it ought to be separated. The common Heliotrope is the most generally known representative of *Ehretiaceæ*, forming however the type of a sectional division characterised by the fruit being dry, not succulent. There are 14 genera and 297 species of this order.

The root of *Ehretia buxifolia* is used in medicine in India. Some of the species of the genus *Ehretia* bear eatable drupes.

EIDER-DUCK. [DUCKS.]

EIRENE. [ACALEPHÆ.]

EKEBERGITE (*Sodaite*), a Mineral, consisting of a silicate of alumina, lime, and soda. It does not occur crystallised, but in compact or finely-fibrous masses, and occasionally in thin laminæ. Its colour is green, grayish, or brownish. The lustre is vitreous or resinous. It is transparent. The following is an analysis by Ekeberg:—

Silica	46
Alumina	28·75
Lime	13·50
Soda	5·25
Oxide of Iron	0·75
Water	2·25

ELÆAGNA'CEÆ, *Oleasters*, a small natural order of Apetalous Exogenous Plants, consisting of trees or shrubs whose leaves are either opposite or alternate, destitute of stipules, and always protected more or less by scurfy scales, which usually give the plants a leprous aspect. The genera of this order have a tubular 4-lobed calyx, the inside of which is lined with a fleshy disc, that sometimes almost closes up the tube; there are 3, 4, or 8 stamens, and a superior ovary containing a single erect ovule. The fruit is soft, succulent, and would be eatable if it were not for its dryness and insipidity. In a few cases, when it is more than usually juicy and acidulated, it is actually considered an excellent fruit. *Elæagnus hortensis* and *E. orientalis* bear a brown fruit about the size of an olive, which is brought to market in Persia under the name of Zinzeyd: in quality it is like a jujube. The red drupes of *E. conferta*, the large olive-shaped ones of *E. arborea*, and the pale orange-coloured ones of *E. triflora* are in like manner eaten in India; another occurs among the drawings of Chinese fruits. It is not a little curious, nearly as *Elæagnaceæ* are related to *Thymelæaceæ*, that they do not seem to participate in any degree in the acridity of that deleterious order. The only species found wild in Great Britain is the *Hippophaë rhamnoides*, a spiny shrub with diœcious flowers, small round orange-coloured acid berries, and narrow leaves like those of rosemary, found growing on cliffs near the sea; its fruit, when the acidity is sufficiently covered by sugar, becomes a rather pleasant preserve. *Elæagnus angustifolia*, called in the gardens the Olivier de Bohême, a native of the eastern parts of Europe, is one of the most fragrant of all plants. Its dull yellow flowers, hardly remarked among the leaves, fill the

Beurreria succulenta.

1, an ovary with the style and double stigma; 2, a ripe fruit with the calyx at the base; 3, a section of the same showing the seeds.

Elæagnus angustifolia.

1, a section of the tube of the calyx, showing the fleshy disc almost closing up the tube, the carpel, with its style and stigma, and the erect solitary ovule; 2, a ripe fruit; 3, the same cut away to show the single furrowed seed.

atmosphere with a delicious perfume, the source of which is not readily discovered by the passer-by. The genera comprising this order are *Elæagnus*, *Hippophaë*, *Conuleum*, and *Shepherdia*. They embrace about 30 species.

ELÆIS, a genus of Palms, so named from *Elaia*, the Olive-Tree, because an oil is yielded by the fruit of its principal if not only species. This is *Elæis Guineensis*, or Oil-Palm, Maba of the natives of the Congo. It is common all along the western coast of Africa. The tree is monœcious, as we are informed that both male and female spadices were obtained from a single plant cut down by Professor Smith. (Brown, in Tuckey's 'Congo.') The stem is tall, about ten inches in diameter, rough, and bristling with the persistent bases of the petioles, of which the margins, as in recent leaves, are fringed with spines. The leaves are pinnate, about 15 feet in length, with two rows of sword-shaped leaflets, each 18 inches long. The fruit is ovoid, about the size of a pigeon's egg, with its outer fleshy covering of a golden yellow colour; and like that of the section *Cocoinæ*, to which it belongs, and analogous to the cocoa-nut, has the foramina of its putamen at the apex, and not at the base, as represented by Gærtner and others.

Mr. Brown has observed it as remarkable that *Cocos Indica* and this palm, which is universally, and he believes justly, considered as having been imported into the West India colonies from the west coast of Africa, should be the only two species of an extensive and very natural section of palms that are not confined to America. The *Elæis occidentalis* of Swartz, the Thatch-Tree of Brown's 'Jamaica,' and the Avoira of Aublet, are probably all identical with the Maba, or Oil-Palm, of the African coast.

The oil is obtained by bruising the fleshy part of the fruit (and not the kernel as sometimes stated), and subjecting the bruised paste to boiling water in wooden mortars; an oil of an orange-yellow colour separates, which concretes when cool to the consistence of butter, and has when fresh the smell of violets or of the root of Florentine iris, with a very slightly sweetish taste. The oil is used by the Africans in cookery and for anointing the body. It forms a considerable article of commerce to Europe, where it is chiefly employed in perfumery and medicine. *Cocos butyracea* (which is referred by Kunth to the genus *Elæis*) is considered by the Edinburgh College to be the plant which yields palm-oil.

Mr. Brown (Tuckey's 'Congo,' Appendix, p. 456) states, "It is probable that *Alfonsia oleifera* of Humboldt, Bonpland, and Kunth belongs to *Elæis*, and possibly may not even differ from the African

Alfonsia oleifera.

species. To this the above authors in the 'Synopsis Plant. Æquinoct.' reply, that in *Elæis*, according to the description of Jacquin, both the floral envelopes are sexifid, while in *Alfonsia* they are trifid. If this moreover be the same as the corozo of Jacquin, another essential difference may be observed in the structure of the fruit of the two plants, the nut in *Elæis* being perforated at the apex, while the corozo has its nut perforated with three foramina at its base;" but this might have been inverted, as that of *Elæis* was by Gærtner. Humboldt and Bonpland moreover found *Alfonsia oleifera* always growing wild, while *Elæis Guineensis*, as they state, is never found except in a cultivated state out of Africa. The compressed nut of the *Alfonsia*, like that of the cocoa-nut, is described as yielding an oil, which is obtained by boiling in water the Manteca del Corozo; it is described as a liquid fat employed for ordinary lamps as well as those of churches.

ELÆOCARPA'CEÆ, *Eleocarps*, a natural order of chiefly Indian Trees, having a strong botanical resemblance to our European Lindens, but differing in having fringed petals, and anthers opening by two pores at the apex.

In the Indian genera, the nuts, cleared of the soft pulp or flesh that covers them, are curiously sculptured, and being bony and taking a fine polish they are frequently set in gold and strung into necklaces. The nuts of *Ganitrus sphæricus*, a middle-sized tree, common in various parts of India, as well as the Malay Archipelago, and those of *Menocera tuberculata*, from the forests of Travancore, are what are principally used for this purpose. The fruits of *Elæocarpus serratus*, which are very much like olives when ripe, are said by Roxburgh to be pickled or dried and used in their curries by the natives of India. *E. cyaneus* has pure white beautifully-fringed petals, and is one of the most ornamental plants of Australia. Lindley, in his 'Vegetable Kingdom,' places this order as a sub-order or division of *Tiliaceæ*.

A flowering shoot of *Elæocarpus cyaneus.*

1, a magnified flower; 2, a petal; 3, the stamens; 4, a ripe fruit; 5, the same cut away to show the wrinkled seed.

ELÆOCOCCA. [EUPHORBIACEÆ.]

ELÆODENDRON (from ἐλαία, an olive, and δένδρον, a tree), a genus of Plants belonging to the natural order *Celastraceæ*. It has a 5-parted calyx; 5 expanding linear-oblong petals; a 5-angled very thick fleshy disc; 5 anthers inserted into the margin of the disc; the filaments at length recurved; anthers with a thick connective, roundish, opening longitudinally; the ovary immersed in the disc, 2-celled; the ovules 2 in each cell; the style short, conical; the stigma simple, obtuse; the fruit drupaceous, dry, or pulpy; the nut 1-2-celled; the seeds usually solitary, with a membranaceous or spongy integument erect. The species are small trees with opposite entire glabrous leaves.

E. glaucum has elliptical serrated leaves, hardly three times longer than the petioles; the cymes loose, nearly the length of the leaves; the flowers pentandrous. It is a small tree, about 14 feet in height and is a native of Ceylon and Caromandel. The tree has been introduced into Great Britain from Ceylon under the name of Ceylon-Tea. It has leaves like those of the tea-plant, but it does not appear to be used as a substitute for that plant.

E. Roxburghii has oblong serrato-crenate, opposite and alternate, hard, smooth, shining leaves, about 4 inches long and 2 inches broad, with the petioles three-quarters of an inch long; the cymes globular, and three times the length of the petioles. It is a native of the mountainous parts of India. It possesses powerful astringent properties, but is not used as an internal medicine.

The fruit of all the species resembles that of the olive, and hence the generic name. *E. orientale* is a native of the Mauritius and Madagascar, where it is called by the French Bois d'Olive. *E. Argam* contains in its fruit a fixed oil like the common olive, which is used by the Moors for the same purpose as olive-oil is used in Europe.

The species of *Elæodendron* will grow freely in a mixture of loam and peat, and ripened cuttings will root in sand under a hand-glass.

(Lindley, *Flora Medica;* Loudon, *Encyclopædia of Plants;* Don, *Dichlamydeous Plants.*)

ELÆOLITE (*Fettstein*), a Mineral, consisting of a silicate of alumina, soda, iron, &c. It occurs in amorphous masses, with cleavages parallel to the lateral planes, and both diagonals of a rhombic prism. Its fracture is conchoidal. Colour dark green, bluish-gray, or grayish or brownish-red. The hardness is 5·5 to 6·0. The lustre resinous, frequently opalescent when cut. Translucent. The specific gravity is 2·54 to 2·62. It is found at Laurvig, Stavern, and Fredrickswärn in Norway. The following is an analysis by Vauquelin:—

Silica	44·00
Alumina	34.00
Soda	16·50
Peroxide of Iron	4·00
Lime	0·12

Gmelin found also 4·733 per cent. of potash, and only 0·651 per cent. of peroxide of iron.

ELAND. [ANTILOPEÆ.]

ELANET, a form of Hawk (*Falco melanopterus*, Daudin) inhabiting Africa, and also India and America. [FALCONIDÆ.]

ELAPHAS. [CERVIDÆ.]

ELAPHRIUM. [CALOPHYLLUM.]

ELAPS. [VIPERIDÆ.]

ELA'SMODUS, a genus of Fossil Placoid Fishes from the London Clay. (Egerton.)

ELA'SMOTHERIUM. [PACHYDERMATA.]

ELASTIC TISSUE. The elements of Elastic Tissue are cylindrical or band-like fibres with dark contours, very minute, and when present in large numbers they exhibit a yellowish colour. Hence it has been called Yellow Tissue. The fibres acquire sometimes little cavities in particular spots, which give these fibres a striated appearance, as seen in the giraffe. The elastic tissue is rarely found in large masses, but it is very frequently mixed with areolar tissue, either in single fibres or in networks of various kinds. [AREOLAR TISSUE.] The organs into which this tissue enters, and constitute their special feature, are:—

1. The elastic ligaments, in which the tissue with only a slight admixture of connective tissue and hardly any vessels and nerves exists, so to speak, in a pure form. Of these we have examples in the ligamentum subflava of the vertebræ, the ligamentum nuchæ, the ligament of the larynx, and stylo-hyoid ligament.

2. The elastic membranes which appear either in the form of fibrous networks or of fenestrated membranes, and are found in the walls of the vessels, especially in those of the arteries, in the trachea and bronchia, and in the fascia superficialis.

(Kölliker, *Manual of Histology*, translated by Busk and Huxley for the Sydenham Society.)

ELATE'RIDÆ, a family of Coleopterous Insects belonging to the section *Sternoxi* (Latreille), and, according to Linnæus, constituting the genus *Elater.*

The insects of this family are of a lengthened form; the head is, in nearly all cases, deeply inserted into the thorax; the thorax is usually of the same width as the elytra, or nearly so, longer than broad, and the posterior angles are acute, and most frequently produced into a pointed spine-like process: the elytra are long and narrow, cover the abdomen, and their external margins are often nearly parallel. The antennæ are of moderate length, either filiform, serrated, or pectinated, and when the insect is at rest they are deposited in two grooves on the under side of the thorax; at least such is the case in very many of the species. The legs are short and rather slender, and the femora and tibiæ are generally compressed.

These beetles are found upon flowers and upon the leaves of trees and plants; some species however are most frequently met with upon the ground.

When upon any elevated situation, if approached, they apply the legs and antennæ close to the body, and allow themselves to fall to the ground; if they fall upon their back they regain their natural position by a leap, which is always accompanied by a snapping noise similar to that which may be made by the finger-nails. When about to leap they bend the thorax backwards, so that the body is arched, or rather forms an angle, the insect then resting upon the apex of the abdomen and the fore part of the thorax. The leap appears to be effected by the sudden relaxation of the muscular effort which kept the thorax bent backwards, there being a peculiarity in its structure which causes it to spring forwards.

Even in a dried specimen, upon attempting to bend the thorax back, we found considerable resistance; but when allowed, it suddenly assumed its natural position, which is a slight inclination forwards.

There is a strong spine, it must be observed, on the under part of the thorax, at its base, which, when the thorax is in its usual position, is deposited in a groove; and it is said that the leap is performed principally by means of this spine, which is at the time forcibly pressed against the margin of the hollow, into which it sinks suddenly, as if by a spring. From this opinion we are inclined to differ; for upon removing the spine we found not the slightest alteration in that natural spring in the thorax which we before mentioned. Not however having at this moment the means of investigating the subject, it would be premature to venture any further remarks.

The larvæ of the *Elateridæ* feed most generally upon vegetable substances: rotten wood affords food to many; others live in the ground, and feed upon the roots of plants; one of them (the larva of *Elater striatus* of Fabricius) is said to attack the roots of the wheat and when in great numbers to do much injury.

These larvæ are long, rather slender, generally cylindrical, and covered with a tough skin: the head and terminal joint of the body are of a corneous texture; the latter is very variable in form, and is often depressed and produced into two bluntly-pointed processes: the former is furnished with the usual parts, such as jaws or mandibles, maxillæ, palpi, labrum, labium, and antennæ. The three segments which constitute the thorax are each furnished with a pair of short legs.

Of the insects included by Linnæus under the generic name of *Elater*, and others of similar general characters which have been discovered since that naturalist's time, there are upwards of five hundred species enumerated, and as these species (which are now regarded as constituting a family) are divided into about sixty genera, it will be impossible, consistent with the plan of this Cyclopædia, to enter into the detail of their characters. We will therefore confine ourselves to some of the more important,—in fact, to those which are given by Latreille in the 'Règne Animal:' these are as follows:—*Galba, Eucnemis, Adelocera, Lissomus, Chelonarium, Throscus, Cerophytum, Cryptostoma, Nematodes, Hemeripus, Stenicera, Elater* (proper), and *Camphylus.* These genera are divided by Latreille into two sections, in the first of which the antennæ are lodged (when the insect is at rest) within two grooves situated on the under side of the thorax.

This section includes the first six genera.

The genus *Galba* (Latreille) has the antennæ filiform, and received into two grooves situated directly under the lateral margin of the thorax; the joints of the tarsi are simple; the thorax is convex; the mandibles are terminated by a simple point; the maxillæ are furnished with a single small lobe; the terminal joint of the palpi is globular, and the body is nearly cylindrical. The species are all from Brazil.

The genus *Eucnemis* (Ahrens) differs from *Galba* chiefly in having the mandibles bifid at the apex, the maxillæ terminated by two lobes, the terminal joint of the palpi securiform, and the body nearly elliptical. Species of this genus are found in Europe and North America.

Adelocera (Latreille).—Here the antennæ are filiform; the joints of the tarsi are simple, and the anterior legs, when contracted, are received into lateral cavities in the under part of the thorax.

Lissomus (Dalman).—The species of this genus have little cushion-like lobes on the under side of each joint of the tarsi.

In the genus *Chelonarium* (Fabricius) the form approaches to an oval, the second and third joints of the antennæ are larger than the following, and of a flattened form, and these alone are received into the sternal grooves. The head is almost hidden by the thorax, which is semicircular, and the anterior legs are larger than the rest. All the species are from South America.

Throscus (Latreille).—This genus is readily distinguished by the antennæ being terminated by a three-jointed knob; the penultimate joint of each tarsus is bifid; the mandibles are simple.

The species of *Throscus* are very minute. *T. dermestoides*, an insect not uncommon in this country, is about one-eighth of an inch in length, of a brown colour, and obscurely covered with an ashy pubescence.

The second section of the *Elateridæ* comprises those species in which the antennæ are free, or not lodged within grooves on the under part of the thorax.

Cerophytum (Latreille).—The principal characters of this genus are:—Terminal joint of the palpi larger than the following, and almost securiform; tarsi with the four basal joints short and triangular, the penultimate joint bilobed; antennæ serrated in the female, and in the male branched internally.

The *C. Elateroides* (Latreille), an European species, affords an example of this genus.

Cryptostoma (Dejean).—Tarsi simple, small, and slender; anterior extremity of the præsternum projecting beneath the head; the apex of the third and seven following joints of the antennæ prolonged; mandibles unidentate; maxillæ with a single lobe; palpi very short.

C. denticornis (Latreille), the only species known, is from Cayenne.

Nematodes (Latreille).—Body nearly linear; antennæ with the basal joint elongated; each of the five following joints in the form of a reversed cone; the remaining joints almost perfoliate, with the exception of the last, which is oval.

Species of this genus have been found in Europe and North America.

Hemeripus (Latreille).—In this genus the parts of the mouth are exposed, that is, not, as in the last two genera, hidden by the projecting process of the præsternum; the antennæ are flabellate at the apex in the males.

All the species of this genus are extra-European.

In the genus *Ctenicera* (Latreille), the antennæ are pectinated in the males, and deeply serrated in the females.

The *C. pectinicornis*, an insect common in some parts of this country, affords an example of this genus. The species is rather more than half an inch in length, and of a brilliant metallic green or copper-like colour: the female is larger and broader than the male.

In the genus *Elater*, as now restricted, the antennæ are simply serrated.

The *E. æneus* of Linnæus will serve to illustrate this genus. This species, which is common in some parts of England, is generally found under stones on hills of but little elevation, and which are more or less covered with heath. It is about three-quarters of an inch in length, and most commonly of a brilliant green colour; some specimens however are blue, and others are of a brassy or bronze hue.

The *E. noctilucus*, according to Latreille, also belongs to this genus. This species is well known in South America, where it is called the Fire-Fly.* It is rather more than an inch in length, of a brown colour, and covered with an ashy down: on each side of the thorax there is a round glossy yellow spot. These spots emit by night a light so brilliant as to enable a person to read by it, and it is a common practice to place several of the insects together in a glass jar or bottle for this purpose. This insect (with upwards of twenty other species, all of which emit light by night) is now included in Illiger's genus *Pyrophorus*. The species of this genus are, some of them, from each of the following localities:—Brazil, Peru, Buenos Ayres, Chili, Cuba, St. Domingo, and Guyana.

In the genus *Campylus* (Fischer) the eyes are more prominent than in the other *Elateridæ*, and the head is protruded from the thorax; the antennæ are inserted beneath a frontal projection on each side, and the body is long and almost linear.

One species of this genus is found in England, the *C. dispar*, which is of a yellowish colour. In some specimens the head, legs, and antennæ are black, and sometimes the elytra are black with a broad pale margin.

ELATERIUM. [MOMORDICA.]

ELATINA'CEÆ, *Water-Peppers*, a natural order of Plants belonging to Lindley's Calycose group of Polypetalous Exogens. The sepals are 3-5, distinct, or slightly connate at the base; the petals hypogynous, alternate with the sepals; the stamens hypogynous, usually twice as numerous as the petals; the ovary with from 3 to 5 cells, an equal number of styles, and capitate stigmas; the fruit capsular, 3-5 celled, with the valves alternate with the septa, which usually adhere to a central axis; the seeds numerous, with a straight embryo, whose radicle is turned to the hilum, and little albumen. The species belonging to this order are annual plants with fistulous rooting stems, and opposite stipulate leaves, inhabitants of marshy places.

This order is nearly allied to *Caryophyllaceæ*, from which it has been separated by Cambessedes, on account of the different organisation of the seeds, capsules, and stigmas. It agrees with *Hypericaceæ* in many points, and especially in possessing receptacles for resinous secretions, but differs in having a persistent central axis in the fruit, definite stamens, and so forth. The species are found in marshy places and under water in all parts of the globe. Cambessedes arranged three genera in this order:—

1. *Merimæa* (named in honour of Prospero Merimes, an old botanist), with a 5-parted calyx; 5 petals; 10 stamens; 5 styles; a 5-valved, 5-celled, many-seeded capsule, the valve separating, and bent in at the margins so as to constitute dissepiments. This is a South American genus, of which but one species, *M. arenarioides*, a native of Brazil, has been described.

2. *Bergia* (after Peter Jonas Bergius, professor of natural history at Stockholm, and author of several works on botany), with a 5-parted calyx; 5 petals; 5 styles approximate; the capsule 5-valved, 5-celled from the edges of the cell being bent inwards. There are four species; one is a native of Egypt, one of Java, one of the East Indies, and one of the Cape of Good Hope.

3. *Elatine*, with a calyx 3-4-parted; 3-4 petals; 3-4 or 6-8 stamens; 3-4 styles; the capsules 3-4-celled, many-seeded, the seeds cylindrical, terete, straight or bent. There are five species of this genus.

* Other insects having the same power of emitting a light by night are undoubtedly confounded with the present species under the name of the Fire-Fly.

E. Hydropiper, Water-Pepper, has opposite leaves shorter then their petioles, the flowers stalked or nearly sessile, with 8 stamens and 4 ovate petals; the capsule roundish, depressed, 4-celled, the seeds bent almost double, pendulous, four in each cell. It has rose-coloured flowers. It grows under water, and is very common in ground subject to inundations throughout France. It is a very rare plant in Great Britain, and has been found only in Wales and Ireland. *E. hexandra* is a minute plant having 6 stamens. It forms small matted tufts under water, and is common in France, but rare in Great Britain. *E. tripetala* of Smith is identical with this species. *E. triandra* has been found in the neighbourhood of Ratisbon. *E. alsinastrum* is found near Paris.

In addition to the above genera, *Tetradiclis*, *Anatropa*, and *Tridia* are now enumerated. There are 6 genera and 22 species.

(Don, *Dichlamydeous Plants*; Babington, *Man. Brit. Bot.*)

ELATINE. [ELATINACEÆ.]

ELCAJA, an Arabian Plant, whose fruit is said to possess emetic properties. Botanists call it *Trichilia emetica*. Forskahl describes it as a large tree, with villous shoots, pinnated leaves, with entire oval-oblong pedicellate leaflets, clustered flowers with 5 greenish-yellow petals, 10 monadelphous stamens, and a downy capsular fruit about an inch long, with 3 valves, 3 angles, and 3 cells, having 2 plano-convex seeds in each cell. The tree is said to be called Roka, and to be common on the mountains of Yemen. The fruit is sold at Beit el fakih, for mixing with fragrant materials with which the Arab women wash their hair. The fruit called 'Djour elkai' is reputed an emetic. The ripe seeds mixed with Sesamum oil are formed into an ointment as a cure for the itch.

ELDER-TREE. [SAMBUCUS.]

ELECAMPANE. [INULA.]

ELECTRA. [CELLARIÆA.]

ELECTRIC-EEL. [ELECTRICITY OF ORGANIC BEINGS.]

ELECTRICITY OF ORGANIC BEINGS. Plants and animals under certain circumstances are known to exhibit electrical phenomena. These however are not so constant or frequent as is sometimes imagined. Considering the connection that is now known to exist between the great forces of nature, as Light, Heat, Chemical Action, and Electricity, it is perhaps matter of surprise that so few electrical phenomena are exhibited by organised bodies.

In Plants it appears that during growth electricity is developed. Pouillet filled several pots with earth, and placed in them different kinds of seeds, and then insulated them. During the process of germination no electric disturbance was discovered, but when the seeds began to sprout a gold-leaf electrometer had its leaves separated at least half an inch from each other. Pouillet concludes that the vegetation on the surface of the earth must produce a vast amount of electricity, and be an active cause of its phenomena in the atmosphere. Other observers have found that, by placing wires in the bark and pith of a growing tree, they have obtained decided indications of the presence of a galvanic current. These exhibitions of electric disturbance are undoubtedly dependent on the chemical changes going on in the plant, and this is one of the many instances in which we find one force in nature representing another. Under the influence of heat and light the chemical and attractive forces are brought into play, and the motile force of the growth of the plant as well as electrical phenomena are the result.

In the Animal Kingdom the same indications of the presence of electricity is afforded during the activity of the vital functions. Matteucci has observed a considerable deflection of the galvanometer when wires were connected with it passing from the liver and stomach of a rabbit. Other experimenters have obtained similar results. It has been supposed that these phenomena were due to the chemical changes going on in the body of the animal, but they cease on the death of the animal. Free electricity is excited by the movements of the human body. This is made evident by rubbing the feet on a woollen rug, when, on applying the hand to a gold-leaf electrometer, the presence of electric disturbance is indicated. Some persons are more liable to this development than others; and Dr. Carpenter says there are persons "who scarcely ever pull off articles of dress which have been worn next the skin without sparks and a crackling noise being produced, especially in dry weather."

Recent experiments of Matteucci and Du Bois-Raymond have shown not only that free electricity is developed in animal bodies, but that there is a true galvanic current both in the muscles and nerves. Galvani attributed the movements, first observed by his wife, induced in a frog's leg by plates of copper and zinc, to a purely animal action. Volta shewed that the movements observed by Galvani were dependent on the chemical action developed in the metals. Matteucci observed the peculiar sensibility of the nerves and muscles of the frog to galvanic action, and made use of the leg, prepared as a galvanometer, in many of his experiments. The mode of using it was simply to take the leg of a recently-killed frog with the crural nerve dissected out of the body, but remaining in connection with it. The leg was then inclosed in a glass tube covered with an insulating varnish, and the nerve allowed to hang freely at its open end. When two points of the nerve thus prepared are brought in contact with any two substances in a different electrical state, the muscles of the frog's leg are thrown into contraction. By this 'galvanscopic frog' Matteucci was able to detect currents of electricity in the muscles of animals, by cutting into them and placing one extremity of the nerve deep in the wound and the other at its lips. The experiments of Matteucci were followed up by Du Bois-Raymond, who has arrived at the following conclusions:—1. That galvanic currents may be observed in any limb of any animal whether cold or warm-blooded. These currents in some limbs are directed downwards, in others upwards. They are of different intensity in different limbs; but their intensity and direction are always the same in the same limb of different individuals of the same species. 2. The electro-motive action on which these currents depend does not arise from the contact of heterogeneous tissues, as Volta supposed; for the different tissues, the nerves, muscles, and tendons, in an electric point of view, are quite homogeneous. 3. These currents are produced by the muscles. If any undissected muscle of any animal be brought into the circuit longitudinally, it generally exhibits an electro-motive action, the direction of which depends on the position of the muscle. The current of the whole limb is nothing, but the resultant of the partial currents which are engendered by each muscle of the limb. It is therefore a 'muscular current.' 4. The law of the muscular current may be expressed as follows: "Any point of the natural or artificial longitudinal section of the muscle is positive in relation to any point of the natural or artificial transverse section." 5. By means of the above-mentioned law an explanation is afforded of the muscular current appearing in one instance an upward one, in another a downward one, which occurs according as the upper or the under of the two transverse sections is made to touch one of the ends of the galvanometer wire, whilst the other end is applied to the longitudinal section of the muscle. This is true even as regards shreds of muscle consisting of only a few primary fibres, and such as only admit of observation by the microscope. 6. The nerves are possessed of an electro-motive power which acts according to the same law as the muscles. Whilst still in organic connection with the muscles, and forming part of a circuit in which the muscles give rise to a current, the nerves simply play the part of an inactive conducting body, provided their own current be prevented from entering the circuit.

There are certain animals which possess the power of accumulating electric force within their bodies, and of discharging it at will in a violent form, and, with the exception of some insects and *Mollusca* which have been said (though this is doubtful) to communicate sensible shocks, these animals are all included in the class of Fishes. About seven species of this class, belonging to five genera, are known to possess electric properties, and it is curious that these genera belong to tribes very dissimilar from one another, and that, though each has a limited geographical range, one species or other is found in almost every part of the world. Thus, the three species of *Torpedo*, belonging to the Ray tribe, are found on most of the coasts of the Atlantic and Mediterranean, and sometimes so abundantly as to be a staple article of food. The *Gymnotus*, or Electric Eel, is confined to the rivers of South America. The *Silurus* (more correctly the *Malapterurus*), which approaches more nearly to the Salmon tribe, occurs in the Niger, the Senegal, and the Nile. The *Trichiurus*, or Indian Sword-Fish, is an inhabitant of the Indian Seas; and the *Tetraodon* (one of a genus allied to the *Diodon*, or Globe-Fish) has only been met with on the coral banks of Johanna, one of the Comoro Islands. These fishes have not all been examined with the same degree of attention, but it seems probable that the phenomena which they exhibit, and the structural peculiarities with which these are connected, are essentially the same throughout.

The peculiar characteristic of all is the power of giving, to any living body which touches them, a shock resembling in its effects that produced by the discharge of a Leyden jar. This is of very variable intensity in different species and individuals, and at different times. The *Gymnotus* will attack and paralyse horses, as well as kill small animals; and the discharges of large fish (which are 20 feet long) sometimes prove sufficient to deprive men of sense and motion. The effects of the contact of the *Torpedo* are less severe, and soon pass off; but the shock is attended with considerable pain when the fish is vigorous. The electrical organs appear to be charged and discharged to a certain extent at the will of the animals. Their power is generally exerted by the approach of some other animal, or by some external irritation; but it is not always possible to call it into action, even in vigorous individuals. It usually diminishes with the general feebleness of the system, though sometimes a dying fish exerts considerable power. All electrical fishes have their energy exhausted by a continued series of discharges; hence it is a common practice with convoys in South America to collect a number of wild horses and drive them into the rivers, in order to save themselves, when they pass, from being injured by the fish. If excessively exhausted, the animals may even die; but they usually recover their electrical energy after a few hours' rest.

The *Torpedo*, from its proximity to European shores, has been most frequently made the subject of observation and experiment; and the following are the most important results of the investigations which have been made upon it by various inquirers:—That the shock received by the organs of sensation in man is really the result of an electric discharge, has now been fully established. Although no one has ever seen a spark emitted from the body of one of the fish, it may be easily manifested by causing the *Torpedo* or *Gymnotus* to send its discharge through a slightly interrupted circuit. The galvanometer is influenced by the discharge of the *Torpedo*, and chemical decomposition may be effected by it, as well as magnetic properties communicated to needles. It seems essential to the proper reception of the shock, that two parts of the body should be touched at the same time, and that these two should be in different electrical states. The most energetic discharge is procured from the *Torpedo* by touching the back and belly simultaneously, the electricity of the dorsal surface being positive, and that of the ventral negative; and by this means the galvanometer may be strongly affected, every part of the back being positive with respect to every part of the opposite surface. When the two wires of the galvanometer are applied to the corresponding parts of the two sides of the same surface, no influence is manifested; but, if the two points do not correspond in situation, whether they be both on the back or both on the belly, the index of the galvanometer is made to deviate. The degree of proximity to the electric organ appears to be the source of the difference in the relative state of different parts of the body; those which are near to it being always positive in respect to those more distant. Dr. Davy found that, however much Torpedoes were irritated through a single point, no discharge took place; and he states that, when one surface only is touched and irritated, the fish themselves appear to make an effort to bring the border of the other surface, by muscular contraction, into contact with the offending body; and that this is even done by fœtal fish. If a fish be placed between two plates of metal, the edges of which are in contact, no shock is perceived by the hands placed upon them, since the metal is a better conductor than the human body; but if the plates be separated, and while still in contact with the opposite sides of the body, the hands be applied to them, the discharge is at once rendered perceptible, and it may be passed through a line formed by the moistened hands of two or more persons, the extremities being brought into relation with the opposite plates. The electrical phenomena of the *Gymnotus* are essentially the same with those of the *Torpedo*; but the opposite electrical states are found to exist, not between the dorsal and ventral surfaces, but between the head and tail; so that the shock is most powerful when the connection is formed between these two extreme points.

It has been ascertained by experiment, that the manifestation of this peculiar power depends upon the integrity of the connection between the nervous centres and certain organs peculiar to electrical fishes. In the *Torpedo* the electrical organs are of a flattened shape, and occupy the front and sides of the body, forming two large masses, which extend backwards and outwards from each side of the head. They are composed of two layers of membrane, between which is a whitish soft pulp, divided into columns by processes of the membrane sent off so as to form partitions like the cells of a honeycomb; the ends of these columns being directed towards the two surfaces of the body. The columns are again subdivided horizontally by more delicate partitions, which form each into a number of distinct cells; the partitions are extremely vascular, and are profusely supplied with nerves, the fibres of which seem to break up into minuter fibrillæ to form plexuses upon these membranes. The fluid contained in the electrical organs forms so large a portion of them, that the specific gravity of the mass is only 1·026, whilst that of the body in general is about 1·060; and from a chemical examination of its constituents, it seems to be little else than water, holding one-tenth part of albumen in solution, with a little chloride of sodium. The electrical organs of *Gymnotus* are essentially the same in structure, though differing in shape, in accordance with the conformation of the animal; they occupy one-third of its whole bulk, and run along nearly its entire length; there are however two distinct pairs, one much larger than the other. The prisms are here less numerous, but are much longer; for they run in the direction of the length of the body, a difference which is productive of a considerable modification of the character of the discharge. In the *Silurus* there is not any electrical organ so definite as those just described; but the thick layer of dense cellular tissue, which completely surrounds the body, appears to be subservient to this function; it is composed of tendinous fibres interwoven together, and of an albuminous substance contained in their interstices, so as to bear a close analogy with the cellular partitions in the special organs of the *Torpedo* and *Gymnotus*. The organs of the other known electrical fishes have not yet come under the notice of any anatomist.

In all these instances the electrical organs are supplied with nerves of very great size, larger than any others in the same animals, and larger than any nerve in other animals of like bulk. They all arise in the *Torpedo* from a ganglionic mass situated behind the cerebellum, and connected with the medulla oblongata, to which the name of 'electric lobe' has been given; the first two of them issue from the cranium in close proximity with the fifth pair, and have been regarded as belonging to it, although their real origin is different; whilst, from the distribution of the third electrical nerve to the stomach, after sending its principal portion to the electrical organ, it would seem analogous to the eighth pair or pneumogastric.

The electrical nerves in the *Gymnotus* are believed to arise from the spinal marrow alone; and those of the *Silurus* are partly intercostals and partly belong to the fifth pair. The integrity of the nerves is essential to the full action of the electrical organs. If all the trunks he cut on one side, the power of that organ will be destroyed, but that of the other may remain uninjured. If the nerves be partially destroyed on either or both sides, the power is retained by the portion of the organs still in connection with the centres. The same effects are produced by tying the nerves as by cutting them. Even slices of the organ entirely separated from the body, except by a nervous fibre, may exhibit electrical properties. Discharges may be excited by irritation of the brain when the nerves are entire, or of the part of the divided trunk distributed on the organ; but on destroying the electric lobe of the brain the electric power of the animal ceases entirely, although all the other ganglionic centres may be removed without impairing it. It is remarkable however that after the section of the electrical nerves Torpedoes appear more lively than before the operation, and actually live longer than others not so injured, which are excited to discharge frequently. Poisons which act violently on the nervous system have a striking effect upon the electrical manifestations of these fish; thus, two grains of muriate of morphia were found by Matteucci to produce death after about ten minutes, during which time the discharges were very numerous and powerful; and strychnia also excited powerful discharges at first, succeeded by weaker ones, the animals dying in violent convulsions. When the animals were under the influence of strychnia it was observed that the slightest irritation occasioned discharges; a blow given to the table on which the animal was placed being sufficient to produce this effect. If the spinal cord were divided however, no irritation of the parts situated below the section called forth a shock. It has also been ascertained by Mattencci that the electric power is suspended when the *Torpedo* is plunged into water at 32°, and is recovered again when it is immersed in water of a temperature from 58° to 68°; and that this alternation may be repeated several times upon the same fish. But if the temperature be raised to 86° the *Torpedo* soon ceases to live, and dies while giving a great number of violent discharges. (Carpenter.)

From these facts it is evident that the electric force is developed as the result of nervous agency. From this it has been sometimes hastily inferred that the electric and nervous forces are identical. This however is not more probable than that the contractile force of the muscles is identical with the nervous force. The best explanation of the phenomena appears to be the correlation of these forces. They are convertible forces, the one being capable of generating the other; the force generated being always the representative of the force generating it. The uses of these electric organs it is somewhat difficult to explain. The *Gymnotus* eats very few of the fishes which it kills by its shocks, and this is the case with the Torpedoes. Dr. John Davy conjectures that the electric discharges decompose the water, and supplying oxygen assist in respiration. Dr. Carpenter suggests that this peculiar action may assist the digestion of the fish, as animals killed by electricity are more digestible. The electrical condition of the animal itself he also thinks may conduce to the easy digestion of its food.

Bènce Joues, *Abstract of Du Bois-Raymond's Researches in Animal Electricity.*)

ELENCHUS. [RHISSOPTERA.]

ELEO'CHARIS, a genus of Plants belonging to the natural order *Cyperaceæ* and the tribe *Scirpeæ.* It has fertile glumes, the lowermost layer with one or two of the lowest empty; 3-6 bristles. The nut compressed, crowned with the persistent dilated base of the style. There are 3 species of this genus, known by the name of Spike-Rushes, found in Great Britain.

E. palustris has a creeping root, and the stem clothed with membranous obtusely-truncate sheaths: it grows in marshy places, forming sometimes a large proportion of the peat found in bogs. *E. multicaulis* has slightly creeping roots, with the stem clothed with obliquely truncate rather acute sheaths. *E. acicularis* has a fibrous root, and numerous slender erect stems, and very small spikes. It is found in damp places upon heaths.

(Babington, *Manual of British Botany.*)

ELEOTRAGUS. [ANTILOPEÆ.]

ELEOTRIS, a genus of Acanthopterygious Fishes belonging to the family *Gobiodæ.* Like the Gobies the species have flexible spines in the first dorsal fin, and an appendage behind the vent, but they have the ventral fins separate and six gill-rays. The species are inhabitants of the fresh waters of warm countries, and conceal themselves in the mud.

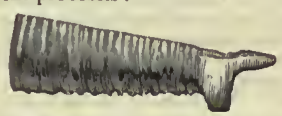
E. dormatrix, the Sleeper, is a large fish. It is found in the West Indian marshes. Other species have been found in Africa, India, and the Mediterranean.

ELEPHANT (in Latin *Elephas* and *Elephantus*, in Greek Ἐλέφας, in Spanish Elefante, in Italian Elefante, in French Elephant, in German Elephant, in Dutch Olyphant), the name of the well-known genus which forms the only living type of the family of true Proboscidians, or Pachydermatous Mammifers with a Proboscis and Tusks. It is the largest of existing terrestrial animals.

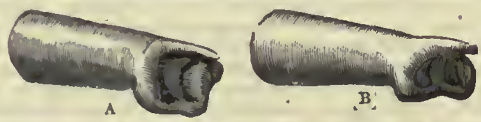
The Proboscis or Trunk, from which the name of the family is derived, demands some attention previous to our inquiry into the rest of the structure, habits, and history of the Elephants.

The great size of the alveoli necessary for the lodgment of the tusks renders, as Cuvier observes, the upper jaw so high and shortens the nasal bones to such a degree, that in the skeleton the nostrils are placed towards the upper part of the face; but in the living animal they are prolonged into a cylindrical trunk or proboscis composed of thousands* of small muscles variously interlaced, so as to bestow on it the most complicated powers of mobility in all the varieties of extension, contraction, and motion in every direction. It is of a tapering sub-conical form, and has internally two perforations. On the upper side of the extremity, immediately above the partition of the nostrils, is an elongated process, which may be considered as a finger; and on the under edge is a sort of tubercle, which acts as an opposeable point; in short, as a thumb. Endowed with exquisite sensibility, nearly 8 feet in length, and stout in proportion to the massive size of the whole animal, this organ, at the volition of the elephant, will uproot trees or gather grass—raise a piece of artillery or pick up a comfit—kill a man or brush off a fly. It conveys the food to the mouth, and pumps up the enormous draughts of water, which by its recurvature are turned into and driven down the capacious throat, or showered over the body. Its length supplies the place of a long neck, which would have been incompatible with the support of the large head and weighty tusks. A glance at the head of an elephant will show the thickness and strength of the trunk at its insertion; and the massy arched bones of the face and thick muscular neck are admirably adapted for supporting and working this powerful and wonderful instrument.

The following cuts will convey some idea of the form and action of the termination of the proboscis:—

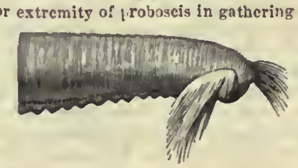


Anterior termination of Elephant's Trunk (profile).



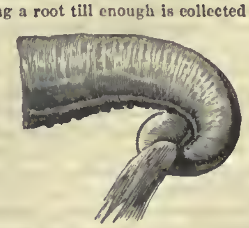
Anterior extremities of the trunks of male (A) and female elephants (B).

Action of anterior extremity of proboscis in gathering long herbage.



Mode of holding herbage when gathered.

Mode of holding a root till enough is collected for a mouthful.



Curled action, when a powerful grasp and much force is required.

* Cuvier gives the number of muscles having the power of distinct action as not far short of 40,000.

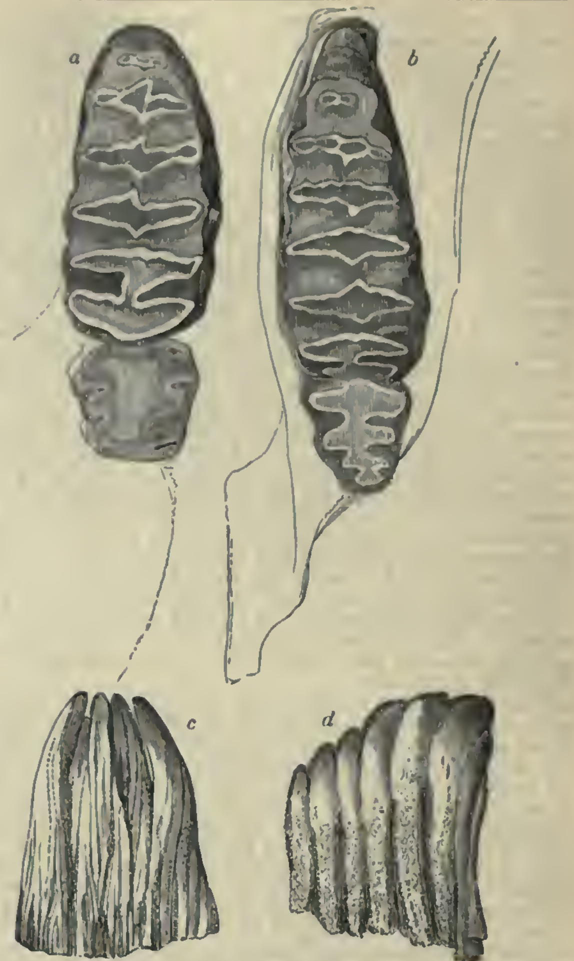
African Elephant: Incisors, $\frac{2}{0}$; Molars, $\frac{4}{4} = 10$.

Asiatic Elephant: Incisors, $\frac{2}{0}$; Molars, $\frac{2}{2} = 6$.

Dentition and Osseous Structure.—The succession of molar teeth in the elephants takes place in a direction from behind forwards; and the tooth last developed pushing against that which preceded it, and in time replacing it, gives as a result that there are never more than two molar teeth on each side of each jaw, and that sometimes there is only one. The last case happens immediately after the shedding of the anterior tooth, which has been pushed out by its successor, and which, in its turn, is to be replaced in like manner. This succession happens many times during the life of the animal, and Mr. Corse noticed it eight times in an Asiatic Elephant. Now, as these teeth show their anterior extremity first, long before the other extremity appears, and as they begin to be worn down anteriorly, it follows that the anterior tooth, when it is shed, is infinitely smaller in size than it once was, and that its form is entirely changed.

In the molar teeth of most graminivorous quadrupeds there is, besides the bony substance and enamel, a third component part, differing in appearance from both the others, but resembling the bone more than the enamel. Blake and others have distinguished this substance by the name of 'crusta petrosa;' Cuvier calls it 'cement.' The distinction of these three substances is perhaps better seen in the molar tooth of an elephant than in any other animal. If a longitudinal vertical section be made and the surface be polished, the crusta petrosa will be distinguished by a greater yellowness and opacity, as well as by a uniformity of appearance, there being no apparent laminæ nor fibres. "The grinding teeth of the elephant," writes Lawrence in his 'Additions' to Blumenbach, "contain the most complete intermixture of these three substances, and have a greater proportion of crusta petrosa than those of any other animal. The pulp forms a number of broad flat processes lying parallel to each other, and placed transversely between the inner and outer laminæ of the alveoli. The bone of the tooth is formed on these in separate shells, commencing at their loose extremities and extending towards the basis, where they are connected together. The capsule sends an equal number of membranous productions, which first cover the bony shells with enamel and then invest them with crusta petrosa, which latter substance unites and consolidates the different portions. The bony shells vary in number from 4 to 23, according to the size of the tooth and the age of the animal; they have been described under the name of denticuli, and have been represented as separate teeth in the first instance. It must however be remembered that they are formed on processes of one single pulp. When the crusta petrosa is completely deposited, the different denticuli are consolidated together. The bony shells are united at the base to the neighbouring ones; the investments of enamel are joined in like manner; and the intervals are filled with the third substance, which really deserves the name bestowed on it by Cuvier of 'cement.' The pulp is then elongated for the purpose of forming the roots or fangs of the tooth. From the peculiar mode of dentition of this animal, the front portion of the tooth has cut the gum and is employed in mastication before the back part is completely formed; even before some of the posterior denticuli have been consolidated. The back of the tooth does not appear in the mouth until the anterior part has been worn down even to the fang. A horizontal section of the elephant's tooth presents a series of narrow bands of bone of the tooth, surrounded by corresponding portions of enamel. Between these are portions of crusta petrosa; and the whole circumference of the section is composed of a thick layer of the same substance. A vertical section in the longitudinal direction exhibits the processes of bone upon the different denticuli, running up from the fangs; a vertical layer of enamel is placed before and another behind each of these. If the tooth is not yet worn by mastication, the two layers of enamel are continuous at the part where the bone terminates in a point; and the front layer of one denticulus is continuous with the back layer of the succeeding one, at the root of the tooth. Crusta petrosa intervenes between the ascending and descending portions of the enamel. As the surface of the tooth is worn down in mastication, the processes of enamel, resisting by their superior hardness, form prominent ridges on the grinding surface, which must adapt it excellently for bruising and comminuting any hard substance. The grinding bases, when worn sufficiently to expose the enamel, in the Asiatic species, represent flattened ovals placed across the tooth. In the African they form a series of lozenges, which touch each other in the middle of the tooth." In the Museum of the Royal College of Surgeons are a series of preparations (Nos. 350 to 354, both inclusive) illustrative of the structure and physiology of the molar teeth of elephants, preceded by an interesting extract from the Hunterian MS. Catalogue. No. 275 B is a portion of the cæmentum of an elephant's grinder, which has been steeped in an acid, dried, and preserved in oil of turpentine, for the purpose of showing the proportion of animal matter which it contains.

Nos. 262 to 264, both inclusive, show the interarticular ligamentous substance from the joint of the lower jaw of the elephant, and the adaptation of the structure for applying two convex surfaces to each other.



Teeth of African Elephant. From F. Cuvier.

a, Upper jaw; *b*, lower jaw; *c*, original state of the tooth when the laminæ which compose it are free; *d*, the laminæ as they are attached in parallels one to the other by the cortical substance in a subsequent state of dentition, but before the crown of the tooth has been worn by mastication, and when it only presents on its surface blunt tubercles.

Teeth of Asiatic Elephant. From F. Cuvier.
a, Upper molar tooth; *b*, lower molar tooth.

More than one molar tooth and part of another are never to be seen through the gum in the Elephaut. When the anterior tooth is gradually worn away by mastication, the absorption of its fangs and alveolus takes place, while the posterior tooth advances to occupy its position; then comes a third to take the place of the second tooth, which undergoes the same process, and so on, as we have stated, for at least eight times. Each succeeding tooth is larger than its predecessor. Thus, the first, or milk-grinder, which cuts the gum soon after birth, has but four transverse plates (denticuli); the second is composed of eight or nine, and appears completely when the animal is two years old; the third consists of twelve or thirteen, and comes at the age of six years; and in the fourth up to the eighth grinder both inclusive, the uumber of plates varies from fifteen to twenty-three. It would seem that every new tooth takes at least a year more for its formation than its predecessor. As the tooth advances gradually, a comparatively small portion only is through the gum at once. A molar tooth, composed of twelve or fourteen plates, shows only two or three of these through the gum, the others being imbedded in the jaw, and in fact the tooth is complete anteriorly, where it is required for mastication, while posteriorly it is very incomplete. As the laminæ advance, they are successively perfected. An elephant's molar tooth is therefore never to be seen in a perfect state; for if it is not worn at all anteriorly, the posterior part is not formed, and the fangs are wanting: nor is the structure of the back part of the tooth perfected until the anterior portion is gone.

Elephants have no canine teeth, but in the upper jaw there are two incisors, better known by the name of tusks. These enormous weapons are round, arched, and terminate in a point; and their capsule is always free, so that the tusk continues to grow as long as the animal lives. The structure of the ivory of which it is composed differs from other tusks; and a transverse section presents striæ forming the arc of a circle from the centre to the circumference, and, in crossing each other, curvilinear lozenges which occupy the whole surface. The tusk is hollow within for a great part of its length, and the cavity contains a vascular pulp, which supplies successive layers internally as the tusk is worn down externally. Blumenbach, iu his 'Comparative Anatomy,' observes, that not to mention other peculiarities of ivory, which have induced some modern naturalists to consider it as a species of horn, the difference between its structure and that of the bone of teeth is evinced iu the remarkable pathological phenomenon resulting from balls with which the animal has been shot when young being found, on sawing through the tooth, imbedded in its substance in a peculiar manner. Haller employed this fact, both to refute Duhamel's opinion of the formation of bones by the periosteum, like that of wood by the bark of a tree, as well as to prove the constant renovation of the hard parts of the animal machine. It is still more important in explanation of that 'nutritio ultra vasa,' which is particularly known through the Petersburgh prize dissertation. Blumenbach farther states that the fact above mentioned may be seen in Buffon (4to. ed., tom. xi. p. 161); in Galandat 'Over de Olyphants Tanden;' in the 'Verhandelingen der Genootsch, te Vlissingen,' tom. ix. p. 352; and in Bonn. 'Descr. Thesauri Hoviani,' p. 146. In all these cases, according to Blumenbach, the balls were of iron; and he adds that he possesses a similar specimen. In the cases we have seen, the balls were also of iron. "But," continues Blumenbach, "there is a still more curious example in my collection, of a leaden bullet contained in the tusk of an East Indian elephant, which must have been equal in size to a man's thigh, without having been flattened. It lies close to the cavity of the tooth; its entrance from without is closed, as it were, by means of a cicatrix; and the ball itself is surrounded apparently by a peculiar covering. The bony matter has been poured out on the side of the cavity iu a stalactitic form." Upou this Lawrence well remarks that the facts here recounted have been sometimes brought forward in order to prove the vascularity of the teeth; a doctrine which is refuted by every circumstance in the formation, structure, and diseases of these organs. When a bullet has entered the substance of the body, the surrounding lacerated and contused parts do not grow to the metal and become firmly attached to its surface, but they inflame and suppurate in order to get rid of the offending matter. "If the ivory be vascular," asks Mr. Lawrence, "why do not the same processes take place in it?" "We can explain very satisfactorily," writes Mr. Lawrence in continuation, "how a bullet may enter the tusk of an elephant, and become imbedded in the ivory without any opening for its admission being perceptible. These tusks are constantly growing during the animal's life by a deposition of successive laminæ within the cavity, while the outer surface and the point are gradually worn away; and the cavity is filled for this purpose with a vascular pulp, similar to that on which teeth are originally formed. If a ball penetrate the side of a tusk, cross its cavity, and lodge in the slightest way on the opposite side, it will become covered towards the cavity by the newly-deposited layers of ivory, while no opening will exist between it and the surface to account for its entrance. If it have only sufficient force to enter, it will probably sink by its own weight between the pulp and the tooth, until it rests at the bottom of the cavity. It there becomes surrounded by new layers of ivory; and as the tusk is gradually worn away and supplied by new depositions, it will soon be found in the centre of the solid part of the tooth. Lastly, a foreign body may enter the tusk from above, as the plate of bone which forms its socket is thin; if this descends to the lower part of the cavity, it may become imbedded by the subsequeut formations of ivory. This must have happened in a case where a spear-head was found in an elephaut's tooth. The long axis of the foreign body corresponded to that of the cavity. No opening for its admission could be discovered, and it is very clear that no human strength could drive such a body through the side of a tusk." ('Phil. Trans.,' 1801, part i.)

The great size to which these tusks grow may be judged of by examining the table published by Cuvier in his 'Ossemens Fossiles,' tom. i. p. 57. It is generally considered that the tusks of the African Elephaut are the largest; but with regard to the table, Cuvier observes that the African tusks could not be distinguished from those of the Indies, and that there is not the certainty that could be wished in the measures employed. According to Mr. Corse, the tusks of the Indian Elephant seldom exceed 72 lbs. in weight, aud do not weigh beyond 50 lbs. in the province of Tiperah, which produces thousands of elephants. There are however in London tusks which weigh 150 lbs., probably from Pegu; for it is from Pegu and Cochin-China that the largest Indian elephants and tusks are brought. The largest recorded in Cuvier's table was a tusk sold at Amsterdam, according to Klokner, which weighed 350 lbs.: this is stated on the authority of Camper; and one possessed by a merchant of Venice, which was 14 feet in length, and resting on the authority of Hartenfels, in his 'Elephantographia.' The largest in the Paris Museum is nearly 7 feet long, and about 5½ inches in diameter at the large eud. These tusks have different degrees of curvature.

Mr. Corse, speaking of the Asiatic Elephant, states that the first or milk tusks of an elephant never grow to any size, but are shed between the first and second year. These, as well as the first grinders, are named by the natives 'Dood-kau-Daunt,' which literally signifies milk-teeth. The tusks which are shed have a considerable part of the root or fang absorbed before this happens. The time at which the tusk cuts the gum seems to vary. Mr. Corse knew a young one which had his tusks when about five months old, while those of another did not cut the gum till he was seven months old. Those tusks which are deciduous, observes the same author, are perfect and without any hollow at the root, in a fœtus which is come to its full time, and at this period the socket of the permanent tusk begins to be formed on the inner side of the deciduous tusk: he gives the following examples of the progress of this part of the dentition:—A youug elephant shed one of his milk-tusks on the 6th of November, 1790, when near thirteen months old, and the other on the 27th of December, when about fourteen months old; they were merely two black-coloured stumps, when shed; but, two months afterwards, the permanent tusks cut the gum, and on the 19th of April, 1791, they were an inch long, but black and ragged at the ends. Wheu they became longer and projected beyond the lip, they soon were worn smooth by the motion and friction of the trunk. Another young elephant did not shed his milk-tusks till he was sixteen months old. The permanent tusks of the female are very small in comparison with those of the male, and do not take their rise so deep in the jaw; but they use them as weapons of offence in the same manner as the male, that is, by putting their head above another elephant, and then pressing their tusks down into the animal.

In the lower jaw there are neither incisors nor canines, and the molar teeth resemble those to which they are opposed.

Cuvier comes to the conclusion that the females of the African species have large tusks, and that the difference between the sexes in this respect is much less than in the Indian elephants; but Burchell attributes the want of success of the elephant-hunters whom he met with to their having only fallen in with females whose tusks were small.

Pursuing our inquiry into the general structure of the skeleton, we shall find a marked difference in the external appearance of the skulls of the African and Indian species.

Here we see that the almost pyramidical form of the skull in the Indian species is strongly contrasted with the more rounded form and contour of that of the African species. The front of the head is concave in the Indian species, while in the African it is rather convex; there are besides other differences.

Internally we find a beautiful provision for increasing the surface necessary for the attachment of muscles combined with strength and lightness.

The other parts of the skull most worthy of note are the nasal bones, of which the elephant possesses only a kind of imitation: the lachrymal bones are entirely wanting. The cervical vertebræ form a short and stiff series, allowing hardly more than a limited motion of the head from side to side, a more extended action being rendered unnecessary by the flexibility of the trunk, and a firm support for the head being the principal object to be attained. The spinous processes of the anterior dorsal vertebræ are exceedingly long for the attachment of the great suspensory ligament of tho neck (ligamentum nuchæ, or pax-wax). Blumenbach puts the number of ribs, and consequently of dorsal vertebræ, at 19 pairs, observing that this, at least, is the case in the skeleton of the Asiatic Elephant at Cassel. Blair, he remarks, found the same number in the individuals of which he has given an account; and a manuscript Italian description of the

Skull of African Elephant.

Skull of Indian Elephant.

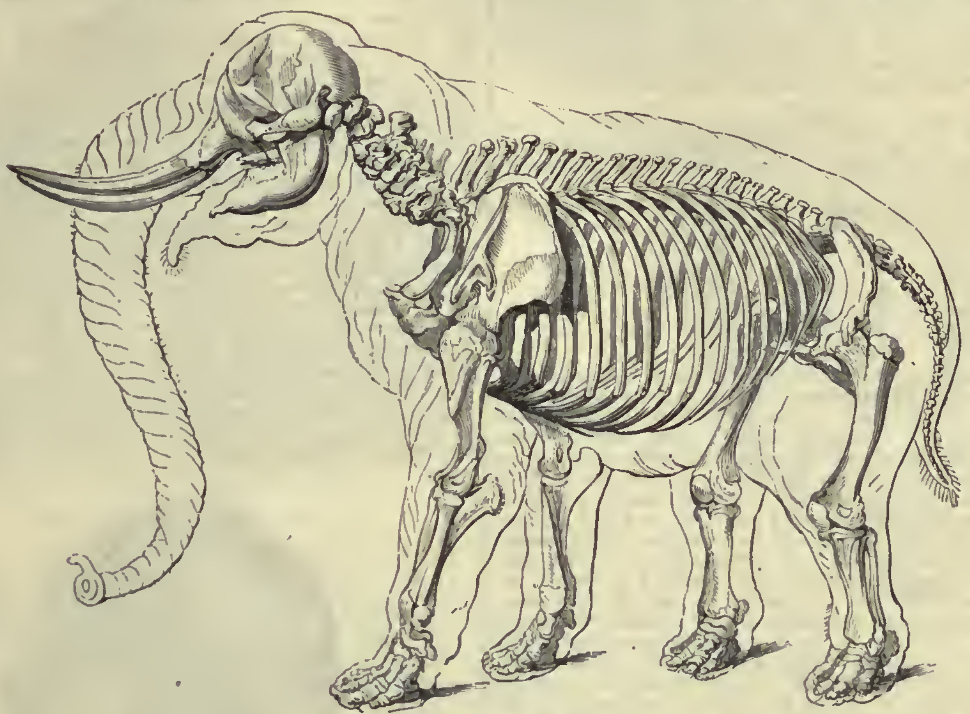
a, shows the opening of the nostrils; *b*, the cellular sinus which separates the external from the internal table of the skull; *c*, the cavity where the brain is lodged.

elephant which died at Florence in 1657 confirms this statement. Allen Moulins, on the contrary ('Anatomical Account of the Elephant burned in Dublin,' London, 1682, 4to.), and Daubenton, represent the number of pairs as 20. The elephant in the Museum of the Royal College of Surgeons (Chunce, formerly of Exeter Change) has 19 pairs of ribs; and that in the British Museum has the same number, 14 true and 5 false; but Dr. Gray informs us that in a second specimen of a young one, the bones of which have not been separated, there are 20 pairs, 15 true and 5 false. There are only three lumbar vertebræ. The margin of the scapula, which is turned towards the spine, and is shortest in most of the proper quadrupeds, is the longest in the Elephant, as it is in the *Cheiroptera*, most of the *Quadrumana*, and especially in man. There is no ligamentum teres, and consequently no impression on the head of the femur or thigh-bone.

Structure of Internal Soft Parts.—The following internal soft parts are more particularly worthy of remark in the Elephant:—Brain, &c., a portion of the dura mater from an Asiatic Elephant may be seen in the Museum of the Royal College of Surgeons, in London (Gallery, No. 1346), where the termination of the falx and the commencement of the tentorium, or process which separates the cerebrum from the cerebellum, are shown. The two fibrous layers of the dura mater are separated by a softer cellular substance, in which the vessels ramify; and it may be observed that the thickness of the dura mater is in proportion to the size of the skull, and of the entire animal, but not to the size of the brain, which does not much exceed that of the human brain, as will be seen in the preparation of the brain of a young Asiatic Elephant (No. 1331). For, though the absolute size of the organ exceeds that of man, the proportion which the cerebrum bears to the rest of the brain, and especially that part of the hemisphere which forms the roof and sides of the lateral ventricle, is much less. The hemispheres are broad and short, with a considerable development of the natiform protuberance. The convolutions are comparatively small and numerous. A lateral section has been removed from the left hemisphere, which shows that the anfractuosities are also deep, extending in some cases more than two-thirds of an inch into the substance of the brain. The hippocampus is comparatively smaller than in the ass, and the corpus striatum larger. The ventricle is seen to be continued into the olfactory bulb. The cerebellum is of considerable width, and its surface, as shown by the lateral section, is increased by numerous and complex anfractuosities. The tuber annulare corresponds in size to the development of the lateral lobes of the cerebellum. The corpora olivaria are remarkably prominent. The origins of all the cerebral nerves are shown, among which the olfactory nerves of the fifth pair, which supplies the proboscis, are remarkable for their prodigious size; whilst the optic nerves, and those which supply the muscles of the eye, are remarkable for their small size. The pia mater is left on with the vessels at the base of the brain. A bristle is placed in the infundibulum. ('Cat. Gallery,' vol. iii.). The brain in man is from $\frac{1}{22}$ to $\frac{1}{35}$ of the body, that of the elephant $\frac{1}{500}$. The stomach is simple, the intestines are very voluminous, and the cæcum enormous. In the sanguiferous system the heart is worthy of note, and a section of the right auricle and ventricle of that of an Asiatic Elephant may be seen in the museum last mentioned (Gallery, No. 924). In this animal, which, in some other respects, singularly resembles the *Rodentia*, three venæ cavæ terminate in the right auricle. Besides the Eustachian valve, which projects between the orifices of the inferior and left superior cavæ, there is also, as in the Porcupine, a rudiment of a superior valve, extending from the posterior side of the orifice of the right superior cava. The tricuspid valve, and its chordæ tendineæ and columnæ carneæ, are also well displayed. ('Cat. Gallery,' vol. ii.)

The period of gestation of the Elephant is twenty months and some days. The breasts of the female are placed under the chest, and the young one sucks, not with the trunk, but with the mouth. "The young of the elephant, at least all those I have seen," writes Mr. Corse, "begin to nibble and suck the breast soon after birth; pressing it with the trunk, which, by natural instinct, they know will make the milk flow more readily into the mouth while sucking. Elephants never lie down to give their young ones suck; and it often happens, when the dam is tall, that she is obliged for some time to bend her body towards her young to enable him to reach the nipple with his mouth; consequently, if ever the trunk was used to lay hold of the nipple, it would be at this period, when he is making laborious efforts to reach it with his mouth, but which he could always easily do with his trunk if it answered the purpose. In sucking, the young elephant always grasps the nipple (which projects horizontally from the breast) with the side of his mouth. I have very often observed this; and so sensible are the attendants of it, that with them it is a common practice to raise a small mound of earth, about 6 or 8 inches high, for the young one to stand on, and thus save the mother the trouble of bending her body every time she gives suck, which she cannot readily do when tied to her picket." The maternal affection does not seem to be very strong in the female elephant, at least in captivity; for the same author states that tame elephants are never suffered to remain loose, as instances occur of the mother leaving her young and escaping into the woods; and he says that if a wild elephant happens to be separated from her young, for only two days, though giving suck, she never afterwards recognises or acknowledges it. "This separation," adds Mr. Corse, "sometimes happens unavoidably, when they were enticed separately into the outlet of the Keddah. I have been much mortified at such unnatural conduct in the mother, particularly when it was evident the young elephant knew its dam, and by its plaintive cries and submissive approaches solicited her assistance."

and Merghee is termed Suukareah (from 'sunkarah,' a mixture), or Merghabauliah (for the most part Merghee); but a farther mixture or crossing of the breed renders it extremely difficult for the hunters to ascertain the variety. Besides the Koomareah, Merghee, and Sunkareah hreeds, several varieties are generally to be found in the same herd; but the uearer an elephaut approaches to the true



Skeleton of Elephant.

There are two living species of the genus *Elephas* :—

E. Indicus, the Asiatic Elephant. It differs from the African species, not only in its greater size and in the characters of the teeth and skull, but also in the comparative smalluess of the ears, the paler hrown colour of the skin, and in having four nails on the hind feet instead of three. The sagacity of this species is also supposed to be greater than that of the African Elephant. But though many wonderful stories are told, and some of them are as true as they are wonderful, of the grateful remembrance which it long retains of henefits conferred, or of the teuacity with which it "treasures up a wrong," and though the instances of its docility, hoth ancient and modern, are very extraordinary, we agree upon the whole with Barou Cuvier, who observes, that after having studied these animals a long time, he never found their intelligence snrpass that of a dog nor of many other carnivorous animals. It is imposing to see such a mountain of vitality obedient to the voice of its keeper, and performing feats at his dictation; and the massive gravity of its physiognomy assists the impression.

The following is Mr. Corse's description of a perfect Asiatic Elephant :—An elephant is said to he perfect when his ears are large and rounded, not ragged or indented at the margin; his eyes of a dark hazel-colour, free from specks; the roof of his mouth and his tongue without dark or black spots of any considerable size; his trunk large, and his tail long, with a tuft of hair reaching nearly to the ground. There must be five nails on each of his fore feet, and four on each of the hind ones, making eighteen in all; his head well set on, and carried rather high; the arch or curve of his back rising gradually from the shoulder to the middle, and thence descendiug to the insertion of the tail, and all his joints firm and strong.

The following are the castes (Zat) or varieties of the Asiatic Elephant noticed by Mr. Corse. Both males and females are divided into two castes hy the natives of Bengal, namely, the Koomareah (of a princely race) and the Merghee (hunting elephant, from 'mrigah,' a deer, or hunting, or from its slender make), and this without any regard to the appearance, shape, or size of the tusks in the male, as these serve merely to characterise some varieties in the species. The Koomareah is deep-bodied, strong, and compact, with a large trunk and short hut thick legs. The Merghee is generally taller but is not so compact nor so stroug: he travels faster, has a lighter body, and his trunk is both short and slender in proportion to his height. As a large trunk is considered a great beauty in an elephant, the Koomareah is preferred, hut not only for this, but for its superior strength, and greater capability of sustaining fatigue. The mixed hreed is held in greater or less estimation in proportion as it partakes of the qualities of the Koomareah or Merghee. A hreed from a pure Koomareah

Koomareah the more he is preferred, especially hy the natives, and the higher will be his price; though Europeans are not so particular, and will sometimes prefer a female Merghee for hunting and riding, when she has good paces, and is mild and tractable.

The variety of male termed Dauntelah (toothy, having large fine teeth,) produces the largest tusks aud the finest ivory: his head is strongly contrasted with that of the Mookuah (prohably from 'mookh,' the mouth or face), which can hardly be distinguished in this respect from a female elephant; and the tusks of some of the females are so small as not to appear beyond the lip, while in others they are almost as large as in the variety of male called Mooknah. The Dauntelah is generally more daring and less manageable than the Mooknah; and for this reason, until the temper and disposition are ascertained, the Europeans prefer the Mooknah; but the natives, who are fond of show, generally take their chance, and prefer the Dauntelah: and though there is a material difference in their appearance as well as in the value of their tusks, yet, if they are of the same caste, size, and disposition, and perfect, there is scarcely any difference in their price.

There are many varieties hetween the Mooknah and Dauntelah, and these are varied according to the variation of the form of the tusks, from the projecting horizontal but rather elevated curve of the Pullung-Daunt * of the true Dauntelah, to the nearly straight tusks of the Mooknah, which point directly downwards.

Thus the Goneish or Ganesa, which is a Dauntelah that has never had hut one tusk and this of the Pullung sort, and which is so called from Ganesa, the Hindoo god of wisdom, who is represented with a head like an elephant's with only one tooth, was sold in Mr. Corse's time to the Hindoo princes for a very high price, to be kept in state and worshipped as a divinity. Another variety of the Dauntelah has the large tusks pointing downwards and projecting only a little beyond the trunk: he is then said to have Soor or Choor-Daunt (Hog's teeth). A third is the Puttel-Dauntee, whose tusks are straight like those of the Mooknah, only much longer and thicker. The Ankoos-Daunteo is a fourth, and has one tusk growing uearly horizontal, like the Pulluug-Daunt, and the other like the Puttel-Daunt, and there are other less distinct varieties.

The term Goondah seems to he used to designate those wandering male elephauts which are much larger and stronger than the males generally taken with the herd, the Goondah departing from it or returning to it according to his desire. The Goondahs are supposed to be rarely taken with the herd: when they are so taken, their violence and ferocity reuder them most destructive. Mr.

* 'Pullung' signifies a bed or cot, and 'daunt' teeth; and, from the tusks projecting so regularly, and being a little curved and elevated at the extremities, the natives suppose a man might lie on them at his ease, as on a bed. (Corse.)

Corse relates an instance of the ungovernable passions and terrible havoc occasioned by the savage disposition of one, or at least a large male that was supposed to be one, when in the Keddah.* He was at length tied and led out, but his untameable spirit could not brook restraint, and after languishing about forty days he died.

Mr. Hodgson, in his paper 'On the Mammalia of Nepaul' ('Zool. Proc.,' 1834), suggests that there are two varieties, or perhaps rather species of the Indian Elephant, *Elephas Indicus*, namely, the Ceylonese, and that of the Saul Forest. The Ceylonese has a smaller and lighter head, which is carried more elevated; it has also higher fore quarters. The elephant of the Saul Forest has sometimes nails on its hinder feet.

The height to which the Asiatic Elephant will attain has been variously stated: but upon a strict examination of alleged great heights, the natural disposition among men to exaggerate has generally been detected.

A male elephant recorded by Mr. Corse was at its birth 35 inches high.

In one year he grew	11	inches,	and was	3	feet	10	inches high.
In the 2nd year	8	"	"	4	"	6	" "
In the 3rd year	6	"	"	5	"	0	" "
In the 4th year	5	"	"	5	"	5	" "
In the 5th year	5	"	"	5	"	10	" "
In the 6th year	3½	"	"	6	"	1½	" "
In the 7th year	2½	"	"	6	"	4	" "

A female elephant was 6 feet 9 inches high at the time she came into Mr. Corse's possession, and was supposed to be 14 years old according to the hunters; but, according to the belief of Mr. Corse, she was only 11 years of age. During the next 5 years, before she was covered, she grew only six inches, but, while pregnant, she grew 5 inches in 21 months, and in the following 17 months, though again pregnant, she grew only half an inch. Mr. Corse then lost sight of her. She was at this time about 19 years old, and had perhaps attained her full growth. Her young one was then not 20 months old, yet he was 4 feet 5½ inches high, having grown 18 inches since his birth. It thus appears that no certain standard of growth, for captive elephants at least, can be depended on: nor do there seem to be any satisfactory data for defining the age at which the animal ceases to grow. Mr. Corse conjectures that elephants attain their full growth between the ages of 18 and 24. With regard to the height, the East India Company's standard for serviceable elephants was, in Mr. Corse's time, 7 feet and upwards, measured at the shoulder in the same manner as horses are. At the middle of the back they are considerably higher; and the curve or arch, particularly in young elephants, makes a difference of several inches. The lessening of this curve is a sign of old age when not brought on by disease or violence. During the war with Tippoo Sultaun, of the 150 elephants under the management of Captain Sandys, not one was 10 feet high, and only a few males 9½ feet high. Mr. Corse was very particular in ascertaining the height of the elephants employed at Madras, and with the army under Marquis Cornwallis, where there were both Ceylon and Bengal elephants, and he was assured that those of Ceylon were neither higher nor superior, in any respect, to those of Bengal: nay, some officers asserted that they were considerably inferior in point of utility.

The only elephant ever heard of by Mr. Corse as exceeding 10 feet, on good authority, was a male belonging to Asaph Ul Dowlah, formerly vizier of Oude. The following were his dimensions:—

	Feet.	Inches.
From foot to foot over the shoulder	22	10½
From the top of the shoulder, perpendicular height	10	6
From the top of the head, when set up as he ought to march in state	12	2
From the front of the face to the insertion of the tail	15	11

And yet the Madras elephants have been said to be from 17 to 20 feet high. Now let us see how dimensions shrink before the severity of measurement. Mr. Corse heard from several gentlemen who had been at Dacca, that the Nabob there had an elephant about 14 feet high. Mr. Corse was desirous to measure him, especially as he had seen the elephant often at a former period, and then supposed him to be 12 feet high. He accordingly went to Dacca. At first he sent for the mahote, or driver, who without hesitation assured him that the elephant was from 10 to 12 cubits, that is, from 15 to 18 feet high; but added that he could not bring the elephant for Mr. Corse's examination without the Nabob's permission. Permission was asked and granted. Mr. Corse measured the elephant exactly, and was rather surprised to find that the animal did not exceed 10 feet in height.

The elephant is subject to albinism, and the white elephants so much esteemed by the Indian sovereigns are merely Albinos.

The Asiatic Elephant inhabits the greater part of the warm countries of Asia, and the large islands of the Indian Archipelago. Mr. Corse states that the elephants for the service of the East India Company are generally taken in the provinces of Chittagong and Tiperah; but from what he had heard, those to the southward of Chittagong, in the Birmah territories and kingdom of Pegu, are of a superior breed. In confirmation of this opinion, he observes that the elephants taken to the south of the Goomty River, which divides the province of Tiperah from east to west, were generally better than those taken to the north of that river; and though elephants were taken at Pilibet as far north as 29° N. lat. in the vizier of Oude's territories, yet the vizier, and also the officers of his court, gave those taken in Chittagong and Tiperah a decided preference, they being much larger and stronger than the Pilibet elephant. Till the year 1790 Tiperah was a part of the Chittagong province; and so sensible was the Bengal government of the superiority of the southern elephants for carrying burdens, enduring fatigue, and being less liable to casualties, that in the then late contracts * for supplying the army, the contractor was bound not to send any elephant to the military stations taken north of the Chittagong province. Hence Mr. Corse concludes the torrid zone to be the natural clime, and the most favourable for producing the largest, the best, and the hardiest elephant; and that when this animal migrates beyond the tropics the species degenerates. He speaks of elephants being taken on the coast of Malabar as far north as the territories of the Coorgah Raja; but adds that those were much inferior to the Ceylon elephant, and that from this circumstance the report of the superiority of the Ceylon elephant to all others probably originated. He remarks that most of the previous accounts respecting the Asiatic Elephant had been given by gentlemen who resided many years ago on the coast of Malabar or Coromandel, where, at that time, they had but few opportunities of seeing the Chittagong or the Pegu elephant.

* Keddah is the name of the inclosure into which the wild elephants are driven and then captured.

Mr. Hodgson, in the paper above noticed, states that *Elephas Indicus* and *Rhinoceros unicornis* are both abundant in the forests and hills of the lower region of Nepaul, whence, in the rainy season, they issue into the cultivated parts of the Tarâi to feed upon the rice crops.

Asiatic Elephant (*Elephas Indicus*).

In a state of nature the Asiatic Elephant lives in great herds, which are generally said to be under the conduct of the old males, or bulls, as they are sometimes termed. From time immemorial the species has been brought under the dominion of man,† and trained to swell the pomp of pageants, and add to the terrors of war, as well as to perform the more useful offices of a beast of burden and draught, and the more dreadful one of executing the sentence of death on criminals. It has been long made the companion of the sports of the Orientalist in the great hunting parties; and from the same early period has been made to minister to the wanton and cruel pleasures of Eastern princes, by being stimulated to combat not only with other elephants but with various wild animals. The reader will find in the second volume of the 'Menageries' in the 'Library of Entertaining Knowledge,' an abundant and amusing collection of anecdotes connected with this subject, as well as a complete History of the Elephant, both in the wild state and as the servant of man.

The tusks of both species still form, as they did from the earliest periods, a valuable article of commerce. The ivory which is now sought for useful purposes and ornaments of minor importance, was in great request with the ancient Greeks and Romans for various domestic uses, as well as for the chrys-elephantine statuary rendered so famous by Phidias. Of these rich statues the Minerva of the Parthenon, and especially the Olympian Jupiter, appear to have been the masterpieces.

E. Africanus, the African Elephant. This animal is less than the Asiatic. The head is rounded; the front convex instead of concave;

* Mr. Corse's paper was read before the Royal Society in 1799.

† The earliest extant account in any European language of the mode of capturing the Indian elephant is in Arrian, 'Indike,' chap. 13.

the ears are much larger than those of the Asiatic species; and the general number of nails on each hind foot is only 3 instead of 4.

It is found in Africa from Senegal to the Cape of Good Hope. Cuvier says that it is not known whether the species is found up the whole oriental side of Africa, or whether it is there replaced by the preceding species.

African Elephant (*Elephas Africanus*).

The flesh of this creature is relished by the inhabitants of many districts of Africa. Major Denham speaks of it as being esteemed by all, and even eaten in secret by the first people about the sheikh; and he says that, though it looked coarse, it was better flavoured than any beef he found in the country. The ancient Romans considered the trunk as the most delicious part; but Le Vaillant speaks of the foot as a dish for a king, and more recent travellers bestow on it equal praise. The disposition of this species is supposed to be more ferocious than that of the Asiatic Elephant, though its habits in a state of nature do not greatly differ. It is not now tamed; but there is good ground for believing that the Carthaginians availed themselves of the services of this species as the Indians did of those of the Asiatic Elephant. The elephants exhibited in the Roman arena by Cæsar and Pompey appear to have been African; and from them principally, if not entirely, the ivory for ornamental purposes and the statues before alluded to seems to have been taken. The tusks of this species are of great size.

The number of the tusks brought to England is very large. In Sheffield alone it is stated that upwards of 45,000 tusks are annually consumed. The workers in ivory in that town are above 500 in number, and the value of the tusks is about 30,000*l.* per annum.

Fossil Elephants.

The third and fourth divisions of the tertiary fresh-water deposits (Pliocene period of Lyell) abound in extinct species of recent genera, and among them the remains of Fossil Elephants are very numerous. The alluvium, the crag, the ossiferous caverns, the osseous breccias, and the subapennine formations afford the most numerous examples. Cuvier ('Règne Animal,' last edit.) observes that there are found under the earth, in almost all parts of both continents, the bones of a species of elephant approximating to the existing Asiatic species, but whose grinders have the ribands of enamel narrower and straighter, the alveoli of the tusks longer in proportion, and the lower jaw more obtuse. An individual, he adds, found in the ice on the coasts of Siberia, appeared to have been covered with hair of two sorts, so that it might have been possible for this species to have lived in cold climates. The species has, he concludes, long since disappeared from the face of the globe. This species he characterises ('Ossemens Fossiles') as having an elongated skull; a concave front; very long alveoli for the tusks; the lower jaw obtuse; the grinders larger, parallel, and marked with closer-set ribands of enamel; and he designates it as the Fossil Elephant (*Elephas primigenius* of Blumenbach; *Elephas Mammonteus* of Fischer; the Mammoth of the Russians).

Mammoths' or elephants' bones and tusks occur throughout Russia, and more particularly in Eastern Siberia and the arctic marshes, &c. The tusks are very numerous, and in so high a state of preservation that they form an article of commerce, and are employed in the same works as what may be termed the living ivory of Asia and Africa, though the fossil tusks fetch an inferior price. Siberian fossil ivory forms the principal material on which the Russian ivory-turner works. The tusks most abound in the Laichovian Isles and on the shores of the Frozen Sea; and the best are found in the countries near the arctic circle, and in the most eastern regions, where the soil in the very short summer is thawed only at the surface: in some years not at all. In 1799 a Tungusian, named Schumachoff, who generally went to hunt and fish at the peninsula of Tamut after the fishing season of the Lena was over, had constructed for his wife some cabins on the banks of the lake Oncoul, and had embarked to seek along the coasts for Mammoth horns (tusks). One day he saw among the blocks of ice a shapeless mass, but did not then discover what it was. In 1800 he perceived that this object was more disengaged from the ice, and that it had two projecting parts; and towards the end of the summer of 1801 the entire side of the animal and one of his tusks were quite free from ice. The summer of 1802 was cold, but in 1803 part of the ice between the earth and the Mammoth, for such was the object, having melted more rapidly than the rest, the plane of its support

Skull of Fossil Elephant (*Elephas Primigenius*).

became inclined, and the enormous mass fell by its own weight on a bank of sand. In March 1804 Schumachoff came to his Mammoth, and having cut off the tusks exchanged them with a merchant for goods of the value of 50 rubles. We shall now let Mr. Adams, from whose account these particulars are abridged, speak for himself:—

"Two years afterwards, or the seventh after the discovery of the Mammoth, I fortunately traversed these distant and desert regions, and I congratulate myself in being able to prove a fact which appears so improbable. I found the Mammoth still in the same place, but altogether mutilated. The prejudices being dissipated because the Tungusian chief had recovered his health,* there was no obstacle to prevent approach to the carcase of the Mammoth; the proprietor was content with his profit from the tusks, and the Jakutski of the neighbourhood had cut off the flesh, with which they fed their dogs during the scarcity. Wild beasts, such as white bears, wolves, wolverines, and foxes, also fed upon it, and the traces of their footsteps were seen around. The skeleton, almost entirely cleared of its flesh, remained whole, with the exception of one fore leg. The spine from the head to the os coccygis,† one scapula, the basin and the other three extremities, were still held together by the ligaments and by parts of the skin. The head was covered with a dry skin; one of the ears, well preserved, was furnished with a tuft of hairs. All these parts have necessarily been injured in transporting them a distance of 11,000 wersts (7330 miles); yet the eyes have been preserved, and the pupil of the eye can still be distinguished.‡ This Mammoth was a male, with a long mane on the neck, but without tail or proboscis." (The places of the insertion of the muscles of the proboscis are, it is asserted, visible on the skull, and it was probably devoured as well as the end of the tail.) "The skin, of which I possess three-fourths, is of a dark grey colour, covered with a reddish wool and black hairs. The dampness of the spot where the animal had lain so long had in some degree destroyed the hair. The entire carcase, of which I collected the bones on the spot, is 4 archines (9 feet 4 inches) high, and 7 archines (16 feet 4 inches) long from the point of the nose to the end of the tail, without including the tusks, which are a toise and a half (9 feet 6 inches, measuring along the curve; the distance from the base or root of the tusk to the point is 3 feet 7 inches) in length; the two together weighed 360 lbs. avoirdupois; the head alone with the tusks weighs $11\frac{1}{2}$ poods (414 lbs. avoirdupois). The principal object of my care was to separate the bones, to arrange them, and put them up safely, which was done with particular attention. I had the satisfaction to find the other scapula, which had remained not far off. I next detached the skin of the side on which the animal had lain, which was well preserved. This skin was of such extraordinary weight that ten persons found great difficulty in transporting it to the shore. After this I dug the ground in different places to ascertain whether any of its bones were buried, but principally to collect all the hairs

* He had fallen sick from alarm on first hearing of the discovery, as it was considered a bad omen.

† An error, as of 28 or 30 caudal vertebræ only 8 remained.

‡ This is doubtful; a dried substance is visible.

which the white bears had trod into the ground while devouring its flesh. Although this was difficult from the want of proper instruments, I succeeded in collecting more than a pood (36 pounds) of hair. In a few days the work was completed, and I found myself in possession of a treasure which amply recompensed me for the fatigues and dangers of the journey, and the considerable expenses of the enterprise. The place where I found the Mammoth is about 60 paces distant from the shore, and nearly 100 paces from the escarpment of the ice from which it had fallen. This escarpment occupies exactly the middle between the two points of the peninsula, and is 3 wersts long (2 miles); and in the place where the Mammoth was found this rock has a perpendicular elevation of 30 or 40 toises. Its substance is a clear pure ice; it inclines towards the sea; its top is covered with a layer of moss and friable earth half an archine (14 inches) in thickness. During the heat of the month of July a part of this crust is melted, but the rest remains frozen. Curiosity induced me to ascend two other hills at some distance from the sea; they were of the same substance, and less covered with moss. In various places were seen enormous pieces of wood of all the kinds produced in Siberia; and also Mammoths' horns (tusks) in great numbers appeared between the hollows of the rocks; they all were of astonishing freshness. How all these things could become collected there, is a question as curious as it is difficult to resolve. The inhabitants of the coast call this kind of wood Adamschina, and distinguish it from the floating pieces of wood which are brought down by the large rivers to the ocean, and collect in masses on the shores of the Frozen Sea. The latter are called Noachina. I have seen, when the ice melts, large lumps of earth detached from the hills mix with the water, and form thick muddy torrents which roll slowly towards the sea. This earth forms wedges which fill up the spaces between the blocks of ice. The escarpment of ice was 35 to 40 toises high; and, according to the report of the Tungusians, the animal was when they first saw it 7 toises below the surface of the ice, &c. On arriving with the Mammoth at Borchaya our first care was to separate the remaining flesh and ligaments from the bones, which were then packed up. When I arrived at Jakutsk I had the good fortune to repurchase the tusks, and thence expedited the whole to St. Petersburgh." The skeleton is now in the Museum of the Academy, and the skin still remains attached to the head and feet. A part of the skin and some of the hair of this animal were sent by Mr. Adams to Sir Joseph Banks, who presented them to the Museum of the Royal College of Surgeons. The hair is entirely separated from the skin excepting in one very small part, where it still remains attached. It consists of two sorts, common hair and bristles, and of each there are several varieties differing in length and thickness. That remaining fixed on the skin is of the colour of the camel, an inch and a half long, very thick set, and curled in locks. It is interspersed with a few bristles about three inches long, of a dark reddish colour. Among the separate parcels of hair are some rather redder than the short hair just mentioned, about four inches long; and some bristles nearly black, much thicker than horse-hair, and from twelve to eighteen inches long. The skin when first brought to the museum was offensive; it is now quite dry and hard, and where most compact is half an inch thick. Its colour is the dull black of the living elephants. ('On the Mammoth, or Fossil Elephant, found in the Ice at the Mouth of the River Lena in Siberia, with a Lithographic Plate of the Skeleton.' From the fifth volume of the 'Memoirs of the Imperial Academy of Sciences of St. Petersburg,' London, 1819, 4to.

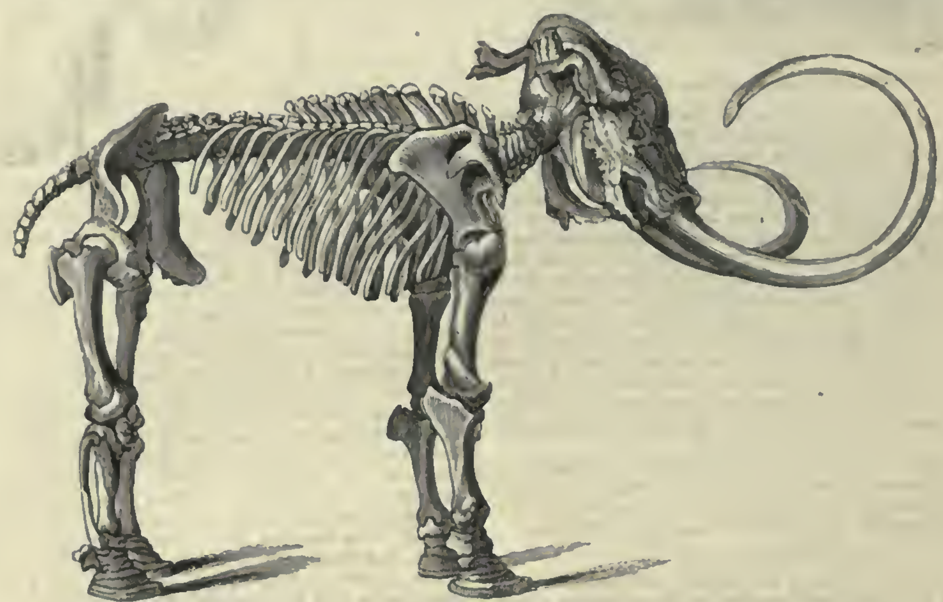
Remains of the *Elephas primigenius* have been found in great numbers in the British Islands. Mr. Woodward, in his 'Geology of Norfolk,' calculates that upwards of 2000 grinders of this animal have been dredged up by the fishermen off Happisburgh in the space of thirteen years. Along the coast of Suffolk the remains of the Mammoth are scarcely less numerous, especially in the pleistocene beds at Stutton. At the village of Walton, near Harwich, abundance of these remains have been found, mixed with the bones of the horse, the ox, and the deer. They have also occurred in many other parts of Essex. They are found at Herne Bay, in the valley of the Thames, at Sheppey, Lewisham, Woolwich, and the Isle of Dogs. They have been dug up in the streets of London, as in Gray's Inn Lane, and in Charles-street, St. James's Square. West of the metropolis they have been dug up at Kensington, Kew, Henley Bottom, Wallingford, and Dorchester. They occur on the south coast at Brighton, Hove, Worthing, Lyme Regis, and Charmouth. Districts in Worcestershire, Warwickshire, Staffordshire, Northamptonshire, Yorkshire, the celebrated cave at Kirkdale, have all yielded remains of this gigantic animal, frequently occurring with the remains of the hippopotamus and rhinoceros. Not only are these remains found on the dry land, but they have been dredged up repeatedly in the German Ocean and the British Channel.

"The remains of the Mammoth," says Professor Owen, "occur on the continent, as in England, in the superficial deposits of sand, gravel, and loam, which are strewed over all parts of Europe; and they are found in still greater abundance in the same formations of Asia, especially in the higher latitudes, where the soil which forms their matrix is perennially frozen.

"Remains of the Mammoth have been found in great abundance in the cliffs of frozen mud on the east side of Behring's Straits, in Eschscholtz's Bay, in Russian America, 66° N. lat.; and they have been traced, but in scantier quantities, as far south as the states of Ohio, Kentuckey, Missouri, and South Carolina.

"But no authentic relics of the *Elephas primigenius* have yet been discovered in tropical latitudes, or in any part of the southern hemisphere. It would thus appear that the primeval elephants formerly ranged over the whole northern hemisphere of the globe, from the 40th to the 60th, and possibly to near the 70th degree of latitude. Here, at least at the mouth of the river Lena, the carcass of a Mammoth has been found preserved entire, in the icy cliffs and frozen soil of that coast. To account for this extraordinary phenomenon geologists and naturalists, biassed more or less by the analogy of the existing elephants, which are restricted to climes where the trees flourish with perennial foliage, have had recourse to the hypothesis of a change of climate in the northern hemisphere either sudden and due to a great geological cataclysm, or gradual and brought about by progressive alternations of land and sea.

"I am far from believing that such changes in the external world were the cause of the ultimate extinction of the *Elephas primigenius;* but I am convinced that the peculiarities in its ascertained organisation are such as to render it quite possible for the animal to have existed as near the pole as is compatible with the growth of hardy trees or shrubs. The fact seems to have been generally overlooked that an animal organised to gain its subsistence from the branches or woody



Mammoth found in Siberia. Reduced from the lithographic plate mentioned at the end of the description.

fibre of trees is thereby rendered independent of the seasons which regulate the development of leaves and fruit; the forest-food of such a species becomes as perennial as the lichens that flourish beneath the winter snows of Lapland; and were such a quadruped to be clothed, like the Rein-Deer, with a natural garment capable of resisting the rigours of an arctic winter, its adaptation would be complete. Had our knowledge of the Mammoth indeed been restricted, as in the case of almost all other extinct animals, to its bones and teeth, it would have been deemed a hazardous speculation to have conceived, à priori, that the extinct ancient elephant, whose remains were so abundant in the frozen soil of Siberia, had been clad, like most existing quadrupeds adapted for such a climate, with a double garment of close fur and coarse hair; seeing that both the existing species of elephants are almost naked, or at best scantily provided when young with scattered coarse hairs of one kind only.

"The wonderful and unlooked-for discovery of an entire Mammoth, demonstrating the arctic character of its natural clothing, has however confirmed the deductions which might have been legitimately founded upon the localities of its most abundant remains, as well as upon the structure of its teeth, namely, that, like the Rein-Deer and Musk-Ox of the present day, it was capable of existing in high northern latitudes."

The kind of food partaken of by these creatures in their northern habitations did not probably differ much from that which they obtain at the present day in tropical climates. Their peculiar teeth enable them to derive a great proportion of their food from the woody fibre of tho branches of trees, and in this respect the structure of the teeth of the extinct species was analogous to that of the recent ones. Forests of hardy trees and shrubs still grow upon the frozeu soil of Siberia, and it is not unreasonable to suppose that at the time the Mammoth existed in the north of Europe it possessed an arboreal vegetation amply sufficient to supply the necessities of this animal, even in districts where the ground was covered during the greater period of the year with snow.

"We may therefore safely infer," says Professor Owen, "from physiological grounds, that the Mammoth would have found the requisite means of subsistence at the present day, and at all seasons, in the sixtieth parallel of latitude; and relying on the body of evidence adduced by Mr. Lyell, in proof of increased severity in the climate of the northern hemisphere, we may assume that the Mammoth habitually frequented still higher latitudes at the period of its actual existence. . . It has been suggested," observes the same philosophical writer, "that, as in our own times, the northern animals migrate, so tho Siberian Elephant and Rhinoceros may have wandered towards the north in summer.

"In making such excursions during the heat of that brief season the Mammoths would be arrested in their northern progress by a condition to which the Rein-Deer and Musk-Ox are not subject, namely, the limits of arboreal vegetation, which however, as represented by the dominating shrubs of polar lands, would allow them to reach the 70th degree of latitude. But with this limitation, if the physiological inferences regarding the food of the Mammoth from the structure of its teeth be adequately appreciated and connected with those which may be legitimately deduced from the ascertained nature of its integument, the necessity of recurring to the forces of mighty rivers, hurrying along a carcass through a devious course, extending through an entire degree of latitude, in order to account for its ultimate entombment in ice, whilst so little decomposed as to have retained the cuticle and hair, will disappear. And it can no longer be regarded as impossible for herds of Mammoths to have obtained subsistence in a country like the southern part of Siberia where trees abound, notwithstanding it is covered during a great part of the year with snow, seeing that the leafless trees during even a long and severe Siberian winter would not necessarily unfit their branches for yielding food to the well-clothed Mammoth. With regard to the extension of the geographical range of the *Elephas primigenius* into temperate latitudes, the distribution of its fossil remains teaches that it reached the 40th degree north of the equator.

"History in like manner records that the Rein-Deer had formerly a more extensive distribution in the temperate latitudes of Europe than it now enjoys. The hairy covering of the Mammoth concurs however with the localities of its most abundant remains, in showiug that, like the Rein-Deer, tho northern extreme of the temperate zone was its metropolis.

"Attempts have been made to account for the extinction of the race of northern elephants by alterations in the climate of their hemisphere, or by violent geological catastrophes, and the like extraneous physical causes. When we seek to apply the same hypotheses to explain tho apparently contemporaneous extinction of the gigantic leaf-eating *Megatheria* of South America, the geological phenomena of that continent appear to negative the occurreuce of such destructive changes. Our comparatively brief experience of tho progress and duration of species within the historical period is surely insufficient to justify, in every case of extinction, the verdict of violent death. With regard to many of the larger *Mammalia*, especially those which have passed away from the American and Australian continents, tho absence of sufficient signs of extrinsic extirpating change or convulsion, makes it almost as reasonable to speculate with Brocchi on the possibility that species, like individuals, may have had the cause of their death inherent in their original constitution, independently of changes in the external world, and that the term of their existence, or the period of exhaustion of the prolific force, may have been ordained from the commencement of each species."

Associated with the *Elephas primigenius* in the Tertiary Beds of England are the remains of another gigantic Proboscidean Animal belonging to the genus *Mastodon.* This genus possesses two enormous tusks projecting from the upper jaw, and was provided with a proboscis, as may be inferred from the length of the tusks, which would have prevented the mouth from reaching the ground. Like the Elephants they were destitute of canine teeth, and provided with a small number of large and complex molar teeth, successively developed from before backwards. The broad crowns of the molar teeth were also cleft by transverse fissures, but these clefts were fewer in number, of less depth, and greater width, than in the Elephants: the transverse ridges were more or less deeply bisected, and the divisions more or less produced in the form of udder-shaped cones, whence the name *Mastodon* (μαστός, and ὄδος), assigned by Cuvier to this genus of Proboscidean *Mammalia.* Two other dental characters pointed out by Professor Owen distinguish the genus *Mastodon* from the genus *Elephas.* The first is the presence of two tusks in the lower jaw of both sexes in the *Mastodon.* These are retained in the male but shed in the female. The second character is the displacement of the first and second molars in the vertical directiou by a tooth of simpler form than the second.

One species of *Mastodon* has been found in England, the *M. angustidens* of Owen, the Mastodon à Dents Etroites of Cuvier. Remains of it occur in the formation called by Sir Charles Lyell the Fluvio-marine Crag. It belongs to the Older Pliocene division of the Tertiary System.

A species of *Mastodon* larger than the *M. angustidens* of Europe has been found fossil in many parts of the United States. This is the *M. giganteus.* A specimen of the auimal nearly perfect was obtained in the state of Missouri in 1840. It was exhibited at the Egyptian Hall, Piccadilly, London, in 1842 and 1843, under the name of the 'Missouri Leviathan.' It was strangely distorted; but having been purchased by the Trustees of the British Museum it has been made to assume its correct proportions, and is now one of the chief objects of attraction in that national collection. The following are the proportions of this gigantic skeleton:—Extreme length, 20 feet 2 inches; height, 9 feet 6¾ inches: cranium, length, 3½ feet; vertical dimensions, 4 feet; width, 2 feet 11 inches; width of pelvis, 5 feet 8 inches: tusks, extreme length, 7 feet 2 inches; projection of the same, 5 feet 2 inches; circumference at the base, 27 inches. It was found near the banks of the river La Pomme de Terre, a tributary of the Osage River, in Burton county, Missouri. The bones were imbedded in a brown sandy deposit full of vegetable matter, with recognisable remains of the cypress, tropical cane, swamp-moss, stems of the palmetto, &c., and this was covered by beds of blue-clay and gravel to a thickness of about fifteen feet. Mr. Koch, the discoverer, states that an Indian flint arrow-head was found beneath the leg-bones of this skeleton, and four similar weapons wero imbedded in the same stratum. This indicates that the formation was more recent than that in which the remains of the British *Mastodon* had been found. Other remains of this *Mastodon* have been found in America, especially in the Big Bone Lick, in Kentucky, where it is said the remains of not less than 100 mastodons, 20 mammoths, with bones of the megalonyx, stag, horse, and bison, havo been discovered.

Amongst the remarkable remains brought from the Sewalik Hills, in Hindustan, by Captain Cautley and Dr. Falconor are the remains of several species of the genus *Elephas* and other proboscidean animals. Dr. Falconer, speaking of the group of animals thus revealed by his researches, says:—

"This fossil Fauna is composed of representative types of *Mammalia* of all geological ages, from the oldest of the tertiary periods down to the most modern; and of all the geographical divisions of the old continent, grouped together into one comprehensive assemblage. Among the forms contaiued in it there are—of tho *Pachydermata* several species of *Mastodon*, Elephant, Hippopotamus, Rhinoceros, *Anoplotherium*, and three species of *Equus*; of the *Ruminantia* the colossal genus *Sivatherium*, which is peculiar to India, with species of *Camelus*, *Bos*, *Cervus*, and *Antilope*; of the *Carnivora*, species of most of the great types, together with several undescribed genera; of the *Rodentia* and *Quadrumana* several species; of the *Reptilia*, a gigautic tortoise (*Colossochelys*), with species of *Emys* and *Trionyx*, and several forms of Gavials aud Crocodiles. To these may be added the remains of Struthious and other birds, and Fishes, *Crustacea*, and *Mollusca*."

The genus *Elephas* in this collection which has beon deposited in the British Museum includes six species.

E. planifrons, distiuguished by the flatness of the forehead and the intermediate character of its molar teeth.

E. Namadicus, with a great development of the cranium, aud teeth closely allied to those of the Indian species.

E. Hysudricus, with a turban-like vortex of the skull and teeth, whose structure approaches that of the African Elephant.

E. Ganesa is the most remarkable of the Sewalik species. A skull exists with remains of the other species in the British Museum. The total length of the cranium and tusks is 14 feet; length of the skull 4 feet 2 inches; width 29 inches; width of the muzzle 2 feet; length of the tusks 10 feet; circumference of the tusk at the base 26 inches.

The other two species are named *E. insignis* and *E. bombifrons*.

The species of *Mastodon*, in the collection from the Sewalik Hills, are *M. Perimensis*, *M. Siralensis*, and *M. latidens*.

Professor Owen states that a species of *Mastodon*, nearly allied to *M. angustidens*, has left its remains in the ossiferous caves and post-tertiary or newer tertiary deposits of Australia. From the conformity of the molar teeth Cuvier regarded a *Mastodon* whose remains have been discovered in Peru as identical in species with the *M. angustidens* of Europe. Professor Owen regards the *M. longirostris* of Kaup, found in Germany, and the *M. Arvernensis* of Croizet and Jobert, dug up in Auvergne, as identical with his *M. angustidens*.

In the collection of the British Museum, in addition to the species which we have mentioned above, will be found remains of *Elephas priscus* and *E. meridionalis*, found in Europe. There is also the remains of a species of *Mastodon*, *M. Andium*, from Buenos Ayres.

(Owen, *British Fossil Mammals and Birds*; Falconer and Cautley, *Fauna Antiqua Siralensis*; Mantell, *Petrefactions and their Teachings*.)

ELEPHANT'S FOOT. [TESTUDINARIA.]

ELEPHA'NTOPUS (from ἐλέφας, an elephant, and πούς, a foot, on account of the shape of its radical leaves), a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Corymbiferæ*, the tribe *Vernoniaceæ*, the sub-tribe *Vernonieæ*, and the division *Elephantopeæ*. It has heads containing 3-4-5 florets, equal flowered, closely collected into a cluster, surrounded by leaves; the involucre compressed in two rows, the leaflets dry, oblong, alternately flat and folded, the inner usually 3-nerved; the receptacle naked; the corolla palmate, with a 5-cleft limb, which has acuminate segments and one recess deeper than the others; the filaments smooth, the branches of the style half subulate; the achenium rather compressed, many ribbed, oblong, hairy; the pappus in one row consisting of several straight paleæ, dilated at the base, but otherwise very narrow, acuminate, equal, and serrated.

E. scaber has a hairy dichotomous stem, the radical leaves scabrous, cuneate, and very much narrowed at the base, those of the stem lanceolate. This plant is common in almost all parts of India, in dry elevated positions. It has a stem a foot high, with the heads of pale-red flowers on long stalks. The roots are fibrous. Both the roots and the leaves are reputed to have active medical properties. The natives on the Malabar coast use a decoction of them in cases of dysuria. There are other species natives of South America and the West Indies.

(Lindley, *Flora Medica*; Loudon, *Encyclopædia of Plants*.)

ELETTA'RIA, a genus of Plants belonging to the natural order *Zingiberaceæ*. The characters of this genus are the same as *Amomum*, but the tube of the corolla is filiform and the anther naked. [AMOMUM.]

E. Cardamomum, True Cardamom, is a native of the mountainous districts of the coast of Malabar, especially above Calicut, in the Wynaad district, between 11° and 12° N. lat., where the best are produced. It is therefore well placed; for Cardamoms formed a portion of the early commerce, which subsisted between this part of India and Arabia, whence they must have been made known to the Greeks, as they are described by Dioscorides, and mentioned as early as the time of Hippocrates.

The Cardamom plant delights in moist and shady places on the declivities of the hills. It is cultivated from partings of the root in the district of Soonda Balaghaut, but the fruit is very inferior; the best grows in a wild state, at least where no other measures are adopted than clearing away the weeds from under the largest trees, which are felled close to the roots. The earth being loosened by the force of the fallen tree, young Cardamom plants shoot forth in a month's time, and are sheltered by the shade of the branches. The tree-like herbaceous plants attain a height of from 9 to 12 feet. The root is as tortuous and tuberous as that of the ginger, and the leaves, with long sheathing foot-stalks, are from one to two feet in length, placed in two rows, and lanceolate in shape, like those of the Indian Shot (*Canna Indica*) common in English gardens. The scapes, or flower- and fruit-bearing stalks, make their appearance in February of the fourth year, from the base of the stems, are three to four in number, and from one to two feet long, lax, and resting on the ground. The fruit is ripe in November, and requires nothing but drying in the sun to be fit for commerce. The seeds are gratefully aromatic and pungent with a flavour of camphor, and are regarded as a necessary article of diet by the inhabitants of Asia. They are used in medicine, and enter into a number of pharmaceutical preparations.

E. Cardamomum medium is a native of the hilly country in the neighbourhood of Sytheh, where the plant is called Do Keswa. The seeds of this species are numerous, obovate, with a groove on one side. Dr. Lindley concludes that this plant yields the *Cardamomum medium* of writers on Materia Medica.

ELEUSINE, a genus of Plants belonging to the natural order of the Grasses. *E. coracana* is cultivated as a corn-plant by the inhabitants of the Coromandel Coast, and is known by the name of Natchuee. According to Schomburg a decoction of another species, *E. Indica*, is employed in Demerara in the convulsions of infants. *E. Tocusso* is an Abyssinian corn-plant belonging to this genus.

ELEUTHERIA. [CROTON.]

ELIDONE. [SEPIADÆ.]

ELK. [CERVIDÆ.]

ELLIPSOLITHES. Mr. Sowerby gave this title to some (compressed?) forms of Fossil *Cephalopoda*, from the Mountain Limestone.

ELLIPSOSTO'MATA, De Blainville's name for a family (the third) of his second order, *Asiphonobranchiata*, of his first sub-class, *Paracephalephora Dioica*, of his second class, *Paracephalophora*, of his *Malacozoa*. The *Ellipsostomata* of De Blainville comprehend the genera *Melania*, *Rissoa*, *Phasianella*, *Ampullaria*, *Helicina* (including *Ampullacera*, De Blainv., and *Olygira*, Say), and *Pleurocerus*. Of these all but *Pleurocerus* are included under the Pectinibranchiate Gasteropods of Cuvier; and as the habits of the included genera are by no means uniform, the genera will be treated of under their several titles. [AMPULLARIA.]

ELM. [ULMUS.]

ELODIANS. [CHELONIA.]

E'LYMUS, a genus of Grasses belonging to the tribe *Hordeineæ*. It has 2 glumes, both on the same side of the spikelet, without awns or setæ, with 2 or more perfect flowers, and the spikelets two or three together. Several species of this genus have been described. Two only are natives of Great Britain.

E. arenarius, Upright Lyme-Grass. It has an upright close spike; the rachis flat, not winged; the glumes lanceolate, downy, not longer than the spikelets. It is a coarse grass, common on sandy sea-shores; and, with other grasses, it sends down long fibrous roots amongst the sand in such a way as to prevent its moving about with the winds. On some parts of the coast immense sandbanks are formed by this grass and others, binding down the sands which are thrown up by occasional and successive high tides. Although this grass, according to Sir H. Davy, yields a large quantity of sugar, it is not eaten by any of our domestic animals.

E. geniculatus, Pendulous Lyme-Grass, has a lax spike bent downwards; the rachis winged; the glumes awl-shaped, glabrous, longer than the spikelets. The stem is 3 or 4 feet high, and the spike 1 or 2 feet long, bent down in a remarkable manner at the second or third spikelet. It has been found near Gravesend. Most of the remaining species are natives of America, both North and South.

(Babington, *Manual of British Botany*; Loudon, *Encyclopædia of Plants*.)

ELYSIA. [PLACOBRANCHIATA.]

ELYSIADÆ. [NUDIBRANCHIATA.]

ELZERINA. [CELLARIÆA.]

EMARGINULA. [FISSURELLIDÆ.]

EMBERIZA. [EMBERIZIDÆ.]

EMBERIZIDÆ, a family of Birds belonging to the order *Insessores* and the tribe *Conirostres*. The most distinguishing genus of the family is *Emberiza*. It comprises however other genera. The general relations of this family are given under FRINGILLIDÆ. We shall confine ourselves here to the British genera of this family known under the name of Buntings.

Plectrophanes.—Beak short, thick, conical, the edges of both mandibles slightly curved inwards; upper mandible smaller than the lower, with a small palatal knot. Nostrils basal, oval, partly hidden by small feathers. Wings long and pointed; the first and second quill-feathers of nearly equal length, and the longest in the wing. Legs with the tarsi of moderate length; anterior toes divided; lateral toes equal in length; hind toe strong; claw elongated, and nearly straight.

P. Lapponica (Gould), the Lapland Bunting. It is the *Emberiza Lapponica* and *E. calcarata* of other writers. Though a native of the arctic regions, Mr. Yarrell records five instances of its being taken in Great Britain. It is found in Siberia and near the Uralian chain. Towards winter a few migrate as far as Switzerland. It inhabits the Faroe Islands, Spitzbergen, Greenland, and Iceland in summer, and thence westward to Hudson's Bay. Sir John Richardson says, that about the middle of May, 1827, it appeared in very large flocks at Carlton House, and a few days later made their appearance at Cumberland House. The eggs are usually seven, and of a pale ochre-yellow spotted with brown.

P. nivalis, the Snow-Bunting. It is the *Emberiza glacialis*, *E. montana*, *E. nivalis*, and *E. mustelina* of authors; and the Tawny-Mountain- and Snow-Bunting of English writers. It was at one time supposed they were different species, but this arose from the great variety of plumage to which these birds are subject. The predominant colour of their plumage is white, hence the name Snow-Bunting. This bird arrives in this country in the end of September and the beginning of October, and extends from the north of Scotland to the south of England. This bird is rather larger than the last.

Emberiza.—Beak conical, strong, hard, and sharp-pointed; the edges of both mandibles curving inwards; the upper mandible narrower and smaller than the under one, and its roof furnished with a hard bony and projecting palatal knob. Nostrils basal and round, partly hidden by small feathers at the base of the bill. Wings of moderate size; the first quill shorter than the third, which is the longest in the wing. Feet with three toes before and one behind, divided to their origin; claws rather long, curved, and strong.

E. miliaria, the Common Bunting, is the most common species of this genus. It remains in the British Islands throughout the year; and on account of its very familiar presence in corn-fields, is frequently called the Corn-Bunting. It builds its nest in April, and lays four or five eggs of a reddish-white or pale purple-red ground, streaked and spotted with dark purple-brown. It feeds on the seeds of the grasses, of the *Polygona*, of sorrels, and of cereal plants; also on Coleopterous Insects.

In both sexes of this species the upper parts are of a light yellowish-brown streaked with blackish-brown, each feather being of that colour along the shaft; lower parts pale yellowish-gray, each feather of the fore neck tipped with a triangular spot of brownish-black, the fore part of the breast and the sides with more elongated and fainter spots.

E. schœniclus, the Reed-Bunting. It is also called, according to MacGillivray, Black-Headed Bunting, Reed-Sparrow, Water-Sparrow, Ring-Bunting, Ring-Bird, Ring-Fowl, and Chuck. It frequents marshy places, where it is seen perching on willows, reeds, sedge, and other aquatic plants. It feeds on insects, seeds, and small *Mollusca*. The nest is placed among aquatic plants, and is composed of stalks and blades of grasses, bits of rushes, and the like. The eggs are four or five in number, of a yellowish-gray, with tortuous or angular lines, and irregular spots of black. This bird is easily distinguished from the other species by its black head and white throat.

E. citrinella, the Yellow Bunting, or Yellow Ammer. It is also called in English Yellow Yelding or Yolding, Yellow Yowley, Yellow Yite, Yeldrock Skute, and Devil's Bird. It is a permanent resident in Great Britain, in cultivated and wooded districts, where it is well known. The back and wings are bright red, the central part of each feather brownish-black. The nest is composed of coarse grasses and twigs, neatly lined with fine grass, fibrous roots, and hairs: it is placed on the ground or in the lower part of a bush. It lays four or five eggs purplish-white, marked with linear and angular streaks and a few irregular dots of black.

E. Cirlus, the Cirl-Bunting. This bird is not so common in this country as the last, which it greatly resembles. It was first distinguished as a British bird by Colonel Montague. It is a native also of the south of Europe, and is more frequent in the south of England than in the north.

E. hortulana, the Ortolan Bunting. A very few specimens only of this bird have been taken in England. It is common in the southern countries of Europe, and migrates as far northward as the Baltic.

(MacGillivray, *Manual of British Birds*; Yarrell, *History of British Birds*.)

E'MBLICA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has monœcious flowers; the calyx 6-parted; 3 stamens combined; 3 styles dichotomous; the fruit fleshy, tricoccous, 6-seeded.

E. officinalis is a native of most parts of India. It is a tree having a crooked trunk, with branches thinly scattered in every direction; the male branches spreading and drooping. The leaves are alternate, spreading, one or two feet long, and about one and a half or two inches broad: the stipules small, withering; the flowers minute, of a greenish colour; the fruit a drupe, fleshy, globular, smooth, 6-striated: the nut obovate, obtusely triangular, 3-celled; the seeds two in each cell. The bark of this tree is astringent, and is used in India as a remedy for diarrhœa. The fruit is acid, and tastes astringent, and when eaten acts as a mild purgative. This plant is the *Phyllanthus Emblica* of Linnæus; and *Myrobalanus Emblica* of Bauhin.

(Lindley, *Flora Medica*.)

EMBRYO. [REPRODUCTION IN ANIMALS; REPRODUCTION IN PLANTS; SEED.]

EMERALD. [BERYL.]

EMERITA. [HIPPA.]

EMERY. [ADAMANTINE SPAR; CORUNDUM.]

EMMET, a name used by early English writers for the Ant. [FORMICA.]

EMPALEMENT, an obsolete name for the stamen of a flower.

EMPEROR-MOTH. [SATURNIA.]

EMPETRA'CEÆ, *Crowberries*, a small natural order of Polypetalous Exogenous Plants, related to *Euphorbiaceæ*. They consist of unisexual heath-like plants with minute flowers, having a calyx with a few imbricated sepals that change into about three membranous petals, a small number of hypogynous stamens, and a superior ovary with from 3 to 9 cells, in each of which there is a single ascending ovule. The fruit is fleshy and berried. They are small acrid plants, of no known use, and comprise a few species from the north and south of Europe, North America, and the Straits of Magalhaens. *Empetrum nigrum*, the Crakeberry or Crowberry, is wild on the mountainous heaths in the north of England. Its black fruit forms an article of food in the northern parts of the world, but is reported to be unwholesome, and to cause headache. A sort of wine has been prepared from it for many centuries in Iceland and Norway; whence the report of real wine which was used at the sacrament being made in those countries.

The white berries of the *Camarinheira* (*Corema*) are employed by the Portuguese in making an acidulous beverage, which the domestic physicians esteem in fevers.

There are 4 genera and 4 species of this order.

EMPETRUM. [EMPETRACEÆ.]

Empetrum rubrum.

1, a female flower, much magnified; 2, a pistil; 3, a transverse section of the same.

EMU. [STRUTHIONIDÆ.]

EMYS. [CHELONIA.]

EMYSAURA. [CHELONIA.]

ENALIOSAURA, a name proposed for the great Fossil Marine Lizards represented by *Ichthyosaurus* and *Plesiosaurus*. [ICHTHYOSAURUS; PLESIOSAURUS; REPTILES.]

ENAMEL. [TEETH; DENTITION.]

ENCELADITE, a Mineral containing Titanium, a variety of *Warwickite*. [WARWICKITE.]

ENCEPHALARTOS, a genus of Plants belonging to the natural order *Cycadaceæ*. The species are found in Africa. Like many of the other forms of Cycadaceous Plants they yield starch in their stems, which are prepared by the natives and eaten; hence these plants are known by the name of Caffer-Bread or Kaffir-Bread.

ENCHANTER'S NIGHT-SHADE. [CIRCÆA.]

ENCHELIS, a genus of Infusorial Animalcules. The species *E. sanguinea* and *E. pulvisculus*, according to Meyen, form the Red and Green Snow-Plants which have been described as *Confervæ*, and referred to *Protococcus*. [SNOW, RED.]

EN'CHODUS, a genus of Fossil Cycloid Fishes, from the Chalk. (Agassiz.)

ENCRINITES, the name by which the petrified radiated animals commonly called Stone Lilies have been long known in Britain: it is also applied generally to the *Crinoidea*, a family of Animals belonging to the order *Echinodermata*. [ECHINODERMATA.]

Lamarck arranged the genus *Encrinus* in his fifth order of Polypes (*Polypi natantes*), fixing its position between *Virgularia* and *Umbellularia*, and recording but two species, one recent, namely *Encrinus Caput-Medusæ* (*Isis Asteria*, Linn.), from the seas of the Antilles; the other fossil, namely *E. liliiformis* (*Lilium lapideum*, Stone-Lily of Ellis and others).

Cuvier includes the Encrinites among his Pedicillated Echinoderms, considering that they should be placed near the *Comatulæ*; and in the 'Règne Animal' they are accordingly to be found between the great group of the Star-Fishes and that of the Echinideans.

De Blainville observes that the beautiful work of Guettard ('Acad. des Sc.' 1755) upon the living and fossil Encrinites, showed long ago the great relationship which there is between these and the *Comatulæ*, and he remarks upon the arrangement of Lamarck, who followed Linnæus and his adherents in placing them among the Zoophytes, notwithstanding Guettard's exposition and Ellis's confirmation. After alluding to Miller's work on the family, and to Mr. Thompson's description of the living specimen found on the coast of Ireland, De Blainville takes as the basis of his terminology the parts which exist in *Comatulæ*, and, adopting the views of Rosinus, rejects that proposed by Miller in his interesting memoir, objecting to the terms 'pelvis,' 'costal,' 'intercostal,' 'scapula,' 'hand,' 'fingers,' &c., as derived from animals of an entirely different type of form, and inapplicable to the radiated structure.

We find, then, that the 'pelvis' of Miller is the centro-dorsal joint (l'article centro-dorsal) of De Blainville. The 'costal' is the first basilary joint of each ray. The 'intercostal' is the second basilary joint. The 'scapula' is the third, or that on which the radii are supported. The 'hand' is the part of the ray which is divided but not separated. The 'fingers' are the digitations or divisions of the rays. Finally, the 'pinnules' are the lateral divisions of the digitations; and De Blainville, like Miller, divides the rays into principal rays and accessory or auxiliary rays.*

Dr. Buckland ('Bridgewater Treatise'), who uses the phraseology of Miller, speaks of these animals as destined to find their nourishment by spreading their nets and moving their bodies through a limited space, from a fixed position at the bottom of the sea; or by employing the same instruments, either when floating singly through the water, or attached, like *Pentelasmis* [CIRRIPEDIA], to floating pieces of wood. He refers to Miller for several instances of their power of repairing casual injuries, and figures a recent *Pentacrinus*, one of whose arms is under the process of being reproduced, as crabs and lobsters reproduce their lost claws and legs, and many lizards their tails and feet, observing that the arms of star-fishes also, when broken off, are in the same manner reproduced. [ECHINODERMATA.] The same author remarks, that although the representatives of the Crinoideans in our modern seas are of rare occurrence, this family was of vast numerical importance among the earliest inhabitants of the ancient deep. "We may judge," says Dr. Buckland, "of the degree to which the individuals of these species multiplied among the first inhabitants of the sea, from the countless myriads of their petrified remains which fill so many limestone beds of the transition formations, and compose vast strata of entrochal marble, extending over large tracts of country in Northern Europe and North America. The substance of this marble is often almost as entirely made up of the petrified bones of Encrinites as a corn-rick is composed of straws. Man applies it to construct his palace and adorn his sepulchre; but there are few who know, and fewer still who duly appreciate, the surprising fact, that much of this marble is composed of the skeletons of millions of organised beings, once endowed with life, and susceptible of enjoyment, which, after performing the part that was for a while assigned to them in living nature, have contributed their remains towards the composition of the mountain masses of the earth. Of more than thirty species of Crinoideans that prevailed to such enormous extent in the transition period, nearly all became extinct before the deposition of the lias, and only one presents the angular column of the Pentacrinite: with this one exception, pentangular columns first began to abound among the Crinoideans at the commencement of the lias, and have from thence extended onwards into our present seas. Their several species and even genera are also limited in their extent; for example, the great Lily Encrinite (*E. moniliformis*) is peculiar to the Muschel-Kalk, and the Pear-Encrinite to the middle region of the Oolitic Formation."

The same author, speaking of the joints which composed the stem, says, "The name of Entrochi, or Wheelstones, has with much propriety been applied to these insulated vertebræ. The perforations in the centre of these joints affording a facility for stringing them as beads, has caused them in ancient times to be used as rosaries. In the northern parts of England they still retain the appellation of 'Saint Cuthbert's beads.'

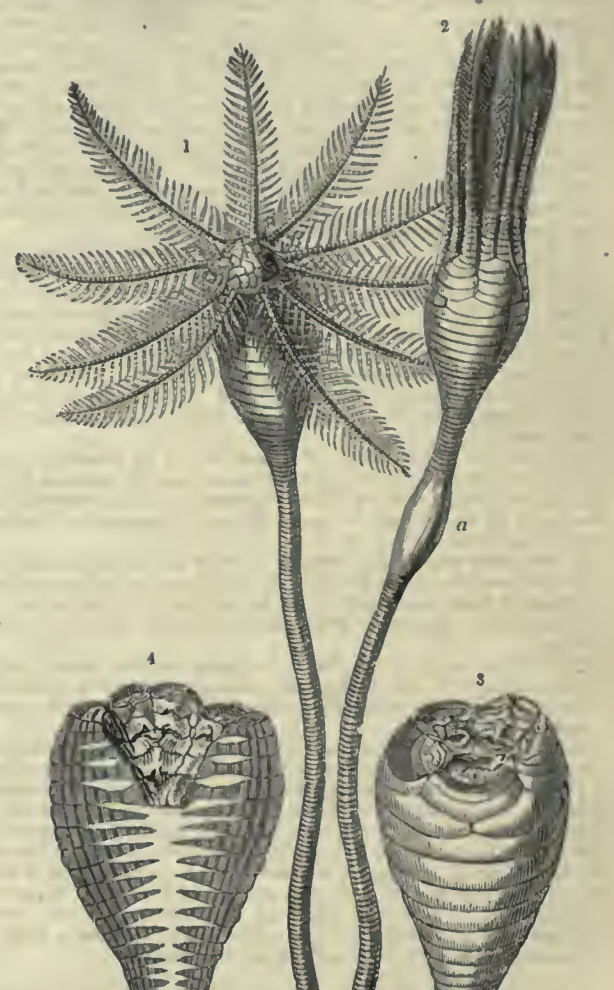
> On a rock by Lindisfarn
> Saint Cuthbert sits, and toils to frame
> The sea-born beads that bear his name.

"Each of these presents a similar series of articulations, varying as we ascend upwards through the body of the animal, every joint being exactly adjusted to give the requisite amount of flexibility and strength. From one extremity of the vertebral column to the other, and throughout the hands and fingers, the surface of each bone articulates with that adjacent to it, with the most perfect regularity and nicety of adjustment. So exact and methodical is this arrangement, even to the extremity of its minutest tentacula, that it is just as improbable that the metals which compose the wheels of a chronometer should for themselves have calculated and arranged the form and number of the teeth of each respective wheel, and that these wheels should have placed themselves in the precise position fitted to attain the end resulting from the combined action of them all, as for the successive hundreds and thousands of little bones that compose an Encrinite to have arranged themselves in a position subordinate to the end produced by the combined effect of their united mechanism, each acting its peculiar part in harmonious subordination to the rest; and all conjointly producing a result which no single series of them acting separately could possibly have effected." ('Bridgewater Treatise.')

De Blainville characterises his Fixed Asterencrinideans (Astérencrinides Fixés) as having a body more or less bursiform, supported upon a long articulated stem, and fixed by a radiciform part.

Genus, *Apiocrinites*.—Miller, who established this genus, characterises it as an animal with a column gradually enlarging at the apex, composed of numerous joints, of which the superior is marked by five diverging ridges, dividing the surface into as many equal portions, sustaining the pelvis, formed of five sub-cuneiform joints, supporting others of a figure nearly similar, from which proceed the arms and tentaculated fingers formed of simple joints having the figure of a horse-shoe.

De Blainville thus defines it:—Body regular, circular, for the rest unknown, contained in a sort of cupule or conical test (têt), composed of three superposed rows, each consisting of five scaphoid plates, united or jointed throughout, the upper one supporting on a radiated surface the rays which are formed by a simple series of non-pinnated (?) articulations. Stem round, at first as large as the body, attenuating by degrees down to the root; articulations circular,



Bradford Pear-Encrinite (*Apiocrinites rotundus*), restored and reduced.

1, expanded; 2, closed; *a*, the remedial effect of calcareous secretions in repairing an injury of the joints of the stem: two young individuals, and the surfaces of two truncated stems appear at the base; 3, pear-shaped body of *Apiocrinites rotundus*, showing at its upper extremity the internal disposition of the bones surrounding the cavity of the stomach; 4, vertical section of the body, showing the cavity of the stomach, and a series of lower cavities, or hollow lenticular spaces, between the central portions of the enlarged joints of the upper portion of the vertebral column. These spaces are considered by Miller as enlargements of the alimentary canal, which descends through the axis of the entire column. The surfaces of the joints of the vertebral column are striated with rays on the adjacent plates, and allow of flexure without risk of dislocation. (Buckland.)

* It is necessary to put the student on his guard against the confusion and error manifest in this part of De Blainville's useful work. This was not a little puzzling when considered as coming from a pen of such high reputation as his; till the arrival of the 'Nouvelles Additions et Corrections' brought the information that "par une transposition singulière du manuscrit, il y a eu une sorte de mélange entre les paragraphes qui appartiennent aux genres *Encrinus* et *Pentacrinus*." In short, among other mistakes, the titles *Encrinus* and *Pentacrinus*, together with whole paragraphs, have been misplaced.

little elevated, pierced by a round hole, and radiated at their surface. Auxiliary rays scattered. This genus has occurred hitherto in a fossil state only, and has alone been found in strata posterior to the Lias.

A. rotundus, Round-Columned, Pear-like, Lily-shaped Animal (Miller). It appears to be the *Astiopoda elegans* (stem) of Defrance. It is the Bradford Pear-Encrinite of Parkinson, and is described by Miller as a crinoidal animal, with a round column, composed of joints adhering by radiating surfaces, of which from 10 to 14 gradually enlarge at its apex, sustaining the pelvis, costæ, and scapulæ, from which the arms and tentaculated fingers proceed. Base formed by exuding calcareous matter, which indurates in laminæ, and permanently attaches the animal to extraneous bodies.

It occurs in the middle region of the Oolite at Bradford in Wiltshire, Abbotsbury, near Weymouth, Dorsetshire, Soissons, Rochelle, &c.

Miller describes and figures a second species, *Apiocrinites ellipticus* (Bottle-Encrinite, Strait-Encrinite, and Stag-Horn Encrinite of Parkinson; Goldfuss refers to it as *A. elongatus*), and gives the Chalk-Pits of Wiltshire and Kent as its localities. The bodies, &c. of this species are the Chalk-Bottles of the quarrymen.

M. Goldfuss, in his great work, records four additional species, namely, *A. rosaceus*, *A. mespiliformis*, and *A. Milleri* (Schlotheim), and *A. flexuosus*, and *A. obconicus* Goldfuss), retaining Miller's *A. ellipticus*, and referring to Miller's description of that species for *A. elongatus* also.

Encrinus (*Encrinites*, True Lily-shaped Animal of Miller.)—Miller characterises his genus *Encrinites* as a crinoidal animal, with a column formed of numerous round depressed joints, adhering by a radiating grooved surface, and becoming subpentangular near the pelvis, which is composed of five pieces, giving a lateral insertion to the first series of costal plates, to which the second series and scapulæ succeed, whence the tentaculated arms or fingers proceed, formed by double series of joints. He observes that the animals of this genus have not hitherto been found in a living state, nor does he believe that their remains have been discovered in England.

E. liliiformis, Lamarck. This is the *E. moniliformis*, Bead-columned, True Lily-shaped Animal of Miller, who describes the species as a crinoidal animal, with a column formed of numerous round joints, alternately, as they approach the pelvis, larger and smaller, becoming subpentangular when nearly in contact with it. On the pelvis, formed of five pieces, adhere laterally the first series of costæ, on which the second series of costæ is placed, succeeded by the scapulæ, from which the ten tentaculated arms or fingers proceed. Animal permanently affixed by exuded indurated matter.

Lily-Shaped Encrinite (*Encrinus liliiformis*).

Miller's *E. moniliformis* is probably the *E. liliiformis* of Lamarck, the Encrine and Lys de Mer of the French, the *Lilium lapideum* of some of the older writers, and the Stone Lily of the English. It is found in the Muschel-Kalk, Hildesheim, Rakenberg near Goslar, Obernscheden and Azzenhausen, not far from Gemenden, in Lower Saxony; Sewerven in Juliers, in Westphalia; the village of Erkerode in Brunswick, about two miles from the town bearing this name, near a wood called the Elm, &c. In this last-named locality the quarry is on the declivity of a hill overgrown with wood, on which account the inhabitants oppose the digging after them. The stratum containing them is hardly fifteen to eighteen inches in thickness. Under the surface of the earth is a friable, porous, argillaceous limestoue, containing millions of columns and columnar joints; but many hours' digging is necessary before a good specimen of the superior part, or stone-lily, can be procured since the moisture in the stone contributes to their rapid destruction, and their occurring on large pieces of stone makes them liable to separation, which accounts for the many mended specimens. Another and harder stratum under the above contains numerous crinoidal remains; but, according to the quarrymen, no stone-lilies. (Miller.) The author last quoted adds that there is good reason to believe that the formation in which the remains are found near Brunswick corresponds with the White Lias of England, as it appears to repose on the newer Red-Sandstone containing salt and gypsum.

Fine specimens of this fossil have always been and still are sought for with great eagerness by collectors. In the 'Beyträge zur Naturgeschichte,' Altenburg, 1774, it is stated that the Emperor of Germany offered 100 dollars for a stone-lily free from the matrix, and attached to its column.

"The peculiarly fine lily encrinite," writes Miller, "figured by Knorr, tab. 11, *a*, was, it is said, purchased ('Naturforscher,' Stück 3) from the labourers at the limestone quarry at Schrapland, near Halle, by Inspector Wilkens, for thirty-two groschen, and given to Professor Lange, who sold it to Baron Niegart. However in the same publication (Stück 6), it is stated that it was not bought by Wilkens, but by Mr. Vitigo, at Farrenstadt, near Querfurt, for two dollars, and given to Lange, who sold it for three louis d'or. If my memory does not misgive me, I think I saw the specimen about twenty years ago in the collection of the Naturforschenden Gesellschaft, at Danzig. Where is it now?"

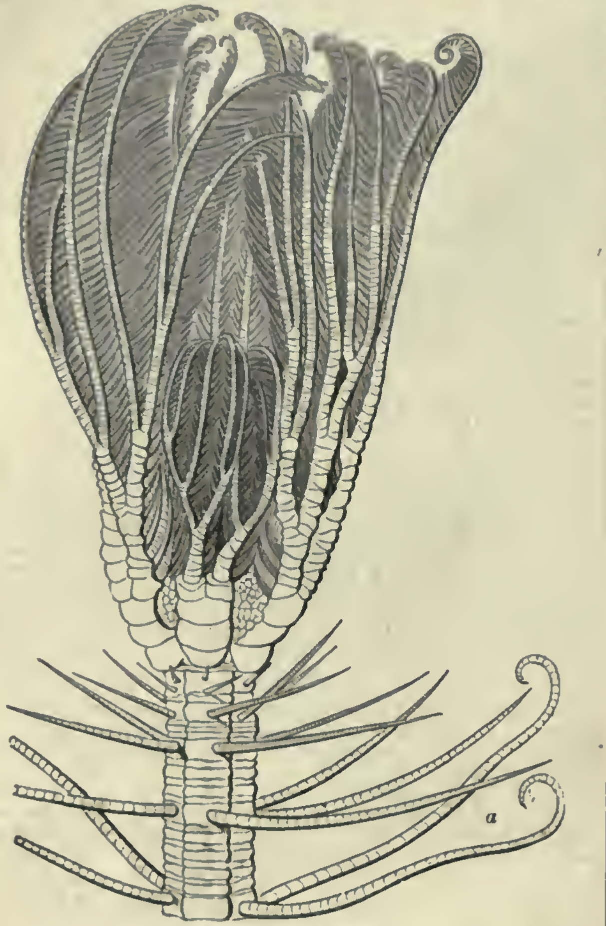
Pentacrinus (*Pentacrinites* vel *Pentacrinus*, Five-Angled Lily-shaped Animal, Miller; *Pentagonites Rafinesque*).—The following is the generic character as given by Miller:—An animal with a column formed of numerous pentangular joints, articulating by surfaces with pentapetalous semistriated markings. Superior columnar joint supporting a pelvis of five joints, on which five first costals rest, succeeded by five second costals and five scapulæ, from which ten arms proceed, having each two hands, composed of several tentaculated fingers. Column long, having numerous auxiliary side-arms. Base not ascertained.

* *Recent Species.*

P. Caput-Medusæ is a crinoidal animal having a column formed of numerous pentangular joints, articulating by surfaces with pentapetalous ovate striated markings; five auxiliary side-arms formed of round joints proceeding from the column at intervals. Superior columnar joints supporting a pelvis of five plates, to which the first costals, second costals, and scapulæ succeed, from which ten arms proceed, each supporting two hands, subdividing into three fingers. Lower extremity, or base, unknown. (Miller.)

It is the *Encrinus Caput-Medusæ* of Lamarck; *Isis Asteria* of Linnæus. It inhabits the seas of the Antilles, and has been taken near the island of Barbadoes (Dr. Hunter's specimen), also off Nevis (specimen formerly belonging to James Tobin, Esq., now in the British Museum), and Martinique (specimen in the Paris Museum). There is also a specimen in the Museum of the Royal College of Surgeons in London, and one in that of the Geological Society of London.

Mr. Miller, in speaking of Mr. Tobin's specimen, says, "In the drawing it up from the bottom of the sea, the animal has clearly been broken off, leaving its posterior portion behind; thus we have lost the chance of ascertaining the fact, whether it adhered by a fixed base, or had a locomotive power. The same accident has befallen the other recent individuals that have been mentioned when speaking of the locality of this species. However, judging from its analogy to the *Encrinus moniliformis*, from its long column, numerous auxiliary side-arms, and the associated manner in which groups of the following species are sometimes found preserved on the surface of a single slab, with the columns all tending towards the same point, as if issuing from a common base, I conceive that this species also adhered by a base to extraneous matter. This idea gains some further ground, from all the recent specimens hitherto found having broken abruptly off in the endeavour to remove them, as not being able to free themselves from the points of adhesion, which certainly would have been the case had the animal possessed a locomotive power." This inference acquires additional confirmation from the observations made by the late J. Tobin, Esq., on another specimen, namely—"Some years ago I was in possession of a larger Pentacrinite, which was brought to me so fresh out of the sea that at the bottom (where it plainly appeared to have been broken off from the rock to which it was fixed) the blood was actually oozing from the vertebræ. This specimen I endeavoured to preserve, but it was totally destroyed by the ants, who ate every cartilage, so that it fell to pieces." Miller observes upon this, that the 'blood' was the fluid in the alimentary canal, and refusing to admit the assertion of Walch, that the Pentacrinite is an animal crawling along the bottom of the sea, conceives it to have generally stood more or less erect in the sea, yielding to the fury of the storm in bending down, and adhering for additional security with its side-arms to extraneous matter, or closing them to the column, and thus offering the least surface possible to the element. The latter, he thinks, is the most probable idea, since he had frequently met with specimens in that state, but had never seen any side-arms clasping round extraneous matter. The author elsewhere states that he has in vain endeavoured to trace apertures at the terminating points of the fingers and tentacula, although Guettard alleges that here orifices existed serving as mouths to the animal in taking its food.



Pentacrinus Caput-Medusæ.

In the front of the figure two of the arms are much smaller than the others, showing that the animal had suffered mutilation, and had employed its power of reproducing the lost parts. *a*, The auxiliary side-arms, articulating at distant intervals with the vertebral column, capable also of being reproduced. (Miller and Buckland.)

Miller observes that columnar fragments, smaller and rather neater than those of this species, occur in the Oolite at Dundry, the Forest Marble at Chippenham, and the Chalk near Lyme, but that it remains to be ascertained, by the acquisition of perfect specimens, whether these belong to a variety of *P. Caput-Medusæ*, or possess peculiar characters sufficient to distinguish them as a new species.

The only living British species of animal representing this family is the *Comatula rosacea*. [COMATULA.] The young of this animal was formerly called *Pentacrinus Europæus*.

** *Fossil Species.*

P. Briareus, the Briarean Pentacriuite, may be taken as an example. It is thus characterised by Miller:—"A crinoidal animal, having a large column formed of numerous pentagonal joints, alternately larger and smaller, articulating by surfaces with pentapetalous compressed semistriated markings; five auxiliary arms, formed of much compressed suboval joints, proceeding at intervals from the column; five joints of the pelvis, supporting first five and second five costal joints, on which the scapulæ affix, from which ten arms proceed, each having two hands, formed of numerous fingers, sometimes amounting to sixteen."

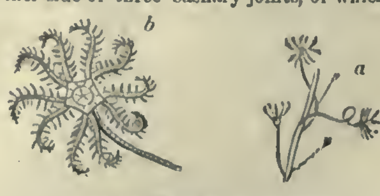
Dr. Buckland observes that the root of the Briarean Pentacrinite was probably slight, and capable of being withdrawn from its attachment. The absence of any large solid secretions like those of the Pear-Encrinite, by which this Pentacrinite could have been fixed permanently at the bottom, and the further fact of its being frequently found in contact with masses of drifted wood converted into jet, leads him to infer that the Briarean Pentacrinite was a locomotive animal, having the power of attaching itself temporarily either to extraneous floating bodies or to rocks at the bottom of the sea, either by its side-arms or by a moveable articulated small root. We confess that we cannot entirely concur with the Professor on this point. That in early youth the animal may have floated till it found a substance fit for it to adhere to, we do not deny; but we think that after it was once established and had attained a good size, it was fixed for ever. The great length of the stem and the numerous side-arms must have secured for it a field of action beyond that of the Pear-Encrinite and the Lily-Encrinite, both of which we know had permanent roots; and if we are to judge by analogy, there is pregnant evidence that the specimens of the living species, more especially the larger one mentioned by Mr. Tobin, who saw it quite fresh out of the sea, and to whose expressions above given we refer the reader, suffered their stems to be torn asunder without quitting their moorings.

It is found in the lower strata of the Oolite Formation, especially the Lias: Lyme, Watchet, Keynsham, &c.

Mr. Miller gives three other fossil species, namely *P. subangularis*, *P. basaltiformis*, and *P. tuberculatus*. Goldfuss has recorded the following additional species, namely *P. scalaris* (Goldfuss), *P. cingulatus* (Münster), *P. pentagonalis* (Goldfuss), *P. moniliformis* (Münster), *P. subsulcatus* (Münster), *P. subteres* (Münster), *P. dubius* (Goldfuss), and *P. priscus* (Goldfuss), and, with a note of interrogation, *Pentacrinus* (?) *paradoxus*.

a, *Pentacrinus Briareus* reduced (Lyme); *b*, rare and beautiful specimen of Briarean Pentacrinite (natural size), from the Lias at Lyme Regis, in the collection of Mr. Johnson, of Bristol, showing the plated integument of the abdominal cavity, terminated upwards by a flexible proboscis, and surrounded by the commencement of the arms and fingers. (Figures and description from Dr. Buckland's 'Bridgewater Treatise.')

Phytocrinus, De Blainville (*Hibernula*, Fleming; *Pentacrinus*, Thompson).—Body regular, circular, covered and surrounded above by a sort of solid cupule, composed of a centro-dorsal undivided piece, round which are articulated, first, a single row of accessory unguiculated rays, then another row of great didymous and pinnated rays on the other side of three basilary joints, of which the first only



Pentacrinus Europæus of Thompson.

a, several individuals in different stages of development adhering by the base of an articulated column to the stem of a coralline; *b*, one of the individuals expanded and magnified.

partially touch each other. Stem articulated, round, and without accessory rays. Mouth central in the midst of five scales, which are foliaceous and bordered by a row of tentacular cirrhi; a large tubular orifice a little behind the mouth.

P. Europæus, *Pentacrinus Europæus*, Thompson. It is now generally admitted that the observations of Mr. J. V. Thompson have proved that this animal is but the young of *Comatula*. If no other species of *Phytocrinus* be found, this genus must be cancelled.

Poteriocrinites.—A crinoidal animal, with a round column, composed of numerous thin joints, having in their centre a round alimentary canal, and articulating by surfaces striated in radii. Round auxiliary side-arms proceeding at irregular distances from the column. Pelvis formed of five pentagonal plate-like joints, supporting five hexagonal intercostal plate-like joints, and five plate-like scapulæ, having on one of the intercostals an interscapulary plate interposed. An arm proceeding from each of the scapulæ. Base probably fascicular, and permanently adhering. (Miller.)

The author of this generic character says, "It is with considerable hesitation that I describe these five plates as belonging to the pelvis; the analogy of their lower articulating surfaces seems perhaps rather to indicate their belonging to the first costal series. I have never yet had an opportunity of seeing the connection of these plates with the first column or joint fairly developed, and it seems possible that the true pelvis may be small and almost concealed. This doubt will be done away by the acquisition of more instructive specimens, and my thus stating the case must be considered as resulting from an anxious desire to check errors. It is not unlikely that the real joints forming the pelvis are so much abbreviated as not to be visible externally. Every one acquainted with fossils must be aware how difficult it is to trace always organic details in them correctly, and how many specimens are sometimes necessary to ascertain a single fact."

De Blainville observes that this genus does not appear to differ from *Apiocrinites*, excepting inasmuch as that the stem is not enlarged at its superior part, and that the basilary pieces of the rays are less approximated, and without doubt less immoveable. The details given by Mr. Miller point out a form differing strongly from that of *Apiocrinites*, and if his data be admitted there can be little doubt of the generic difference which he records.

P. tenuis, Thin, Vase-like, Lily-shaped Animal. A crinoidal animal, with a column formed of numerous round thin joints, surface of articulation radiating and striated. The plate-like joints forming the cup-like body, articulating by minute striæ. One arm proceeding from each scapula, supporting two fingers. It is found in the Mountain Limestone of the Mendip Hills and in the Black Rock, the 14th bed of Dr. Bright's series ('Geol. Trans.,' vol. iv. p. 193), near the river Avon, Bristol, belonging to the same formation. (Miller.)

The other species recorded by Miller is *Poteriocrinites crassus*, from the Mountain Limestone in Yorkshire, and the Mountain Limestone at Bristol, near the river Avon, bed 1 and 14 of Dr. Bright's paper in 'Trans. of Geol. Soc.,' vol. iv. p. 193, and in the Magnesian beds of the Mountain Limestone, Clevedon Bay, Somersetshire. Miller further states that the specimen mentioned in Dr. Woodward's 'Catalogue of Foreign Fossils' (page 19, 8. 1.) as coming from Syria, is of this species, and that he (Miller) is indebted to the Rev. A. Sedgwick, Woodwardian Professor, Cambridge, for ascertaining this fact, he having kindly furnished Mr. Miller with a drawing made from the original, now in Dr. Woodward's collection, and under his care.

Platycrinites.—A crinoidal animal, with an elliptic or (in one species) pentagonal column, formed of numerous joints, having a few side-arms at irregular distances. Pelvis saucer-shaped, formed of three unequal pieces, from which five large plate-like scapulæ proceed. Base provided with numerous fibres for attachment. Miller, who thus characterises the genus, observes that the want of costæ supplied by the large plate-like scapulæ gives the superior part of these animals a pentagonal appearance, and furnishes so conspicuous a character that they are readily distinguished from all other genera.

P. lævis, Smooth, Broad-Plated, Lily-shaped Animal. A crinoidal animal, with a column formed of very muscular elliptical joints adhering by a transverse ridge. Round side-arms occasionally proceeding from the column, whose joints adhere by radiated surfaces. Pelvis saucer-shaped, with the five scapulæ adhering to it, from each of which an arm proceeds supporting two hands, having each two fingers. Pelvis and scapulæ smooth. Locality in the Mountain Limestone of the Mendip Hills, the Black Rock (14th bed of Dr. Bright's series in 'Geol. Trans.,' vol. iv.) near Bristol; Dublin; Cork. (Miller.)

Miller remarks that he has noticed in the collection of Richard Bright, Esq., of Ham Green, near Bristol, numerous joints, probably appertaining to an animal forming a variety, or a distinct species. They came, he states, from Mnirkirk, in Dumfriesshire; and he adds that the scapulæ are shorter in proportion than those of the former species, and that the columnar joints are finely tuberculated.

The same author records the following species:—*P. rugosus*, from the Mountain Limestone at Caldy Island, on the south coast of Wales, and at the Mendip Hills; *P. tuberculatus*, from the Mountain Limestone strata; *P. granulatus*, from the Mountain Limestone of the Mendip Hills; *P. striatus*, from the Black Rock (14th bed of Dr. Bright's series); and *P. pentangularis*, from the Mountain Limestone of the Mendip Hills, at Weston-super-Mare, Black Rock near Bristol, and at Mitchel-Dean; also occasionally in Transition Limestone of Dinevawr Park, and Dudley.

Goldfuss names and describes two additional species, namely, *P. depressus* and *P. ventricosus*.

Cyathocrinites.—A crinoidal animal, with a round or pentagonal column, formed of numerous joints, having side-arms proceeding irregularly from it. On the summit adheres a saucer-shaped pelvis of five pieces, on which are placed in successive series five costal plates, five scapulæ, and an intervening plate. From each scapula proceeds one arm, having two hands. Locality, Transition and Mountain-Limestone strata. (Miller.)

C. planus.—A crinoidal animal, with a round column formed of numerous depressed joints, articulating by radiating surfaces, and perforated by an alimentary canal, pentagonal near the pelvis, which becomes round further from it. From each of the scapulæ, which rest on the summit of the cup formed by the pelvis and costæ, proceeds an arm supporting two hands, each being provided with two series of fingers. It is found at Clevedon, in the Magnesian beds of the Mountain Limestone; at Wood-Spring, Black Rock (14th bed of Dr. Bright's series), near Bristol. (Miller.)

Miller observes that a specimen had occurred to him where the columnar joints were alternately smaller and larger, but that he was not aware whether it possessed sufficient character to be considered a variety of the former species. The same author records three other species, and Goldfuss has added three more, namely, *C. pinnatus*, *C. geometricus*, and *C. pentagonus*.

Actinocrinites.—A crinoidal animal, with a round column composed of numerous joints, and perforated by a round alimentary canal. At the summit of the column is placed a pelvis formed of three plates, on which five first costals and one irregular costal adhere, which are succeeded by the second costals and intercostals and the scapulæ, from whence five arms proceed, forming two hands with several tentaculated fingers. Round side-arms proceed at irregular distances from the column, which terminates at the base in a fascicular bundle or root of fibres.

A. triacontadactylus, Thirty-Fingered, Radiated, Lily-shaped Animal (Miller); Rock-Plant (Beaumont); Nave Encrinite (Parkinson). A crinoidal animal with a round column formed of many joints, on whose summit is placed a pelvis of three plates supporting five hexagonal and one pentagonal costal plate, on which the second costals, intercostals, and scapulæ in series adhere, the latter sending off five arms, having each two hands provided with three fingers. Column sending off at irregular distances auxiliary side-arms, and terminating at the base in a bundle of fibrous elongations resembling roots. It is found in Mountain Limestone at the villages of Broughton and Stokes in Craven, Yorkshire (Lister, 1674), Mountain Lime formation of the Mendip Hills (Beaumont), and the Black Rock near Bristol. (Miller.) (See Figure in col. 531.)

Miller describes another species, *A. polydactylus*, from the Mountain Limestone of the Mendip Hills and Caldy Island. De Blainville observes that among the five (seven) new species which Goldfuss refers to this genus—namely, *A. granulatus*, *A. tesseracontadactylus*, *A. cingulatus*, *A. muricatus*, *A. nodulosus*, *A. moniliferus*, and *A. tesseratus*—*A. tesseracontadactylus* appears to De Blainville to offer a new combination of the pieces of the test, and even perhaps of the ten rays of the root, each division being dichotomous.

Melocrinites (Goldfuss).—Column smooth, perforated by a smooth or quinquelobate canal. Auxiliary arms . . . Pelvis composed of four articulations or pieces. Primary and secondary costals five hexagonal, alternately placed (sibi invicem impositi). Intercostals five, hexagonal. Scapulæ five, hexagonal, placed upon the costals. Interscapulars four, in the region of the mouth five. Arms five. Mouth at the side of the vertex.

M. hieroglyphicus, Goldfuss. *Melocrinites* with the articulations or pieces of the cup or calyx nodulous. Locality, Mountain Lime. Goldfuss records a second species, namely *M. lævis*.

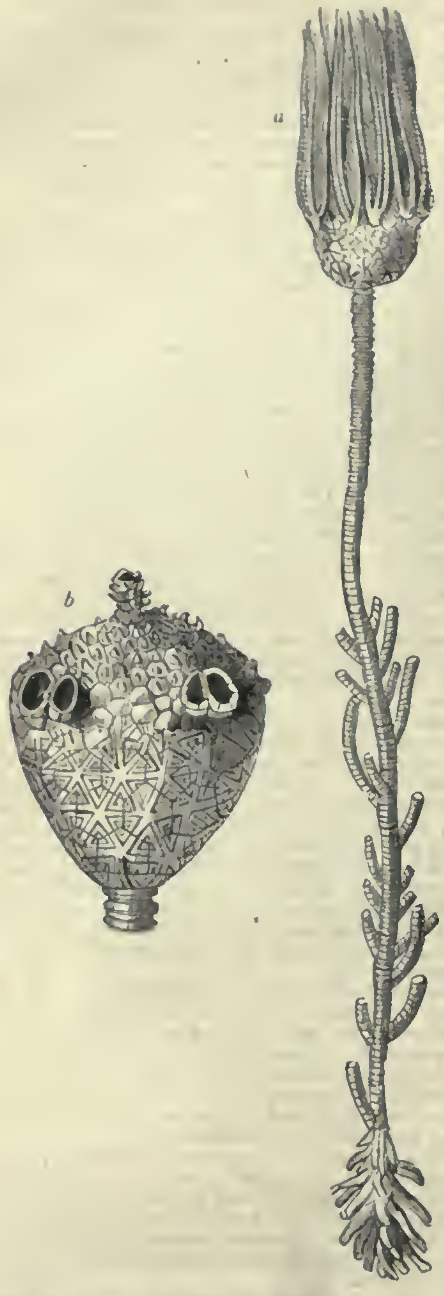
Rhodocrinites (Miller).—A crinoidal animal, with a round and sometimes slightly pentagonal column, formed of numerous joints perforated by a pentapetalous alimentary canal. The pelvis formed of three pieces supporting five square plates, in the spaces of whose lateral bevelled angles five heptagonal first costals are inserted. From the scapulæ proceeds an arm supporting two hands. (Miller.)

R. verus, True Rose-like Lily-shaped Animal. Locality, upper bed, No. 1, and one of the lower beds, No. 15, of Dr. Bright's series, distinguishing the Mountain Limestone formation along the river Avon, near Bristol, the Mendip Hills, Mitchel-Dean, the Transition Limestone at Dudley. (Miller.)

Goldfuss adds four species, namely, *R. gyratus*, *R. quinquepartitus*, *R. canaliculatus*, and *R. echinatus*, the last being *Encrinus echinatus* of Schlotheim.

Eugeniacrinites (Miller).—Superior columnar joint subpentangular, enlarging above, having the five plates of the pelvis adhering to it by a solid anchylosis. Base, column, joints resting on the pelvis, and fingers, unknown. (Miller.)

E. quinquangularis (Miller); Clove Encrinite of Parkinson; *Caryophyllus lapideus*, Caryophyllite of Knorr. Found in Switzerland, at Mount Randen (Knorr); also in the canton Zurich and Schaffhausen. (Miller.) Goldfuss records the following additional species, namely



a, *Actinocrinites triacontadactylus* (reduced); *b*, body of the same (natural size). (Miller and Buckland.)

E. caryophyllatus, *E. nutans*, *E. compressus*, *E. pyriformis*. *E. moniliformis*, and *E. Hoferi*. (Münster.)

Solanocrinites (Goldfuss).—Column very short, pentagonal, perforated by a pentagonal canal, radiato-rugose at the base, depressed or hollowed out at the sides by the glenoid cavities of the auxiliary arms, articulated with the pelvis by slightly prominent rays which are trochitic and coadnnate. Pelvis with five articulations. Scapulæ, arms (?). Auxiliary arms of the column thick and close-set. (Goldfuss.)

S. costatus (Goldfuss), with a turbinated column, 10 or 15-ribbed longitudinally; articulations of the pelvis linear. Silicified. It is found at Würtemberg in Jurassic Limestone. (Goldfuss).

M. Goldfuss describes two other species, *S. scorbiculatus* (Münster), and *S. Jaegeri* (calcareous) (Goldfuss), from the Jurassic Limestone. Baireuth.

Caryocrinites (Say).—Pelvis of four plates. Costal plates six. Column not dilated. Alimentary canal round. Articulating surface of the columnar joints radiated. Auxiliary side-arms cylindrical and placed irregularly.

C. ornatus. Costals, four pentagonal and two hexagonal. Column inserted into a cavity at the base of the pelvis. Pelvis rather large; two of the plates quadrangular, attenuated to the base, where they are truncated and a little recurved at the junction with the column; discs, particularly towards the base, granulated, with a distinct elevated interrupted line; two remaining plates pentangular, attenuated to the base where they are truncated and a little recurved at the junction with the column; disc with elevated granules, and with two elevated interrupted lines extending to the terminal angles. Costals, four pentagonal and two hexagonal, all with elevated interrupted lines, radiating from the centre to the angles, with a series of truncated granules on each side and a few granules in the intervening spaces; interscapulars, two hexagonal, situated immediately above the hexagonal costals; scapulars six pentagonal, the upper sides of which are more or less irregular by projecting a little between the scapulæ, all with prominent lines granulated, similar to those of the preceding. Arms six. Capital plates with a heptagonal one in the middle, surrounded by five heptagonal plates and two irregular ones at the mouth. Mouth not prominent, situated on one side of the middle, a little within the line of the arms, closed by small valvular pieces, its inferior side resting on the superior angle of one of the scapulars. Longitudinal diameter from three-quarters to one inch and a half; transverse diameter from seven-tenths to one inch and two-fifths. Mr. Say, who gives this description, records and describes another species with one of the costals hexagonal, namely *C. loricatus*. It was found by Dr. Bigsby loose in brown clay at the foot of the ravine at Lockport, in which the New York Canal mounts the parallel ridge of Lake Ontario.

Marsupites, Mantell (*Marsupiocrinites*, De Blainville).—Body regular, oval, bursiform, rounded at the dorsal extremity, truncated and flattened at the other, enveloped in a sort of shell or test composed of great polygonal plates, articulated to each other, one centrodorsal, and three rows superposed, of which the terminal one supports ten simple rays. Mouth in the midst of four squamiform pieces. Stem none. This is De Blainville's character. The following is Miller's:—"An unattached animal with a subglobose body containing the viscera protected by calcareous plates, of which that in the centre at the base is angular, having a series of costal plates resting on it, admitting intercostals at their superior angles, these giving insertion to the scapulæ from which the arms proceed. Space between the scapulæ covered by an integument, protected by numerous small plates.

M. ornatus, Ornamented Purse-like Animal (Miller), Tortoise Encrinite (Parkinson). A purse-like animal, having the central plate at the base of its subglobose body containing the viscera; pentagonal, supporting at its edge five similar costals, which admit at their superior angles five hexagonal intercostals, into the angles of which five scapulæ are inserted sending off the arms. All the plates ornamented by ridges proceeding from the centre, and forming angular markings near the corners. It is found at Offham Chalk-Pits near Lewes; Clayton Chalk-Pits, Hurstperpoint, Sussex; Preston Chalk-Pits, near Brighton (Mantell); Chalk-Pits of Kent, and Chalk-Pits, near Warminster. (Miller.)

Mr. Miller does not admit *Marsupites* among the *Crinoidea*, but considers it as the immediate link between that family and *Euryale*.

Pentremites (Say).—Column cylindrical, perforated; segments articulating by radiated surfaces, with cylindrical side-arms at irregular intervals; pelvis of three unequal pieces, two pentagonal and one tetragonal; scapulæ large, very profoundly emarginate for the reception of the lips of the radiating ambulacra, obliquely truncated at the extremities on each side for the reception of one side of a subrhomboidal plate or interscapular; ambulacra five, radiating from the summit, and terminating at the tips of the emarginations of the scapulæ: each with a longitudinal indented line, and numerous transverse striæ which terminate in a marginal series of pores, for the transmission of respiratory tubes; summit with five rounded openings (ovaries) and an angulated central one (mouth and anus). (Say.)

"This singular genus," observes M. Say, "is so remotely allied to any hitherto discovered, that I do not think it can, with propriety, be referred to any family yet instituted. By its columnar support it is related to the family *Crinoidea*; but the total absence of arms and hands excludes it from that very natural group. The superior termination, in which the ambulacra, the rounded openings, and the central angulated one, are situated, has some affinity to the family *Echinidea* [ECHINIDÆ], but the columnar support shows that it cannot be arranged there. Having thus on its inferior portion a resemblance to the *Crinoidea*, and on its superior surface a decided analogy to the *Echinidea*, I think it may with propriety form an intermediate family under the following name and characters: Family, *Blastoidea*. Column composed of numerous articulating segments, supporting at its summit a number of plates, so united as to form a calyciform body containing the viscera; arms none; branchiæ arranged in ambulacra. In a natural series their bodies constitute the link between the *Crinoidea* and the *Echinidea*, on the one hand; whilst, on the other, the former is unquestionably, but not more obviously, connected with the *Stelleridea* by the unequivocal intervention of *Comatula* and *Marsupites*. Of all the genera of *Crinoidea*, it is to *Platycrinites* that Pentremite seems most closely related."

M. Say describes three species, namely *P. globosa*, brought from England, and said to have been found in the vicinity of Bath; and *P. pyriformis* and *P. florealis*, from Kentucky. He gives, as the synonyms of the latter, Kentucky Asterial Fossil (Parkinson), and *Encrinites florealis* (Schlotheim), as quoted by Miller, and thus proceeds: "This is extremely abundant in many parts of Kentucky, and on the margins of the Mississippi in a few places. Near Huntsville they are very numerous; and on the surface of a fragment of rock, three inches long by two and a quarter inches wide, sent to the Academy by Mr. Hazard of that place, I have enumerated eighteen specimens of this species more or less entire, and two specimens of the preceding (*P. pyriformis*). On another still smaller piece of rock are twenty-one specimens, all in alto relievo, two of which are of the preceding species. On a third fragment of. rock thirty may be counted, and on a fourth upwards of fifty. That these animals were pedunculated and fixed, there cannot be any doubt. We see at the base of the pelvis a small rounded surface, perforated in the centre for the passage of the alimentary canal, and on the outer margin are very short but distinct radii of elevated lines, evidently intended for articulation with the first joint of the column. The column itself is always found in fragments accompanying the body of the animal, but never attached to it. I think it highly probable that the branchial apparatus commuuicated with the surrounding fluid through the pores of the ambulacra by means of filamentous processes: these may also have performed the office of tentacula in conveying the food to the mouth, which was perhaps provided with an exsertile proboscis; or may we not rather suppose that the animal fed on the minute beings that abounded in the sea-water, and that it obtained them in the manner of *Ascidia*, by taking them in with the water? The residuum of digestion appears to have been rejected through the mouth."

Mr. G. B. Sowerby observes, that all the specimens received in this country from Kentucky were changed iuto a sort of chalcedony or chert, a circumstance which has perhaps not only prevented British naturalists from forming a correct judgment of their natural affiuities as a family, but appears also to have had the effect of preventing them from recognising the generic resemblance to the species that occur here, which, bearing so much greater a similarity to some of the *Echinidæ*, has caused some of our naturalists to class them together: for it is observable, he remarks, that of perhaps twenty specimens of the Kentucky Asterial Fossil that he had examined only one individual showed the sutures that separate what Say calls the "pelvic scapular and interscapular plates or pieces." The examination of the new species however suggested to Mr. Sowerby the probability that part of the three unequal pieces which Say calls the pelvis, may in fact prove to be costals, thus evideucing one more relation to the *Crinoidea*. Mr. Sowerby records and describes two species, premising that the circumstance of Say's first species, *P. globosa*, having beeu brought from England, led Mr. Sowerby at first to suppose that Say might refer to one of those species that had come into Mr. Sowerby's hands. Say's description, however, in Mr. Sowerby's opinion is so incomplete, and the terms he has used are so vague, that Mr. Sowerby had not been able to ascertain the fact, but thinks, nevertheless, that 'Pelvis deep, saucer-shaped, convex,' may serve to distinguish it from both. Mr. Sowerby's two species are *Pentremites Derbiensis* from Derbyshire (limestone) and *P. elliptica* from near Preston in Lancashire.

In a paper ('Zool. Journ.,' vol. iv.) Mr. Sowerby changes the name to *Pentatrematites*, and records three more species, namely *P. angulata*, *P. inflata*, and *P. oblonga;* all from the calamine mines belonging to the Duke of Buccleuch, on the Lancashire side of the Hodder; and in the last volume of the 'Zoological Journal,' he describes three in addition, namely *P. orbicularis*, *P. acuta*, and *P. pentangularis;* the last he considers to be the *Platycrinites pentangularis* of Miller, the arms being imaginary in his figure. Goldfuss describes a species from the transition limestone near Dusseldorf.

De Blainville places this genus at the end of the Crinoideans. It appears to be the connecting link between the *Crinoidea* and the *Echinidæ*, but to have a much stronger relationship to the former than to the latter. *Marsupites* may be regarded as a connection between the true Crinoideans and the *Comatulæ*.

The following is a summary of the distribution of this group of animals, by Professor E. Forbes:—

"This important tribe had its greatest development during the palæozoic and secondary epochs, diminishing materially towards the close of the latter, and becoming scant and scarce during the tertiary and historical epochs. They commence their existence with the earliest sedimentary deposits, and arrive at their maximum of development before the close of the palæozoic periods. In the Lower Silurian they are fragmentary, but common; in the upper beds of that formation many fine species occur ofteu well-preserved in limestone. *Actinocrinus*, *Cyathocrinus*, *Dimerocrinus*, *Rhodocrinus*, *Eugenocrinus*, *Taxocrinus*, *Trochocrinus*, and *Hypanthocrinus* are British Silurian genera. During the Devonian epoch we find the genera *Cyathocrinus* and *Platycrinus*, *Taxocrinus*, and *Adelocrinus*. The limestones of the carboniferous period abound in *Crinoideæ*. Numerous species of *Actinocrinus*, *Platycrinus*, *Cyathocrinus*, *Poteriocrinus* occur, with others of the genera *Rhodocrinus*, *Symbathocrinus*, *Gilbertsocrinus*, *Taxocrinus*, &c. The commencement of the secondary period is marked by abundance of *Pentacrini*, indicative of a new series of crinoidal forms. At Lyme Regis, where they have been found in great uumbers, they occur associated with fossil wood in such a manner, that there can be little doubt that they lived attached to floating masses of wood, probably in shallows. Higher up among the oolitic strata, we find the curious *Apiocrinus* (the Pear-Encrinite) which appears to have lived attached to ancient banks of coral. During the cretaceous epoch the free Crinoids begin to appear, and *Comatulæ* seem to have been not uncommon. Tho genus *Marsupites* is a remarkable form of this group, and disappears before the commencement of the tertiaries. The last of the fossil *Pentacrinites* appear in eocene strata, but as the genus still lives it is probable that intermediate species will he found. *Comatulæ* existed during all the tertiary epochs. In Britain however no trace of it has been found in pleistocene strata. The supposed genera of *Echinidæ*, *Ganymeda* of Gray, and *Glenotremites* of Goldfuss, are only the cups of *Comatulæ*.

"It may be noted generally respecting Fossil Crinoids—1st., That all the genera of the family *Actinocrinidæ* (including such as have cups composed of thin and slightly articulated pieces and having much divided arms), as *Rhodocrinus*, *Actinocrinus*, *Gilbertsocrinus*, *Melocrinus*, *Scyphocrinus*, *Cyathocrinus*, *Platycrinus*, *Dimerocrinus*, *Hypanthocrinus*, &c., are confined to palæozoic strata. 2nd. That all the genera of the family *Poteriocrinidæ* (composed of such as have their cups made up of large and strong segments, but in general aspect closely resembling the members of the first tribe), as *Poteriocrinus*, *Isocrinus*, and *Symbathocrinus*, are palæozoic. 3rd. That the genera of the family *Pentacrinidæ* (characterised by the strongly articulated segments of their cups and head of the column, and by the side-arms of the latter) range from the triassic epoch to our own times, having their maximum during the oolitic epoch. 4th. That the genera of the family *Apiocrinidæ* (characterised by the pear-shaped and articulated summits of the stem and cup, and the naked column), as *Apiocrinus*, *Guettardocrinus*, *Millericrinus*, *Encrinus*, and *Eugenocrinus*, are secondary, and for the most part oolitic. *Encrinus* is a genus not found in British strata, and characteristic of the trias (Muschel-Kalk). It is the well-known Stonc-Lily or Lily-Encrinite of collectious. The genus *Bonigeraticrinus* of D'Orbigny, of which two species are however from the chalk, is an exception to the above rule, if the remains of a Crinoid, found preserved in the recent blauk of the Autilles, be rightly referred to it. 5th. The Free Crinoids, *Comatulidæ*, appear to have ranged from tho oolitic period to the present time; for in the lithographic slates of Bavaria we find several remains of animals closely allied to *Comatulæ*. This family appears to have attained its greatest development during our own epoch, and as certain living species are known to pass through stages exactly comparable to the adult state of the Stalked Crinoid, we must regard the *Comatulidæ* as the most advanced of crinoidal forms."

(Johnston, *Physical Atlas.*)

ENDECA'NDRIA, the ninth class of the Linnæan system of Botauy, distinguished by having nine stamens separate from each other.

ENDIVE. [CICHORIUM.]

ENDOCARP. [FRUIT.]

ENDOGENITES, the name for certain Fossil Plant-Stems, as *E. erosa*, from the Tilgate Beds. (Mantell.)

E'NDOGENS. One of the large primary classes into which the Vegetable Kingdom is divided bears this name, in cousequence of its new woody matter being constantly developed in the first instance towards the interior of the trunk, only curving outwards iu its subsequent course dowuwards. That palm-trees grow iu this way was known so long siuce as tbe time of Theophrastus, who distinctly speaks of the differeuces between endogenous and exogenous wood.

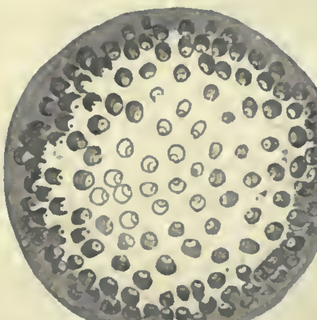
But that this peculiarity is also extended to a considerable part of the vegetable kingdom is a modern fact, the discovery of which we owe to the French naturalists Daubenton and Desfontaines. The path being thus opened, the inquiry has subsequeutly, aud more particularly of late years, been much extended, especially by Professor Mohl, in an elaborate essay upon the anatomy of palms.

Mohl is of opinion that the first year's wood of au Exogen is analogous in arrangement to that of an Endogen, the woody bundles of each leaf curving upwards and outwards to the base of the leaf, and dowuwards and outwards towards the bark, crossing through those which have been previously developed.

The phenomena of growth in a palm-tree may be takeu as typical of the endogenous structure. In the beginning the embryo of a palm consists of a cellular basis, in which a certain number of cords of ligneous fibre are arranged circularly (*fig.* 1), down the radicle, deriving their origin from the plumule. Immediately subsequent to germination, and as soon as the rudimentary leaves of the plumule begin to lengthen, spiral and dotted vessels appear in their tissue in connection with the ligneous cords; the latter increase in quantity as the plant advances in growth, shooting downwards through the cellular tissue, and keeping parallel with the outside of the root. At the same time the cellular tissue increases in diameter to make room for the descending ligneous cords (or woody bundles, as they are also called). At last a young leaf is developed with a considerable number of such cords proceeding from its base downwards, and, as its base passes all round the plumule, consequently passing downwards alike on all sides of the centre that it surrounds. Within this a second leaf gradually unfolds, the cellular tissuo increasing horizontally at the same time; the ligneous cords, however, soon cease to maintain anything like a parallel direction, but curve outwards as they pass downwards, losing their extremities in the roots, or in the cellular integument on the outside of the first circle of cords (*fig.* 1); at the same time the second leaf pushes the first leaf a little from the centre towards the circumference of the plane or cone of growth; the consequence of which is that the ligneous cords next the base of the first leaf are drawn a little outwards, and form descending axes which henceforwards are found at first to curve inwards towards the centre of the young stem, and afterwards outwards towards its circumference. In this manner leaf after leaf is developed, the horizontal cellular system enlarging all the time, and every successive leaf, as it forms at the growing point, emitting more woody bundles curving downwards and outwards, and consequently intersecting the older arcs at some place or other; the result of this is that the first formed leaf will have the upper end of the arcs which belong to it longest, and much stretched outwardly, while the youngest will have the arcs the straightest; and the appearance produced in the stem will be that of a confused entanglement of woody bundles in the midst of a quantity of cellular tissue. As the stem extends its cellular tissue longitudinally while this is going on, the woody arcs are consequently in proportion long, and in fact usually appear to the eye as if almost parallel, excepting here and there, where two arcs abruptly intersect each other. As in all cases the greater number of arcs curve outwards as they descend, and eventually break up their ends into a multitude of fine divisions next the circumference, where they form a cortical integument, it will follow that the greater part of the woody matter of the stem will be collected near the circumference, while the centre is kept comparatively open, and will consist chiefly of cellular tissue; and when, as in many palms, the stem has a limited circumference, beyond which it is its specific nature not to distend, the density of the circumference must, it is obvious, be proportionably augmented. It is, however, a mistake to suppose that the great hardness of the circumference of old palm-wood is owing merely to the presence of augmenting matter upon a fixed circumference; this will account but little for the phenomena. We find that the woody bundles next the circumference are larger and harder than they originally were, and consequently we must suppose that they have the power of increasing their own diameter subsequent to their first formation, and that they also act as reservoirs of secretions of a hard and solid nature, after the manner of the heartwood of Exogens.

When the growth of the stem of an Endogen goes on in this regular manner, with no power of extending horizontally beyond a specifically limited diameter, a stem is formed, the transverse section of which presents the appearance shown in the following cut.

Fig. 1.



There are a number of curved spots crowded together in a confused way, most thick and numerous at the circumference, comparatively small and thinly placed at the centre; and the only regular structure that is observable with the naked eye is that the curves always present their convexity to the circumference.

When there is no limited circumference assigned by nature to an Endogen, then the curved spots, which are sections of the woody arcs, are much more equally arranged, and are less crowded at the circumference. Never is there any distinct column of pith, or medullary rays, or concentric arrangement of the woody arcs; nor does the cortical integument of the surface of endogenous stems assume the character of bark, separating from the wood below it; on the contrary, as the cortical integument consists very much of the finely divided extremities of the woody arcs, they necessarily hold it fast to the wood of which they are themselves prolongations, and the cortical integument can only be stripped off by tearing it away from the whole surface of the wood, from which it does not separate without leaving myriads of little broken threads behind.

This account of the structure of the Endogenous Stem is identical with that given by Dr. Lindley in his 'Vegetable Kingdom.' Schleiden's view of the structure of the stem, as given by Dr. Lindley, is somewhat different. The following passage expounds this view:—

"In all plants, the woody bundles, whose development always proceeds from the interior to the exterior, are either limited or unlimited in their growth. Commonly every woody bundle consists of three different physiological parts; firstly, of a tissue of extreme delicacy, capable of rapid development, in which new cells are continually generated, and deposited in various ways, in two different directions, namely, next the circumference in the shape of a peculiar kind of lengthened cellular tissue with very thick walls, the liber, and next the centre in the form of annular, spiral, reticulate, and porous vessels; secondly of woody cells, which are either uniform in appearance or different, and form wood, properly so called. Up to a certain period the development of the vascular system in Monocotyledons and Dicotyledons proceeds on the same plan; but in Monocotyledons (Endogens) the active, thin, solid, delicate, cellular tissue suddenly changes; the partitions of its cells become thicker, their generating power ceases, and when all the surrounding cells are fully developed, they assume a peculiar form, ceasing to convey gum, mucilage, and other kinds of thick formative sap." From this cause all further development of vascular bundles is rendered impossible, and therefore Schleiden calls the woody bundles of such plants 'limited.' In Dicotyledons (Exogens), on the contrary, this tissue retains during the whole lifetime of the plant its vital power of formation, continues to develop new cells, and so increases the mass, ceaselessly augmenting both the exterior (liber) and the interior faces (wood), for which reason Schleiden calls such woody bundles 'unlimited.' "This," he continues, "happens according to the climate and nature of the plant either pretty continuously, as in *Cactaceæ*, or by abrupt periodical advances and cessations, as occurs in forest-trees of Europe. In the latter, the stem forms an uninterrupted tissue from the pith to the bark during every period of life, and the bark is never organically separated from the stem; what is considered their natural separation in the spring is only a rent, produced by tearing the delicate tissue already spoken of, which is present even during winter, and constitutes the foundation of new annual zones, although compressed, and filled with gum, starch, and other secretions. In the spring, being expanded and swollen by the new amount of sap, it is deprived of its contents by their solution." (Lindley, 'Vegetable Kingdom.')

Schleiden's account of the structure of the Eudogenous or Monocotyledonous stem, as given in his 'Principles of Scientific Botany,' is as follows:—

"The most simple plants of this division have no vascular bundles, as for instance *Wolffia*. Those nearest allied amongst the *Lemnaceæ* first exhibit definite indications of these; in *Spirodela* we even find them combined with spiral vessels, but distributed in a plane surface as the necessary accompaniment of a flat stalk. Many of the *Naiadeæ*, as for instance *Naias*, *Zanichellia*, *Ruppia*, have only a central vascular bundle. In the remainder we meet with the following modifications:—

"1. Developed Internodes.—The stalks and stems have always several rings of vascular bundles, which occasionally inclose a pith, where a circle of vascular bundles are connected by a ring of thickened parenchyma. This is often the most external (usually), often a more internal one, as in *Pothos*. A portion of the vascular bundle passes through the nodes into the leaf, whilst a part rises into the next internode. Small twigs branch off from all the vascular bundles that pass through the nodes, forming a confused plexus in the node, which, for the most part, merges into the axillary bud. The innermost vascular bundles in the nodes supply the lowest leaves, the external bundles the upper ones, as in Grasses, the Cane-stemmed Palms, and the *Commelinaceæ*. There are many groups that have not yet been examined. The whole of the vascular bundles in the same internode are simultaneously formed and developed, and the internode itself, when perennial, does not continue to increase in thickness, whether the plant becomes branched or not. The primary axes, like the secondary, only grow upwards; in fact they are devoid of a cambium-layer.

"2. Undeveloped Internodes.—The stalks (in *Pistia obovata* for instance), and the stems of Palms, herbaceous *Liliaceæ*, bulbs of *Allium*, *Lilium*, &c., have a conical terminal bud, sometimes shorter, in accordance with which the vascular bundles run from below and the exterior, upwards and towards the interior, and then from thence upwards and externally, to pass into a leaf. The arc, which is convex towards the interior, is longer or shorter according to the terminal bud; and the vascular bundle likewise passes through a longer or shorter portion of the whole axis, according to the same conditions. In the full-grown stems of the Palms, the vascular bundles connected with the upper leaves do not reach the base of the stem, notwithstanding the length of the arc. In the simplest case the vascular bundles are wholly isolated; they are however more frequently connected by intermediate branches, seldom from within externally, but often laterally with one another. From this cause, as well as from a more or less extended vertical course of the vascular bundles before they form the arc, the external part of the stem is composed of a thicker cylinder of vascular bundles, whilst the inner portion, composed only of arcs, becoming more and more isolated towards the centre, and cellular tissue increasing in quantity in the inverse proportion, appears much looser.

"However simple we may consider the course of the vascular bundles, in the Monocotyledons, in judging of them according to H. Mohl's researches, it is in fact but seldom so; nevertheless H. Mohl's representation affords the simplest and clearest delineation, and gives the type from which all the analagous structures must be deduced. The separate vascular bundles, especially so far as they form the arc, by no means always run in one and the same vertical plane, their emergence deviating frequently about 50° and more of the circumference of the stem, laterally from the vertical of their starting point, as may be easily observed for instance in *Yucca gloriosa*. The *Xanthorhœa Australis* appears to me to differ most strikingly from the simple type of the stem. Here the fascicles of the vascular bundles emerging into the leaves, evidently have a threefold origin from three different zones of the stem. Quite in the interior another plexus of vascular bundles appears, the course of which however I conld not make out, as the piece in my possession was not sufficiently large for me to have it. Still it appeared to me that the vascular bundles had not quite reached the middle of the stem. It will at least suffice to draw the attention of more favoured observers to this striking structure. Perhaps the history of the development of *Aletris fragrans* will afford some conclusions on the point. An old stem of about 4·25 Paris inches in diameter consists of two parts; the primary stem about 7 lines in diameter, in which the vascular bundles exhibit the usual arc-like course and an external much more solid zone, gradually formed by the cambium-layer. The vascular bundles passing from within to the leaf-cicatrices permeate this external layer in a perfectly horizontal direction. The external layer becomes however divided again into four zones, which produce the appearance of annual rings when seen in the transverse section. The three external ones are when taken together of about the same thickness as the fourth internal one; they differ in this, that in the external ones the fibres do not ascend vertically but obliquely, consequently in a spiral round the axis, and wind towards the left; in the second, in like manner, but winding towards the right; in the third again, turned towards the left; and finally becoming gradually horizontal in the fourth. I may remark here that whilst the parenchyma is arranged in vertical rows in the primary stem, it appears to be in horizontal rows between the external vascular, in the manner of the medullary rays.

"An essential difference presents itself here, according as the formative layer is limited to the terminal bud, or whether there is a continuous layer in the whole circumference of the stem below the rind, which is there bounded internally by it. The latter occurs in the case of normally branching stems, as for instance in the *Dracænæ*, *Aloineæ*, and *Aroideæ*, the former in normally simple stems, as for instance in the *Tulipaceæ* and Palms, with undeveloped internodes. Beautiful investigations on this subject may be found accompanied by the carefully selected results of earlier observations in Unger, (see his 'Bau und Wachsthum des Dikotyledonenstammes,' Petersburg, 1840, page 34). I must finally make mention of the singular stem-formation in the tropical *Orchidaceæ*. A large portion of these, such for instance as are commonly described as having tubers, have not very thick stems (generally branched) with abbreviated internodes. Those branches however which come to blossom produce a peculiar form, which has hitherto been known as tuber (knolle). Either one of the more central internodes of the blossom-bearing branch swells into a disproportionate mass of very varying shape, or all the lower internodes of the branch form a longer or shorter, more or less thick fleshy mass. In both, as for instance in *Epidendrum cochleatum*, and *Bletia Tankervilliæ*, the regular course of the vascular bundles may be distinctly observed, but in the case of the last-named plant (I know not whether the same holds good for all similarly formed) there is a peculiar vascular system intended for the new lateral buds. Little branches pass from the external vascular bundles, and rnn together in a horizontal direction below the rind from both sides up to the buds. On cutting vertically through one of these stems we find a transversely-severed strikingly-large group of vascular bundles below the rind, corresponding to each internode. It unfortunately happens with the *Orchidaceæ* as with the *Cacti* that it is a matter of difficulty to obtain a sufficient quantity of material to ascertain its anatomy or its history of development."

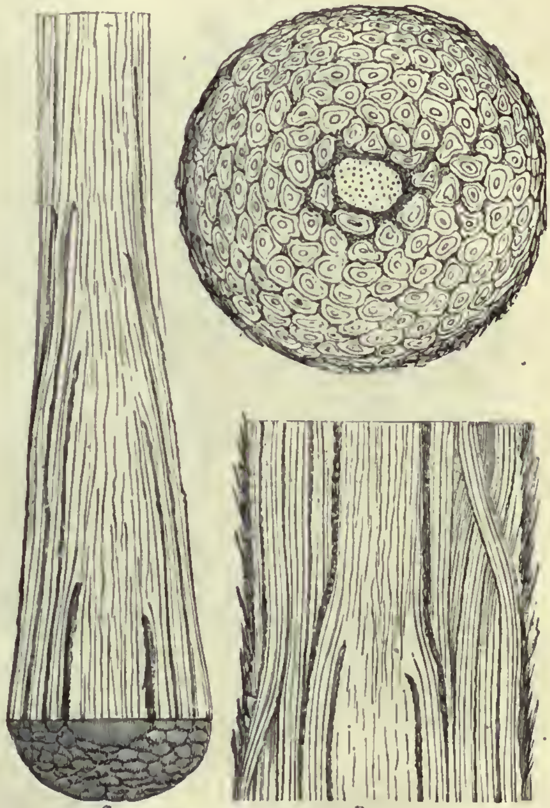
Grasses are Endogens with hollow stems strengthened by transverse plates at the nodes. This is seen in the bamboo, whose joints are used as cases to hold rolls, or in any of our indigenous species. In this case the deviation from habitual structure is owing to the circumference growing faster than the centre, the consequence of which is the tearing the latter into a fistular passage, except at the nodes, where the arcs of ligneous tissue originating in the leaves cross over from one side of the stem to the other, and by their entanglement and extensibility prevent the possibility of any rupture taking place. That this is so is proved by the fact that the stems of all Grasses are solid, or nearly so, as long as they grow slowly; and that it is when the rapidity of their development is much accelerated that they assume their habitual fistular character. Independently of that circumstance their organisation is quite normal.

Xanthorhœa hastilis has been shown by De Candolle to have an anomalous aspect. When cut through transversely the section exhibits an appearance of medullary rays proceeding with considerable regularity from near the centre to the very circumference. ('Organographie Végétale,' t. 7.) But such horizontal rays are not constructed of muriform cellular tissue like real medullary processes, but are composed of ligneous cords lying across the other woody tissue: they are in fact the upper ends of the woody arcs pulled from a vertical into a horizontal direction by the growth of the stem and the thrusting of the leaves to which they belong from the centre to the circumference. Such a case throws great light upon the real nature of the more regular forms of endogenous wood.

Other appearances are owing to imperfect development, as in some of the aquatic species of this class. *Lemna*, for example, has its stem and leaves fused together into a small lenticular cavernous body; and in *Zannichellia* and others a few tubes of lengthened cellular tissue constitute almost all the axis; but the examination of such cases is comparatively unimportant, and would lead too much into details of subordinate interest.

By far the most striking kind of anomaly in the stem of Endogens is that which occurs in *Barbacenia*. In an uupublished species of *Barbacenia* from Rio Janeiro, allied to *B. purpurea*, the stems appear externally like those of any other rough-barked plant, only that their surface is unusually fibrous and ragged when old, and closely coated by the remains of sheathing leaves when young. Upon examining a transverse section of it the stem is found to consist of a small firm pale central circle, having the ordinary endogenous organisation, and of a large number of smaller and very irregular oval spaces, pressed closely together but having no organic connection; between these are traces of a chaffy ragged kind of tissue which seems as if principally absorbed and destroyed (*fig.* 2, A).

Fig. 2. A



C B

A vertical section of the thickest part of this stem exhibits, in addition to a pale central endogenous column, woody bundles crossing each other or lying parallel, after the manner of the ordinary ligneous tissue of a palm stem (*fig.* 2, B), only the bundles do not adhere to each other, and are not embodied as usual in a cellular substance. These bundles may be readily traced to the central column, particularly in the younger branches (*fig.* 2, C), and are plainly the roots of the stem, of exactly the same nature as those aërial roots which serve to stay the stem of a Screw-Pine (*Pandanus*). When they reach the earth the woody bundles become more apparently roots, dividiug at their points into fine segments, and entirely resembling on a small scale the roots of the palm-tree. The central column is much smaller at the base of the stem than near the upper extremity.

The age of endogenous trees has been little studied. When the circumference of their stem is limited specifically it is obvious that their lives will be limited also; and hence we find the longevity of palms inconsiderable when compared with that of exogenous trees. Two or three hundred years are estimated to form the extreme extent of life in a Date-Palm and in many others. But where, as in *Dracæna*, the degree to which the stem will grow in diameter is indefinite the age seems, as in Exogens, to be indefinite also; thus a famous Dragon-Tree, *Dracæna Draco*, of Oratava, in Teneriffe, was an object of great antiquity so long ago as A.D. 1402, and is still alive.

Important as the character furnished by the internal manner of growth of an Endogen obviously is, it is much enhanced in value by its being found very generally accompanied by peculiarities of organisation in other parts. The leaves have in almost all cases the veins placed in parallel lines, merely connected by transverse single or nearly single bars. Straight-veined foliage is therefore an external symptom of an endogenous mode of growth. When such an appearance is found in Exogens it is always fallacious, and is found to be owing to the excessive size and peculiar direction of a few of the larger veins, and not to be a general character of all the venous system; as is sufficiently obvious in *Plantago lanceolata*, *Gentiana lutea*, and many more.

The flowers too of Endogens have in most cases their sepals, petals, and stamens corresponding with the number three, or clearly referrible to that type; and the pistil usually participates in the same peculiarity. Where such a proportion exists in Exogens it is usually confined to the sepals and petals by themselves, or to the pistil by itself, not extending to the other organs. In Endogens it is almost universal in all the whorls of the flower, although sometimes obscured by the abortion, dislocation, or cohesion of particular parts, as happens in the whole of the extensive natural order of grasses.

and a plumule from a little above the radicle; in other cases its embryo has a slit on one side, in the cavity of which the plumule reposes, or, finally, the embryo is a flat plate as in Grasses, with the plumule and radicle attached to its face near the base. In the latter case the flat plate is a solitary cotyledon, which in the second instance is folded together so as to give the embryo the appearance of being slit, and, which in the first or most habitual condition is not only folded up but united at its edges into a case, entirely burying the plumule and cotyledon. Hence the embryo of an Endogen is called Monocotyledonous; a name that is really unexceptionable, notwithstanding the occasional appearance of a second rudimentary cotyledon, as occurs in common wheat.

It has already been stated that the radicle is protruded in germination from within the substance of the embryo; the base of the radicle is consequently surrounded by a minute collar formed of the edges of the aperture produced by the radicle upon its egress. For this reason Exogens are called endorhizal.

Hence the great natural class of plants forming the subject of these remarks has five most important physiological peculiarities, by all which combined, or usually by each of which separately, the class may be characterised :—

Endogenous Vegetation.

Palmaceæ, consisting of *Cocos capitata* (*a*); *Manicaria saccifera* (*b*); *Iriartea ventricosa* (*f*). *Pandanaceæ*, represented by *Pandanus odoratissimus* (*c*); *Musaceæ*, by *Musa Sapientum* (*d*); *Graminaceæ*, by *Bambusa arundinacea* (*e*); and Arborescent *Amaryllidaceæ*, by *Agave Americana* (*g*). The fore and back grounds are composed of small palms, grasses, rushes, and liliaceous plants.

The effect of the manner of growth in Endogens is to give them a very peculiar appearance. Their trunks frequently resemble columns rising majestically with a plume of leaves upon their summit; and the leaves, often very large—the fan-shaped leaves of some palms are from 20 to 30 feet wide—have most commonly a lengthened form, resembling a sword-blade if stiff, or a strap if weak and broad. A landscape consisting entirely of Endogens would have such an appearance as is presented by the cut in this page.

These peculiarities are connected with others belonging to endogenous vegetation in its most rudimentary condition. The embryo of an Endogen is in its commonest state a small undivided cylinder, which protrudes from within its substance a radicle from one end

1. The wood is endogenous.
2. The leaves are straight-veined.
3. The organs of fructification are ternary.
4. The embryo is monocotyledonous.
5. The germination is endorhizal.

This explains why Endogens are also called Monocotyledons and *Endorhizæ*; they have moreover been called *Cryptocotyledoneæ* by Agardh, *Acroblastæ* by Reichenbach, and *Caulophytæ* by the school of Oken.

It may however be readily supposed that, viewed as a large class of plants, Endogens are essentially characterised only by the combination of these five peculiarities, and that occasional deviations may occur from every one of them. Thus in *Nais*, *Caulinia*, *Zannichellia*, and others which constitute a part of what Professor Schultz names Homorganous Floriferous Plants, the whole organisation of the stem is so imperfect that the endogenous character is lost; but their true nature is nevertheless sufficiently indicated by their straight veins, monocotyledonous embryo, &c. Again, in *Smilax*, the common reticulated leaves of Exogens are found; but the endogenous stem, the ternary organs of fructification, the embryo and germination of that order, are all good evidences of its real nature; and so with other cases. Such occurrences are instances of endogenous developmeut tending towards the exogenous, and are usually looked upon as cases of transition from one form to the other—perhaps not very correctly. Of this nature are the resemblances between the columnar Cycadaceous Gymnosperme and Palms, between the livid, fœtid, one-sided calyx of *Aristolochia*, and the equally livid, fœtid, one-sided spathe of Araceous Endogens, or, in another point of view, between such lenticular plants as *Lemna* in Endogens, with the leaves and stems fused as it were together, and similar forms of stem and leaf among Marchantiaceous Acrogens.

With regard to really intermediate forms of vegetation connecting Endogens with other classes, they are extremely uncommon. One of the most striking is that which occurs between *Ranunculaceæ* and *Nymphæaceæ* on the part of Exogens, and *Alismaceæ* and *Hydrocharaceæ* on that of Endogens; if *Ranunculus lingua*, or better *R. parnassifolius*, is contrasted with *Alisma Plantago*, or *Damasonium*, leaving out of consideration subordinate differences, it will be found that there is little of a positive nature to distinguish them except the albuminous dicotyledonous seeds of the former as compared with the exalbuminous monocotyledonous seeds of the latter; and the resemblances between *Hydropeltis* and *Hydrocharis* in the other case, are so very great that Schultz and others actually refer them to the same class.

Endogens probably contain more plants contributing to the food of man, and fewer poisonous species in proportion to their whole number, than Exogens. Grasses, with their flowery albumen, form a large portion of this class, to which are to be added Palms yielding fruit, wine, sugar, sago; *Araceæ*, *Marantaceæ*, some *Amaryllidaceæ*, &c., producing arrow-root, the nutritious fruit of the Plantains, the aromatic secretions of *Zingiberaceæ*, *Orchidaceæ*, forming salep, and *Dioscoreaceæ*, the mothers of Yams. Among the deleterious species we have little worth notice beyond the poisonous mucilage in the bulbs of certain *Amaryllidaceæ*, and the acrid secretions of *Araceæ*.

In these, as in all other large groups, we find the extremes of development so exceedingly far apart, that one would be almost tempted to doubt the possibility of their being mere forms of each other, were it not certain that numerous traces exist in the vegetable kingdom of a frequent tendency to produce the typical structure of a natural association of whatever kind in both an exaggerated and degraded state, if such figurative terms may be employed in science. For instance, the genus *Ficus* contains some species creeping on the ground like diminutive herbaceous plants, and others rising into the air to the height of 150 feet, overspreading with the arms of their colossal trunks a sufficient space of ground to protect a multitude of men. The type of organisation in the willow is in like manner represented on the one hand by the tiny *Salix herbacea*, which can hardly raise its head above the dwarf moss and saxifrages that surround it; and on the other by *Salix alba*, a tree 60 feet high. Then among natural orders we have the Rosaceous structure, exaggerated on the one hand into the arborescent *Pomeæ*, and degraded on the other into the apetalous imperfect *Sanguisorbeæ*; the Onagraceous type, highly developed in *Fuchsia*, and almost obliterated in *Halorageæ*; the Urticaceous, in excess in *Artocarpus*, and most imperfect in *Ceratophyllum*; Grasses, presenting the most striking differences of perfection between the moss-like *Knappia*, and Bamboos 100 feet high; and the Liliaceous occurs in equally different states of development, when Asparagus is compared with the Dragon-Tree, or an autumnal squill with an arborescent *Yucca*. So, in like manner, we find at one extreme of the organisation of the class of Endogens, palms, plantains, and arborescent liliaceous plants, and at the other, such submersed plants as *Potamogeton*, *Zannichellia*, and Duckweed, the latter of which has not even the distinction of leaf and stem, and bears its flowers, reduced to one carpel and two stamens, without either calyx or corolla—therefore at the minimum of reduction, if to remain flowers at all—in little chinks in its edges.

The classification of Endogens is not a subject upon which there is any very great diversity of opinion among botanists; if the natural orders are sometimes not distinctly limited, they are, upon the whole, grouped much better than those of Exogens; and although it may be expected, whenever more positive rules for classification than are yet known shall have been discovered, that great changes will be introduced into this part of systematic botany, yet we do not contemplate the probability of disturbing the limits of the natural orders themselves to any considerable extent.

The system we have followed in this work is that of Dr. Lindley as given in his 'Vegetable Kingdom.' In the arrangement of the Endogens, in the first place, all those species whose flowers are like Grasses are placed together under the Glumal alliance. They may be justly regarded as the lowest point of structure to which Endogens are reduced. Their flowers are made up of scales or bracts, without any attempt at the regularity of arrangement which we find occuring with plants which have a calyx and corolla present. The relatiou of the Bullrushes (*Typhaceæ*) to these is obvious, but their flowers are more regular, and hence they are placed with *Araceæ* in the Aral alliance, and this is followed by the Palms and a small group of water-plants, the *Hydrales*. These all have the stamens and pistils on separate flowers, those which follow have the stamens and pistils together in the same flower. In the following analysis signs are used for this distinction, thus— ♂ indicates flowers bearing pistils alone; ♀ stamens alone; and ⚥ bearing both together. 0 indicates the absence of the organ against which it is placed.

Alliances of Endogens.

I. Glumales.—Flowers glumaceous (that is to say, composed of bracts not collected in true whorls, but consisting of imbricated, colourless, or herbaceous scales).

Graminaceæ.—Ovary 1-celled, with 2 or more distinct (or united) styles. Ovule ascending. Embryo lateral, naked.

Cyperaceæ.—Ovary 1-celled, with 2 or more (distinct or) united styles. Ovule erect. Embryo basal.

Desvauxiaceæ.—Ovary several (sometimes united), with 1 style to each. Ovule pendulous; glumes only. Stamens 1-2. Anthers 1-celled. Embryo terminal.

Restiaceæ.—Ovary 1-2-3-celled, with 2 or 3 styles always. Ovule pendulous; glumes only. Stigmas 2-3. Anthers 1-celled. Embryo terminal.

Eriocaulaceæ.—Ovary 2-3-celled, with 1 style to each cell. Ovule pendulous; a membranous 3-lobed cup within the glumes. Anthers 2-celled. Embryo terminal.

II. Flowers petaloid, or furnished with a true calyx or corolla, or with both, or absolutely naked. ♂ ♀ (that is, having sexes altogether in different flowers.)

Arales.—Flowers naked or consisting of scales, 2 or 3 together, or numerous, and then sessile on a simple naked spadix. Embryo axile. Albumen mealy or fleshy. (Some have no albumeu.)

Pistiaceæ.—Flowers 2 or 3, of which 1 only is ♀. Spadix 0. Ovary 1-celled. Ovules erect. Embryo slit.

Typhaceæ.—Flowers ♂ ♀, on a naked spadix. Calyx scaly or hairy. Anthers with long filaments. . Ovule solitary, pendulous. Seed adherent to the pericarp. Embryo slit.

Araceæ.—Flowers ♂ ♀, naked on a solitary spadix covered by a single hooded spathe. Anthers sessile. Seed loose. Embryo slit, axile.

Pandanaceæ.—Flowers ♂ ♀. Naked or scaly, on a spadix covered by many spathes. Anthers stalked. Seeds loose. Embryo solid, minute.

Palmales.—Flowers perfect (with both calyx and corolla), sessile, on a branched scaly spadix. Embryo vague, solid. Albumen horny or fleshy. (Some Palms are ⚥.)

Palmaceæ.—Characters as in the alliance.

Hydrales.—Flowers perfect or imperfect, usually scattered. Embryo axile, without albumen. Aquatic. Some are ⚥.

Hydrocharidaceæ.—Stamens epigynous. Ovary adherent.

Naiadaceæ.—Stamens hypogynous. Ovary free. Pollen globose.

Zosteraceæ.—Stamens hypogynous. Ovary free. Pollen confervoid.

III. Flowers furnished with a true calyx and corolla, adhereut to the ovary. ⚥.

Narcissales.—Flowers symmetrical. Stamens 3 or 6 or more; all perfect. Seeds with albumen. Flowers unsymmetrical. Some *Bromeliaceæ* have a free calyx and corolla.

Bromeliaceæ.—Flowers tripetaloideous, 6-leaved, imbricated. Albumen mealy.

Taccaceæ.—Flowers half tripetaloideous, tubular. Albumen fleshy.

Hæmodoraceæ.—Flowers hexapetaloideous, tubular, scarcely imbricated. Stamens 3, opposite the petals, or 6 anthers turned inwards. Radicle remote from the hilum, which is naked.

Hypoxidaceæ.—Flowers hexapetaloideous, much imbricated. Stamens 6. Anthers turned inwards. Radicle remote from the hilum, which is often strophiolate.

Amaryllidaceæ.—Flowers hexapetaloideous, much imbricated. Stamens 6 or more. Anthers turned inwards. Radicle next the hilum.

Iridaceæ.—Flowers hexapetaloideous. Stamens 3, opposite the sepals. Anthers turned outwards.

Amomales.—Flowers unsymmetrical. Stamens 1 to 5, some at least of which are petaloid. Seeds with albumen.

Musaceæ.—Stamens more than 1. Anthers 2-celled. No vitellus.

Zingiberaceæ.—Stamen but 1. Anther 2-celled. Embryo in a vitellus.

Marantaceæ.—Stamen but 1. Anther 1-celled (halved). No vitellus.

Orchidales.—Stamens 1 to 3. Seeds without albumen.

Burmanniaceæ.—Flowers regular. Stamens free, perigynous.

Orchidaceæ.—Flowers irregular, gynandrous. Placenta parietal.

Apostasiaceæ.—Flowers regular, half gynandrous. Placenta axile.

IV. Flowers furnished with a true calyx and corolla, free from the ovary. ☿

XYRIDALES.—Flowers half herbaceous, 2-3 petaloideous. Albumen copious.

Philydraceæ.—Sepals 0. Petals 2. Stamens 3, of which 2 are abortive. Embryo axile, in fleshy albumen.

Xyridaceæ.—Sepals 3. Petals 3. Stamens 3, fertile. Carpels opposite sepals. Placenta parietal. Embryo minute, on the outside of fleshy albumen.

Commelynaceæ.—Sepals 3. Petals 3. Stamens 6 (or 3). Carpels opposite sepals. Placentæ axile. Embryo trochlear, half immersed in fleshy albumen.

Mayaceæ.—Sepals 3. Petals 3. Stamens 3 (anthers 1-celled). Carpels opposite petals. Placentæ parietal. Embryo minute on the outside of fleshy albumen.

JUNCALES.—Flowers herbaceous, dry and permanent, scarious if coloured. Albumen copious. (Some Callas have no albumen.)

Juncaceæ.—Flowers scattered. Embryo minute, undivided.

Orontiaceæ.—Flowers spadiceous. Embryo axile, with a conspicuous cleft on one side.

LILIALES.—Flowers hexapetaloideous, succulent, and withering. Albumen copious.

Gilliesiaceæ.—Perianth surrounded by a calycine involucre, the inner bracts of which are coloured and petaloid.

Melanthaceæ.—Perianth naked, flat when withering. Anthers turned outwards; styles distinct. Albumen fleshy.

Liliaceæ.—Perianth naked, flat when withering. Anthers turned inwards; styles consolidated. Albumen fleshy.

Pontederaceæ.—Perianth naked, circinate when withering. Anthers turned inwards. Albumen mealy.

ALISMALES.—Flowers 3-6, petaloideous, apocarpal. Albumen none. (Some *Alismaceæ* are absolutely ♀ ♂.)

Butomaceæ.—Flowers 3, petaloideous. Placentæ many-seeded, netted, and parietal.

Alismaceæ.—Flowers 3, petaloideous. Placentæ few-seeded, simple, and axile, or basal. Embryo solid.

Juncaginaceæ.—Flowers scaly. Placentæ few-seeded, simple, and axile, or basal, slit on one side, with a very large plumule.

The Endogenous Orders probably contain more plants yielding food for man, and less plants yielding poisons in proportion to their numbers, than those belonging to Exogens. The *Graminaceæ* are found all over the world, and are cultivated by most civilised and semi-civilised nations, and yield a large proportion of the substantive food of the human family. Palms are of the utmost importance in countries where they grow, yielding fruits, wine, sugar, sago, and other products. Many of them yield starch from their root-stocks, as the arrow-root plants, Arums, Orchises, and the like. Aromatic secretions are yielded by the Gingers, and deleterious substances by the *Melanthaceæ* and *Araceæ* more particularly.

ENDOPHLEUM. [BARK.]

ENDORHIZÆ. [ENDOGENS.]

ENDOSMOSIS, a name given by Dutrochet to the process by which fluids pass from the exterior to the interior of a cell. This process seems to result from two distinct agencies, which are always brought into operation where fluids pass through a membrane. The one is the imbibition of the fluid by the porous cell-membrane, and the other is the mutual diffusion of miscible fluids. From the researches of Matteucci and others there can be little doubt that the passage of a gas or liquid through an animal or vegetable membrane is but the modification of the process of attraction by which fluids are absorbed by solid bodies. This process is carried on with various degrees of force in different materials, and seems to depend on the degree of attraction subsisting between the particles of the solid and those of the fluid. Matteucci found that when glass tubes of about three-quarters of an inch diameter were filled with fine sand previously dried, and introduced without pressure, and were immersed at their lower ends into the following liquids, the action of imbibition raised the liquids in the tubes to the following height:—

Solution of Carbonate of Potash	85	millimetres.
Solution of Sulphate of Copper	75	"
Serum of Blood	70	"
Solution of Carbonate of Ammonia	62	"
Distilled Water	60	"
Solution of Common Salt	58	"
Milk	55	"
White of Egg, diluted with its own volume of water	35	"

In these cases the imbibition took place at first rapidly, then more slowly, and ceased entirely at the end of ten hours. When thick solutions of gum, or starch, or fixed oils were employed, scarcely any imbibition took place, and it was but little more when strong saline solutions were used. The degree in which different fluids pass into different solids will be seen in the following table:—

	Sand.	Pounded Glass.	Saw-dust.
Alcohol	85 mill.	175 mill.	125 mill.
Water	175 "	182 "	60 "

Thus showing that water passed more freely than alcohol into sand, but less freely into saw-dust, and both fluids passed with equal facility into pounded glass. The size of the tubes employed in these experiments and the temperature affected considerably the results. The fluids rose higher in proportion as the temperature increased. This enables us to understand the influence of heat on life by the physical effects it produces.

Not only is the passage of fluids from the exterior to the interior of a cell facilitated by the attraction between the cell-wall and the fluids, but the fluids on either side of the membrane have a tendency to mix with each other, which cannot but assist in this process. Professor Graham has shown that not only have gases an inherent tendency to mix with each other, independent of the laws of gravity, but that this law also applies to the miscibility of liquids. In a Memoir on this subject in the 'Philosophical Transactions' for 1850, he has shown the laws which this diffusion of liquids obeys. Different substances possess this property in different degrees. Thus, when solutions of the following substances were used, of the strength of 20 parts to 100 parts of water, the relative quantities diffused in a given time were as follows:—

Chloride of Sodium	58·68
Sulphate of Magnesia	27·42
Nitrate of Soda	51·56
Sulphate of Water	69·32
Crystallised Cane-Sugar	26·74
Starch-Sugar (Glucose)	26·94
Gum Arabic	13·24

The experiments from which these results were obtained, were performed by inverting a phial containing the solution to be diffused in a large jar of pure water. The diffusion was stopped after seven or eight days, and the amount of diffusion was determined by evaporating the water of the jar to dryness. There can be little doubt that the relative diffusibility of the juices of plants and animals must have an important influence on the changes which go on in the cells during the performance of the functions of the vegetable or animal body. "Thus," observes Dr. Carpenter, "the low diffusibility of albumen obviously tends to the retention of the serous fluids within the tissues; whilst the high diffusibility of urea will favour its escape from them." The following is an account of the process of Endosmosis, and some of the conclusions at which we may arrive, from Dr. Carpenter's 'Principles of Physiology:'—

"If into a tube, closed at one end with a piece of bladder or other membrane, be put a solution of gum or sugar, and the closed end be immersed in water, a passage of fluid will take place from the exterior to the interior of the tube, through the membranous septum; so that the quantity of the combined solution will be greatly increased, its strength being proportionably diminished. At the same time, there will be a counter-current in the opposite direction; a portion of the gummy or saccharine solution passing through the membrane to mingle with the exterior fluid, but in much less quantity.

"The first current is termed Endosmose, and the counter-current Exosmose. The increase on either side will of course be due to the relative velocity of the currents; and the changes will continue until the densities of the two fluids are so nearly alike as to be incapable of maintaining it. The greater the original difference (provided that the denser be not actually viscid, but be capable of mixing with the other), the more rapidly and powerfully will the process be performed. The best means of experimenting upon the phenomena is afforded by a tube, narrow above, but widely dilated below, so as to afford a large surface to the membrane, compared with that of the superincumbent column, which will then increase in height with great rapidity. By bending this tube in the form of a syphon, and introducing into its curve a quantity of mercury, the force as well as the rapidity of the Endosmose between different fluids may be estimated with precision. In this way it was ascertained by Dutrochet, in some of his experiments, that fluid might be raised against a pressure of no less than 4½ atmospheres, or nearly 70 lbs. to the square inch. Although it is not universally true that the activity of the process depends upon the difference in density of the two fluids (for in one or two cases the stronger current passes from the denser to the lighter), it seems to be so with regard to particular solutions, as those of gummy or saccharine matter. No endosmose takes place between fluids which will not mingle, such as oil and water; and very little between such as act chemically on each other. Although an organic membrane forms the best septum, yet it has been found that thin laminæ of baked pipe-clay will suffice for the evident production of the phenomenon; and that porous limestones possess the same property in an inferior degree. Although it may not yet be possible to explain all the phenomena of Endosmose upon physical principles, yet these will go so far towards it that the general conditions of the process may be considered as well understood. Supposing that two mutually diffusible liquids are on the opposite sides of a porous septum, which is not equally penetrable by them, then the one which is most readily imbibed will tend to occupy the capillary passages of the septum, and will thus be brought into contact with the liquid on the opposite side. This contact will permit the diffusion of that which has passed through the pores of the septum; and as fast as that which occupies these pores is removed by diffusion, so fast will it be renewed on the other side,—just as oil continues to ascend through the capillary channels in the wick of a lamp, so long as it is being dissipated by the combustive process at its summit. In this way then an endosmotic current is produced, the force of which will depend upon the diffusion-powers of the two liquids, and upon the difference of the attractive power which the capillary tubes of the septum have for the two respectively. Thus when a solution of sugar or gum is on one side of the septum, and water on the other, the water is the most readily imbibed; and consequently the chief mixture and diffusion of the liquids, the one through the other, takes place at the surface of the septum in contact with the more viscid liquid. But at the same time this liquid is tending to diffuse itself through the water which occupies the capillary channels of the septum; and as it is not repelled by the septum, but is only attracted by it in a less degree than the water, a portion of it finds its way in a direction opposed to the principal current, and diffuses itself through the water on the other side, thus constituting Exosmose. Thus it happens that the direction of the principal current, or Endosmose, will be determined by the attractive power of the septum for one or the other of the liquids; though the diffusion-power of the liquids through each other will help to determine its force. When alcohol and water, for example, are separated by a septum composed of animal membrane, the endosmotic current will be from the water towards the alcohol, because the former liquid more readily 'wets' the membrane, and consequently tends most strongly to occupy its capillary passages; but, on the other hand, when the separation is made by a thin lamina of caoutchouc, the endosmotic current is from the alcohol towards the water, because the former is most readily imbibed by the septum. It has further been ascertained by the experiments of Matteucci, that when an organic membrane is employed as a septum, the rapidity of transmission is considerably affected by the direction in which the endosmotic current traverses the membrane. Thus, when the skin of the Torpedo was employed, with a solution of sugar on one side of it and water on the other, although there was always an endosmotic current from the water to the sugar, yet this current was strong enough to raise the interior liquid to 80° when the water was in contact with the internal surface of the membrano, in the same time that was occupied by its rise to 20° when the external surface of the membrane was turned towards the water. Again, when the mucous membrane of the stomach of a dog was used as the septum, and its external (or muscular) surface was placed in contact with alcohol, the passage of water from the other side took place with such rapidity as to raise the liquid in the tube to 130°; whilst if the internal (or mucous) surface of the membrane were placed in contact with the alcohol, and the muscular surface with water, the current was only sufficient to raise the liquid 6 degrees in the same time; so that it is evident that the transudation of water takes place much more readily from the mucous lining of the stomach towards the outer side of the viscus than in an opposite direction, in virtue simply of the physical properties of the membrane. In fact, according to Professor Matteucci, the cases are very rare in which, with fresh membranes, Endosmose takes place with equal readiness, whichever of the two sides is exposed to the water.

"The direction which is most favourable to Endosmose through skins is usually from the internal to the external surface, with the exception of the skin of the frog, in which the endosmotic current, in the single case of water and alcohol, takes place most readily from the external to the internal surface. But when stomachs and urinary bladders are employed, the direction varies much more, according to the nature of the liquids employed. This variation appears to have some relation to the physiological conditions in which these membranes are placed in the living animal; thus, the direction most favourable to Endosmose between water and a saccharine solution, is not the same for the stomach of a ruminant as for that of a carnivorous animal: as yet however no positive statement can be made on this subject. When membranes are employed that have been dried or altered by putrefaction, we either do not observe the usual difference arising from the position of the surfaces, or Endosmose no longer takes place; thus affording another indication that it is to the physical condition of the perfectly-organised membrane that we are to look for many of the peculiarities which are noticeable in the transudation of fluids through them. The exosmotic current does not bear any constant relation to the endosmotic, as may be easily comprehended from the preceding explanation; for if the liquids have a strong tendency to mutual diffusion, and the difference in attractive power which the septum has for them respectively is not great, each may find its way towards the other, and a considerable exosmose may ensue, with very little change of level. The amount of the exosmotic as of the endosmotic current, varies with the direction in which it traverses the membrane; thus, when sugar, albumen, or gum was employed in solution, its transudation towards water took place most readily from the internal towards the external surface of all the skins examined by Matteucci, a fact which is not without its significance, when it is remembered that it is in this direction that the secretion of mucus takes place on the skins of fishes, frogs, &c.

"Applying these considerations to the phenomena of imbibition of liquids into the tissues and canals of the living body, we shall have to inquire how far they are capable of being accounted for on physical principles, which have been now brought forward. It has been maintained by some that absorption is a purely vital operation, because it does not occur save during the continuance of life. But this is not true, since imbibition will take place into dead tissues, though more slowly than into some parts when living; and the difference of rate seems to be fully accounted for by the difference of the condition between a mass of tissue, all whose fluids are stagnant, and another in which an active circulation is taking place. Thus, as Matteucci has shown, if the hind legs of a frog recently killed be immersed for some hours in a solution of ferrocyanide of potassium, it will be found that every part of the viscera is so penetrated with the salt, that by touching it with a glass rod moistened with a solution of chloride of iron, a more or less deep blue stain is the result. Now, the same effect is produced much more speedily in a living frog; and it is easily proved that the imbibition takes place in the latter case into the blood-vessels, and that the salt is conveyed to the remoter parts of the body by the circulation, instead of having slowly to make its way by transudation through the tissues, as in the dead animal. But further, not only does the movement of blood in the vessels promote the diffusion of liquid, which has been already observed, it also increases the rapidity of the absorption itself in a very extraordinary degree. Thus, if a membranous tube, such as a piece of small intestine, or of a large vein of an animal, be fixed by one extremity to an opening at the bottom of a vessel filled with water, and have a stop-cock attached at the other extremity, and be then immersed in water ascidulated with sulphuric or hydochloric acid, it will be some time before the acid will penetrate to the interior of the tube, which is distended with water; but if the stop-cock be opened, and the water be allowed to discharge itself, the presence of the acid will be immediately discovered (by tincture of litmus) in the liquid which flows out, showing that the acid has been assisted in its penetration of the walls of the tube by the current traversing its interior. Thus, the continuance of circulation is obviously one of the most patent of all the conditions of absorption, and the difference in the rate of the process in the dead and living organisms, placed under the same circumstances, may be accounted for in great part, if not entirely, by the stoppage of the circulation in the former. All the circumstances which are laid down by physiologists as favouring absorption are in strict accordance with the physical principles which have been now explained. These circumstances are—1. The ready miscibility of the liquids to be absorbed with the juices of the body. 2. The penetrability of the tissue through which the absorption takes place. 3. The absence of previous distention in the tissues or canals towards which the flow takes place. 4. The elevation of the temperature within certain limits. 5. The vascularity of the tissues, and the rate of movement of the blood through the vessels. And the results of experiments upon recently-dead membranes which retain almost exactly the same physical conditions as those which they possessed during life, but have entirely lost their vital properties, seem most decidedly to indicate that the relative facility with which different substances are absorbed, and the direction most favourable to their passage through the tissues, are determined in great part by the physical relations of those tissues (and of the vessels which traverse them) to the liquid which is seeking to enter them. In this way, then, many of the phenomena of selective absorption are probably to be explained, especially in plants and the lower animals. The special absorbent vessels, however, of *Vertebrata* seem to possess properties which can scarcely be thus accounted for." ('Principles of Physiology.') [ABSORPTION; ABSORBENT VESSELS.]

ENDYMION, a genus of Plants belonging to the class of Endogens, the order *Liliaceæ*, and the tribe *Hemerocallideæ*. It has a tubular bell-shaped perianth, composed of six connivent leaves, with reflexed points combined below. The stamens are inserted below the middle of the perianth; the filaments decurrent.

E. nutans, the English Blue-Bell. It is also the *Scilla nutans*, the *Hyacinthus non-scriptus*, and *Agraphis nutans* of various botanical writers. It has linear leaves, with nodding racemes, the flowers bell-shaped, cylindrical; the apex of the sepals revolute; the bracts 2. This is a very common plant, flowering in May in the woods and thickets of England. It is also common in France and Belgium. The flower-stalk is about a foot high. The leaves are shorter than the flower-stalk. The flowers are generally blue. A white variety is however occasionally seen.

ENGRAULIS. [ANCHOVY; CLUPEIDÆ.]

ENGYSTOMA. [AMPHIBIA.]

ENHALUS, a genus of Plants belonging to the natural order *Hydrocharidaceæ*, the fruit of which, according to Agardh, is eatable, and the fibres capable of being woven.

ENHYDRA. [OTTERS.]

ENNEAGONA. [ACALEPHÆ.]

ENTALOPHORA. [SERTULARIADÆ.]

ENTEROMORPHA. [ALGÆ.]

ENTO'BIA, a genus of Fossil *Annelida*. (Portlock.)

ENTOMOCO'NCHUS, a genus of Fossil *Crustacea*, from the Mountain Limestone of Ireland. (M'Coy.)

ENTOMO'LOGY, that branch of science which treats upon insects.

The term Entomology literally signifies a discourse upon insects, it being derived from the two Greek words "Εντομον, an insect, and Λόγος, a discourse.

The term Entoma was first applied to these animals by Aristotle, and is synonymous with the Latin word *insecta* (whence is derived the English name 'insects'), both having reference to a striking character exhibited in the insect tribe, that of having the body insected, or, as it were, cut and divided into numerous segments. [INSECTA.]

ENTOMOSTO'MATA, De Blainville's name for his second family of his first order, *Siphonobranchiata*, of his first sub-class *Paracephalophora Dioica*, of his second class, *Paracephalophora*, of *Malacozoa*. This family appears to be nearly the same with the genus *Buccinum* of Linnæus and family *Buccinidæ* of other naturalists. It is thus characterised by De Blainville :—

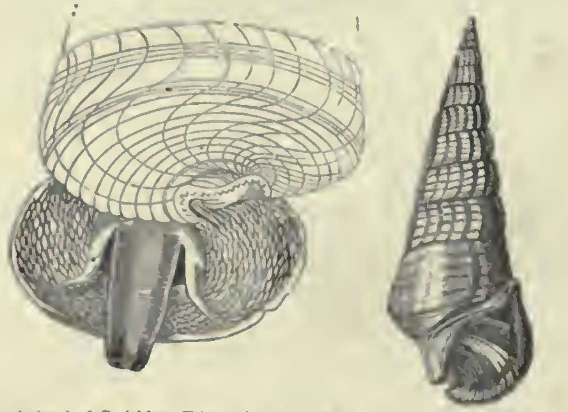
Animal spiral, with the foot, which is shorter than the shell, rounded in front. Mantle provided in front of the respiratory cavity with a long canal always uncovered, which the animal uses as an organ of prehension. Head furnished with a single pair of blackish tentacula, which carry the eyes on an enlargement (renflement) of the half of their base. Month armed with a proboscis, as in the preceding family (*Siphonostomata*), without any labial tooth, but with a small tongue. Organs of respiration formed by two unequal pectinated branchiæ. Organs of generation—termination of the oviduct in the females at the right side, at the entrance of the branchial cavity. Termination of the deferent canal at the extremity of a long flattened contractile excitatory appendage, situated at the right side of the neck. Shell very variable in form, whose opening, sometimes very large and sometimes very small, is without an apparent canal, or with a very short one suddenly recurved upwards, but always more or less deeply notched anteriorly. Operculum horny, unguiform, oval, subconcentric, with the summit a little marked and marginal.

De Blainville observes that this family differs evidently very little from that of the *Siphonostômata*, whether in the soft parts or in the shell. The species which it embraces are not all absolutely marine, though a very great number of them are: some live at the mouths of rivers, and a very small number are entirely fluviatile.

The following are the principal genera of this family :—

* Turriculated.

Cerithium.—Animal very much elongated, the mantle prolonged into a canal at its right side, but without a distinct tube; the foot terminated by a depressed proboscidiform muzzle; tentacula very distant, with large rings, swollen, as it were, in the lower part of their length, and carrying the eyes at the summit of this enlargement. Mouth terminal, in the form of a vertical slit, without any labial tooth, and with a very small tongue furnished with regularly disposed reflexed teeth. A single straight branchia.



Animal of *Cerithium Telescopium*, and shell of *Cerithium palustre*.

Shell more or less turriculated, tuberculous; aperture small, oval, oblique; the columellar border very much excavated, callous; the right lip sharp-edged, and dilating a little with age. Operculum horny, oval, rounded, sub-spiral, and striated on its external surface; sunk, and bordered on its internal surface.

α.

Species which have evidently a small canal, very short, and obliquely recurved towards the back.

Ex. *C. Vertagus.* Locality, Indian Ocean and Moluccas. (Lamarck.)

β.

Species which have a still smaller canal, but straight throughout, and a well-formed sinus at the posterior union of the two borders.

Ex. *C. Aluco.* Locality, Indian Ocean and Moluccas. (Lam.)

γ.

Species whose aperture is divided into three by the shutting of the short anterior tube, and that of the posterior sinus. (Genus, *Triphore*, or *Tristome* (Deshayes), *Triforis* (?), Deshayes.

Ex. *C. tristoma.*

δ.

Species which have a small straight canal, and the whorls of the spire flat and ribanded, with a deep umbilicus, two decurrent plaits on the columella, and one on the right lip. (Genus, *Nerinea*, Defrance.)

Ex. *C. Nerinea.*

ε.

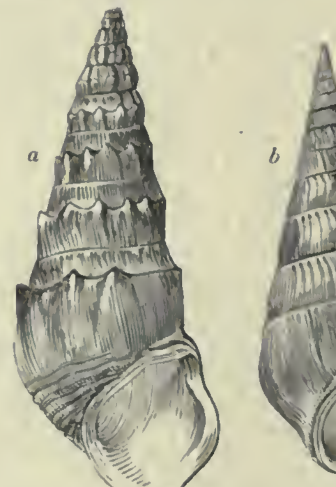
Species which have no canal, but a simple notch, and whose right lip is much dilated in age. (Genus, *Potamides*, Brongniart; *Pyrazus*, De Montfort.)

Ex. *C. palustre.* Locality, coasts of the East Indies, in the salt marshes. (Lam.)

ζ.

Species whose aperture, without a canal, is a little notched in front and rear, the notch being replaced by a sinus; the columellar border curved in its middle; the right lip not dilated. (Genus, *Pirena*, Lam.)

Ex. *C. Madagascariense.*



a, *Cerithium Madagascariense* (Lam.); *b*, *C. Madagascariense* (*Pirena*, Lam.), according to De Blainville. N.B. It is not clear that these are not the same species, notwithstanding the comparative smoothness of *b*.

De Blainville makes the genus *Cerithium*, as established by him, contain 56 species characterised by Lamarck; adding that the greater part are marine, but many from the mouths of rivers, and some entirely lacustrine, and that there is but one belonging to the French seas, whilst more than a hundred fossil species are found in France and Italy. M. Defrance's genus *Nerinea*, he remarks, would be better placed among the *Pyramidellæ*.

The species of this genus with those of *Potamides*, *Nerinea*, *Aporrhais*, and *Struthiolaria*, are often referred to the family *Certhiadæ*, (Woodward, 'Manual of the Mollusca.')

Lamarck places *Cerithium* at the commencement of the first section (Canalifères) of his Zoophagous Trachelipods, immediately after *Turritella*, the last of his Phytophagous (Plant-Eating) Trachelipods.

Cuvier gives it a position after *Purpura*, *Cassis*, and *Terebra*, and before *Murex*. This, as the Rev. M. J. Berkeley and Mr. Hoffman observe, in their interesting paper on the anatomical structure of *Cerithium Telescopium*, would imply a structure of the parts of the mouth adapted for boring shells, according to the known habits of *Murex* and certain allied genera; but, they remark, a single glance at Adanson's figure is sufficient for conviction that the animal is much more nearly allied to the *Trochoides*; and that Lamarck judged rightly, according to the evidence before him, in placing it on the confines of his two great classes. This is corroborated, they add, by the little additional information of M. Sander Rang, who describes the month as toothless, but furnished with a small tongue.

M. Sander Rang states that this genus, so numerous in species both living and fossil, contains only marine animals; but, nevertheless, there are some of them which live at the mouths of rivers, and these are precisely the individuals which M. Brongniart has united to form the genus *Potamides*, which cannot be adopted in Zoology, inasmuch as it does not rest upon sufficiently marked characters. M. Rang adopts generally the divisions of De Blainville with approbation, but he rejects the sixth group (ζ), which comprehends the genus *Pirena*, which Rang, following the example of M. de Férussac, places with *Melanopsis*. Rang agrees with De Blainville in thinking that the division containing Defrance's *Nerinea* is perhaps doubtful, and that its position would be better near the *Pyramidellæ*. He observes that they have in France but two or three living *Cerithia*, but a great number of fossil species.

Deshayes makes the number of living species eighty-seven; not reckoning *Triforis*, of which he gives three species, nor *Pirena*, of which he also gives three; of the latter Lamarck records four. The number of species of *Cerithia* at present described exceed one hundred.

Adanson, speaking of the habits of one of the species of *Cerithium*, says that it lives in the sand amongst grass and mangroves, feeding on 'scolopendres' and other small marine worms. The individual which formed one of the subjects of the investigation by Mr. Berkeley and Mr. Hoffman, and which was brought from Calcutta, though placed in fresh sea-water, the utmost care being taken to renew it frequently, and though all kinds of marine substances were supplied to the animal for food, refused all nourishment, contenting itself with simply walking over the substances, and, in so doing, touching them with its proboscis. As it would not feed, this individual was killed by immersion in spirit. The other specimen, which was anatomised by the zoologists above mentioned, was brought from Ceylon. Dr. J. E. Gray (March 25, 1834) read a note to the Zoological Society of London, giving an account of the arrival in England of two living specimens of *Cerithium armatum*, which had been obtained at the Mauritius, and had been brought thence in a dry state. That the inhabitants of land-shells will remain alive without moisture for many months is, he remarked, well known. [BULINUS.] He had had occasion to observe that various marine *Mollusca* will retain life in a state of torpidity for a considerable time; some facts, in illustration of which, he had communicated to the Society. ('Zool. Proc.,' part i. p. 116.) The present instance included however a torpidity of so long a continuance as to induce him to mention it particularly. The animal, though deeply contracted within the shell, was apparently healthy, and beautifully coloured. It emitted a considerable quantity of bright green fluid, which stained paper of a grass-green colour; it also coloured two or three ounces of pure water. This green solution, after standing twelve hours in a stoppered bottle, became purplish at the upper part; but the paper retained its green colour though exposed to the atmosphere. A specimen of *C. Telescopium*, sent from Calcutta to Mr. G. B. Sowerby in sea-water, lived out of water in a small tin box for more than a week. *Cerithium* has been found in the sea on various bottoms, and in æstuaries at a depth ranging from the surface to seventeen fathoms.

Fossil Cerithia.—Deshayes, in his tables, gives the number of fossil (tertiary) *Cerithia* at 220, and of these he records *C. vulgatum*, *C. Latreillii*, *C. doliolum*, *C. giganteum*, *C. alucaster*, *C. granulosum*, and *C. bicinctum*, as both living and fossil. He gives two fossil (tertiary) species of *Pirena* and two of *Triforis*. The form is found from the Supracretaceous to the Oolitic group, both inclusive. *Potamides* is recorded in the Weald-Clay, Sussex (Mant.); and *Nerinea* in the Oolitic group (Bailly) near Auxerre, St. Mehiel (Meuse), Kimmeridge Clay, Coral Rag, Bernese Jura, Forest Marble, Oxford Oolite, Dorset (*Nerinea Goodhallii*), Inferior Oolite.

Dr. Lea ('Contributions to Geology') describes and figures from the Claiborne Beds, in America, a shell which he names provisionally *Cerithium* (?) *striatum*; observing that he is by no means satisfied in placing this shell among the *Cerithia*. It has a stronger resemblance in the mouth to the genus *Melania*, but being a marine shell, cannot, he remarks, with propriety be placed in that genus. De Blainville, he adds, figures a shell ('Malacologie,' pl. 21, bis, fig. 2), under the name of *Potamides fragilis*, which certainly ought to belong to the same genus with this, the mouth being very nearly the same. Until more species shall be obtained, Dr. Lea has forborne to create for it a new genus. He further states that there have been no *Cerithia* yet found in the beds at Claiborne, although they abound in England and on the Continent in the Tertiary Formation, there being 137 species in the Paris Basin alone. Woodward states that the fossil species exceed 460 in number.

Melanopsis.—Animal furnished with a proboscidiform muzzle, with two contractile, conical, annulated tentacula, having each at their external base an oculated peduncle; foot attached to the neck; respiratory orifice in the canal formed by the union of the mantle with the body. Shell with an epidermis, elongated, fusiform, or conico-cylindrical, with a pointed summit; whorls of the spire from 6 to 15, the last often forming two-thirds of the shell; aperture oval, oblong; columella solid, callous, truncated at its base, separated from the anterior border by a sinus, the callosity prolonged upon the convexity of the penultimate whorl, forming a canal backwards; sometimes a sinus at the posterior part of the right border. Operculum horny, subspiral.

The genus is rather fluviatile than marine, contrary to *Cerithium*, according to De Blainville. Lamarck, who gives but two species, *M. costata* and *M. lævigata*, speaks of them decidedly as fluviatile. Rang says that the genus was established by M. de Férussac for fresh-water shells, whose callous and truncated columella did not permit their arrangement with *Melania*. The latter, in his Monograph, divides them into two groups, the first consisting of those species which have a single sinus at the border of the aperture, separating it from the columella (*Melanopsis*, Lam.; *M. buccinoidea*); the second consisting of those species which have two distinct sinuses at the external border of the aperture, one which separates it from the columella, the other situated near the union of this border with the penultimate whorl. (*Pirena*, Lam.) De Blainville gives the following division of the genus:—

α. Subturriculated Species.

Ex. *M. costata.*

Locality, Syria, in the Orontes. (Lamarck.)

Melanopsis costata.

β. Oval Species.

Ex. *M. buccinoidea.*

γ. Convex Species (Espèces Renflées).

Ex. *M. Bouei.* [MELANOPSIS.]

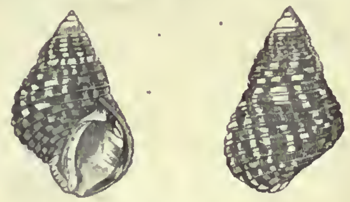
The genus *Melania* is related to *Melanopsis*, and is sometimes included with *Paludomus* in the family *Melaniadæ*. [MELANIA.]

Planaxis.—Animal unknown. Shell oval, conical, solid, transversely furrowed; aperture oblong; columella flattened and truncated anteriorly, separated from the right border or lip by a sinus; right lip furrowed or rayed within, and thickened by a decurrent callosity at its origin. Operculum horny, oval, delicate, subspiral.

Lamarck established this genus for certain small shells approximating closely to the *Phasianellæ*, but differing from them by the truncation of the anterior part of the columella. He only records two species, namely *P. sulcata* and *P. undulata*. M. Rang states that he possesses six well-distinguished species. Woodward, in his 'Manual of the Mollusca,' gives eleven species. They are found in the West Indies, Red Sea, Bourbon, India, the Pacific, and Peru.

The *Planaxis* is a littoral shell, and is sometimes found under stones. M. Rang says that he had had occasion to observe the animal at the Isle of France (Mauritius), where the rocks are sometimes covered with them, but, having lost his notes, he is unable to give its principal characters. According to his recollection, the animal differed very little from that of *Phasianella*. M. Deshayes, in his Tables, puts the living species at four.

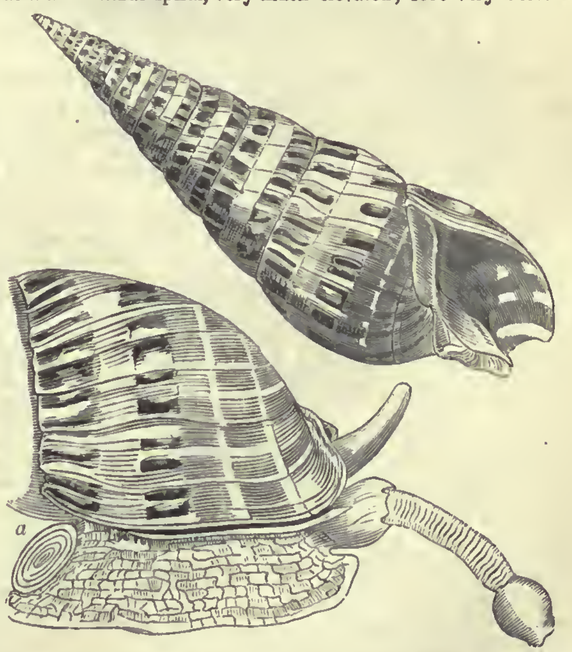
Ex. *P. sulcata.*



Planaxis sulcata.

Deshayes, in his Tables, gives five species as fossil in the Tertiary strata.

Subula.—Animal spiral, very much elevated; foot very short and



Shell of *Subula maculata*, and last whorl of the shell with the animal and operculum *a*.

round; head with extremely small triangular tentacula, bearing the eyes at their summit; a long labial proboscis without hooks (crotchets), at the bottom of which is the mouth equally unarmed. Shell without an epidermis, turriculated, and with a pointed spire; whorls smooth, ribanded, bifid; aperture oval, small, deeply notched anteriorly; external lip thin and sharp-edged; internal or columellar lip with an oblique bourrelet at its extremity. Operculum oval, horny, lamellar, and as it were imbricated.

De Blainville thus characterises a genus which he says he found himself compelled to establish upon examining the animal brought home by Messrs. Quoy and Gaimard, the shell of which had been hitherto confounded with the *Terebræ;* and he arranges under this new genus all those species whose shell is very much elevated, whose spire is very pointed, and whose whorls are ribanded; and consequently the greatest number of the twenty-four living species characterised by Lamarck, and which nearly all belong to the East Indies and Australasia.

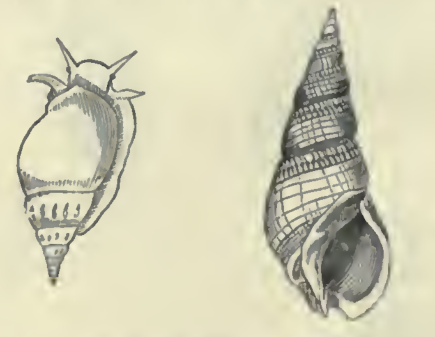
Ex. *S. maculata* (Lam.), *Buccinum maculatum* (Linn.).

It inhabits the Moluccas and Pacific Ocean, according to Lamarck, who speaks of his possession of a specimen taken on the shores of Owhyhee.

** Turbinaceous; or genera whose spire is moderately elongated, rarely subturriculated.

Terebra.—Animal spiral, rather elevated; foot oval, with a transverse anterior furrow and two lateral auricles; head bordered with a small fringe; cylindrical tentacula terminated in a point, and very distant; eyes but little apparent at the origin and outside of the tentacula; mouth without a proboscis; tube of the respiratory cavity very long. Shell without an epidermis, inclining to oval; spire sharp, not much elevated or subturriculated; aperture large, oval, strongly notched anteriorly; columella with an oblique bourrelet at its extremity. No operculum. (De Blainville.)

M. De Blainville only leaves in this genus, which he thinks ought perhaps to belong to the family of non-operculated *Entomostomata*, those species of Lamarck's *Terebræ* which in their general form bear some resemblance to the *Buccina*, such for example as his Vis Buccinée (*Terebra vittata*); because De Blainville supposes that the animal resembles that of the Miran of Adanson, which is the type, and which differs much from that of the subulated species to which De Blainville gives the generic name of *Subula*—Alène in French.



Animal of *Terebra* (Vis Miran) from Adanson, and shell of *Terebra vittata.*

The species, De Blainville observes, appear to come from warm climates only, like the *Subulæ*. *Terebra* (Lamarck) occurs at depths ranging from the surface to 17 fathoms. The species sometimes creep on reefs out of the water, but within reach of the spray.

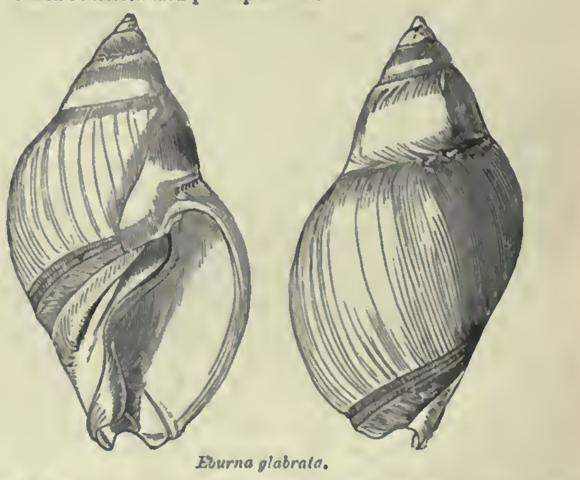
Since the publication of the works of M. De Blainville and of M. Rang, Dr. J. E. Gray has enumerated 45 species, all of them either in the British Museum or in his own private collection. He states that the animal has a small foot, and a very long proboscis, at the base of which are seated two very small tentacula; the operculum is ovate, thin, horny, rounded behind, and rather tapering in front. The shell is covered by a very thin, pellucid, horn-coloured periostraca; it is usually white, variously streaked with brown, the streaks being often interrupted or broken into spots by the two spiral bands of the shell; one of these bands is placed near the spiral groove and the other on the middle of the whorl. The apex of the cavity is frequently filled up by a calcareous deposition; but this deposition has never been observed in *T. duplicata*. Dr. Gray divides the species into the three following sections:—1st. "Anfractibus sulco spirali cingulum posterius efformante; labio interiore, tenui concavo." He observes upon this section that the cingulum is most conspicuous in young shells; and that the internal lip is very rarely thickened in adults. To this section he refers 30 species (*T. maculata*, Lam., &c.), 15 of them new. 2nd. "Anfractibus sulco spirali cingulum posterius efformante; labio interiore incrassato, subelevato." He observes that the species of this section (7, 5 of which are new) somewhat resemble the *Cerithia* in the aperture. 3rd. "Anfractibus sulco postico nullo." These last he divides into two sub-sections, "* with a thin internal lip," which he subdivides into (*a*) those species which have an elongated slender shell, and (*b*) those which have a short shell, and "** with the internal lip thickened and elevated, and the shell short;" and he observes that these approximate somewhat to the *Nassæ*, but have neither the internal dilated lip nor the external thickened lip. This third section contains 8 species, one of which is new.

Dr. Gray does not notice *Subula* of De Blainville, and it may therefore be considered that he does not admit the generic distinction. Woodward makes *Subula* a synonym of *Terebra*, and records 109 recent species.

Fossil Subulæ and Terebræ.—De Blainville refers to his genus *Subula* many of the fossil species which had been considered as *Terebræ*, and which coincide with his definition of the former genus; but he does not enumerate the species, nor draw any distinct line of demarcation between the fossils of these respective genera. He remarks that M. Defrance makes the fossil species of both these genera 17, of which 5 are identical, 3 from Italy, 1 from Grignon, and 1 from Bourdeaux. The 'vis scalarine fossile de l'arnes' De Blainville thinks should be referred to the genus *Terebra*. M. Deshayes, in his Tables, makes *Terebra* (of Bruguière and Lamarck we presume, for he does not notice *Subula*) consist of 44 living species and 16 fossil (tertiary), of which last he considers two new species, and *T. Faval*, *T. strigilata*, and *T. pertusa* to be both living and fossil (tertiary). Dr. Fitton, in his stratigraphical and local distribution of the fossils of the strata below the chalk, records *T. Portlandica* as occurring in the Portland Stone in Dorset, South Wilts, North Wilts, Oxford, and Bucks. Dr. Lea describes and figures three additional species of *Terebra* (Lamarck) from the Claiborne Beds, remarking that 4 species of the genus have been observed in England, 3 in the Oolitic group and 1 in the London Clay. He refers to the 16 species given for the tertiary by M. Deshayes, and says that 10 of these are found at Baden (Miocene) and 7 at Bourdeaux (Miocene). Here is evidently an error in the number. He adds that Mr. Conrad had observed one species, which he calls 'simplex,' in the tertiary of Maryland, "being the only one heretofore observed," adds Dr. Lea, "in our formations." Woodward gives the number of fossil species as 21, and states that they are from the Eocene Beds of Britain, France, and Chili.

Eburna.—Shell oval or elongated, smooth; spire pointed, whorls running together as it were without a marked distinction of suture; aperture inclining to oval, elongated, widened, and deeply notched in front; right lip entire; columella callous posteriorly, umbilicated, subcanaliculated at its external part.

They are found in the seas of warm climates. Of the 9 living species Lamarck refers the locality of three to the East Indies and one to South America and perhaps India.



Eburna glabrata.

Fossil Eburnæ.—De Blainville states in his 'Malacologie' (1825) that no *Eburnæ* had then been discovered in a fossil state. M. Rang remarks (1829) in his 'Manuel' that there are fossil species. Deshayes, in his Tables, records 5 living species and 1 (new species) fossil (tertiary).

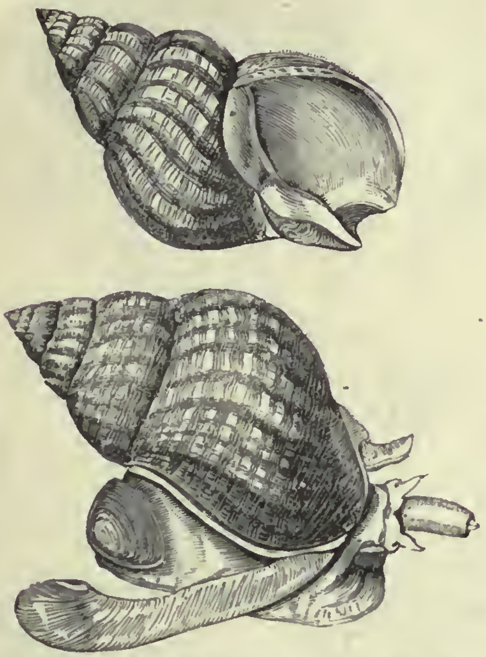
Buccinum.—Shell oval, elongated, with a pointed but moderately-elevated spire; aperture oblong or oval, deeply notched anteriorly; right lip entire, sometimes thick; columella simple or callous; operculum horny, oval, subconcentric; summit but little marked and marginal. [BUCCINUM.]

The geographical distribution is very wide. Species occur in almost all seas. *B. glaciale* and *B. Sabinii* are noted in the 'Supplement to the Appendix of Captain Parry's First Voyage' as having been met with during the period in which the expedition remained within the arctic circle.

The species are very numerous, and have been found at depths ranging from the surface to 17 fathoms. The greater part of the genus is littoral.

De Blainville subdivides the species into many sections comprehending the true *Buccina*, including the genera *Alectrion* (*B. papillosum*) and *Cyclops* (*B. neriteum*) of De Montfort, and the genus *Nassa*, Lamarck. M. De Férussac divides the genus into two sub-genera, namely, the *Buccina* properly so called, of which *B. undatum* may be considered the type, and the *Eburnæ*. M. Sander Rang adopts his arrangement. We confine ourselves to the true *Buccina*.

Ex. *B. undatum*, the Common Whelk. This is the species so commonly exposed for sale as food on the street stalls in the metropolis.



Shell of Common Whelk (*Buccinum undatum*), and animal (male) creeping with its shell and operculum.

B. Lapillus (*Purpura*) is one of the English shells that produce the purple dye, analogous to the *Purpura* of the ancients; and Mr. William Cole, of Bristol, thus describes (1684) the process of obtaining the English *Purpura*:—"The shells being harder than most of other kinds are to be broken with a smart stroke with a hammer, on a plate of iron or firm piece of timber (with their mouths downwards), so as not to crush the body of the fish within; the broken pieces being picked off there will appear a white vein, lying transversely in a little furrow or cleft next to the head of the fish, which must be digged out with the stiff point of a horsehair pencil, being made short and tapering. The letters, figures, or what else shall be made on the linen (and perhaps silk too) will presently appear of a pleasant light green colour, and if placed in the sun will change into the following colours, that is, if in winter about noon; if in the summer an hour or two after sun-rising, and so much before setting; for in the heat of the day in summer the colours will come on so fast that the succession of each colour will scarcely be distinguished. Next to the first light green it will appear of a deep green, and in a few minutes change into a sea green; after which, in a few minutes more, it will alter into a watchet-blue; from that, in a little time more, it will be of a purplish-red; after which, lying an hour or two (supposing the sun still shining), it will be of a very deep purple-red, beyond which the sun can do no more. But then the last and most beautiful colour, after washing in scalding water and soap, will (the matter being again put into the sun or wind to dry) be of a fair bright crimson, or near to the prince's colour, which afterwards, notwithstanding there is no use of any stiptic to bind the colour, will continue the same, if well ordered, as I have found in handkerchiefs that have been washed more than forty times; only it will be somewhat allayed from what it was after the first washing. While the cloth so writ upon lies in the sun it will yield a very strong and fœtid smell, as if garlic and asafœtida were mixed together." ('Phil. Trans.,' Abr. II. 826.)

We have inserted this account here, because the shell which is the subject of it may be more familiar to our readers under the Linnæan name of *Buccinum Lapillus* than of *Purpura Lapillus*, but it is properly arranged under the genus *Purpura*.

Fossil Buccina.—M. Deshayes, in his Tables, makes the number of fossil (tertiary) species 95, and he records the following as both living and fossil (tertiary), *Nassa* not appearing as a genus in his list—*B. undatum, reticulatum, maculosum, mutabile, clathratum, neriteum, Desnoyersi, prismaticum, asperulum, musivum, inflatum, polygonum, D'Orbignii, Linnæi, politum*, and five new species, the names of which are not given. Dr. Fitton notes two species below the Chalk, namely, *B. angulatum* and *B. naticoide* in the Portland Stone (North Wilts, South Wilts, Bucks), and the last-named species in the Portland Sand (Bucks). Dr. Lea notes one species (new), *B. Sowerbii*, in the Claiborne Beds, Alabama. He observes that of the genus 27 species, including *Nassa*, have been observed in Great Britain, several as low as the Mountain Limestone, but chiefly in the London Clay and the Crag. After repeating the number given by Deshayes, Dr. Lea says that the genus appears to be much more abundant in the upper formations. The Pliocene of the Sub-Apennines furnishes 27 species. Bourdeaux (Miocene) 21 species. Paris (Eocene) 9 species. In America, he adds, four species have been found, Mr. Say having described two from the older Pliocene, Maryland, and Mr. Conrad two from York Town, Virginia, also older Pliocene. The fossil species now known, including those of *Purpura*, are about 150.

Nassa.—Animal very much depressed, with a very large foot extending beyond the body on all sides, but especially in front, where it is large and angular, whilst posteriorly it is insensibly narrowed. For the rest like the animal of *Purpura*. Shell globular, oval, or subturriculated; aperture oblong, notched anteriorly; right lip sharp-edged, often plaited within; columellar lip covered with a large callous plate, extending more or less far. Operculum horny.

Dr. Lea ('Contributions to Geology') says, "I have not hesitated to separate this genus from *Buccinum* (although Lamarck united them after having made the division), because they certainly form a very natural group. Cuvier separates it, as De Blainville also does, into a sub-genus." De Blainville certainly makes one of his sections of *Buccinum* consist of the genus *Nassa*; but Rang separates it decisively.

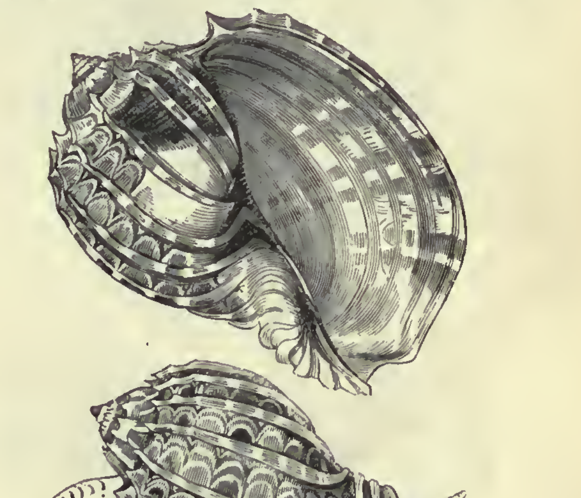
The species of *Nassa* have a world-wide distribution, being found in arctic, tropical, and antarctic seas. They have been found on reefs, coral sand, sand, sandy-mud, and under stones, at depths ranging from the surface to 15 fathoms. About 70 species are known. *N. reticulata* is common on English shores, and called the Dog-Whelk by fishermen. [NASSA.]

Fossil Nassæ.—The species of Fossil *Nassæ* are above 20. They are found in the Eocene Strata of Britain and North America.

*** Ampullaceous *Entomostomata*, or those whose shells are in general globular.

Harpa.—Animal with a large head, without a proboscis, having the mouth opened below; two anterior tentacula, conical, and very much approximated, carrying the eyes upon an enlargement situated externally a little below the middle; foot large, furnished anteriorly with a sort of heel; siphon rather large and a little elongated; branchial pectinations unequal, two in number; orifice of the oviduct at the entrance of the branchial cavity of the right side, orifice in the deferent canal at the extremity of a very voluminous excitatory organ; vent on the same side.

Shell oblong, more or less convex, generally rather delicate, enamelled, furnished with regular longitudinal ribs; spire a little elevated and pointed, the last whorl very large; aperture oval, elongated, widely notched anteriorly, the right lip with an external bourrelet; columella simple, pointed anteriorly. No operculum, according to M. Reynaud.



Shell of *Harpa ventricosa*, and animal crawling with its shell.

The genus is found in the seas of warm climates, and is more especially abundant at the Mauritius and the neighbouring islands, whence the finest of the more common species and the many-ribbed Harps are procured. The animal is said to be of a rich vermilion red. The fishery is principally carried on at low water with a small rake, to which a net is attached, on sand-banks at night, and at sunrise when the Harps are probably out upon their feed. They have been known to take the bait on the fishing-lines laid for olives (*Oliva*). Messrs. Quoy and Gaimard, and afterwards M. Reynaud state, that the animal of the Harp can sometimes, when attacked by an enemy, disembarrass itself of the posterior part of the foot, and completely withdraw itself into the shell. M. Reynaud explains this phenomenon by giving his opinion that the tranverse laceration which causes, in the movement of contraction exerted by the animal, the separation of the posterior part of the foot, arises from the resistance which that part, too voluminous to enter the shell after the animal, encounters from the edges of the shell. M. Rang observes, that though no operculum has been found (and the animal appears to have been carefully examined), he does not hesitate to leave the genus among those which are provided with one, because, in the first place, *Harpa* is similarly organised, and, in the next, if deprived of that appendage, it has, at least, the posterior part of the foot to take, in some sort, its place.

Authors generally make the number of living species eight, and of these the most precious, though lately greatly depressed in value, is the Many-Ribbed Harp (*H. imperialis*). But some of the species are very difficult of definition, though others are well marked. The shells when in fine condition are great favourites with collectors, and indeed a drawer of fine Harps in all the freshness of their beauty is a sight worth seeing. Care should be taken to keep them with their mouths downwards and from the sun and light, or their brilliant colours will soon fade.

Ex. *H. ventricosa*. Locality, Mauritius, &c.

Fossil Harpæ.—Four species are recorded, in the Tertiary Formation.

Dolium.—Animal generally resembling that of *Purpura*. Shell delicate, nearly globular, ventricose, furrowed transversely; spire but little elevated, pointed, the last whorl forming nearly the whole of the shell; aperture large, oval, right lip undulated. Columella often twisted; operculum horny.

The species are found in the seas of warm climates, especially those of India. They are also found in Australia and the Pacific. One species, *D. galea*, inhabits the Mediterranean. The species are often found on reefs, some of them are very large. Fourteen seems to be the greatest number hitherto recorded, and Cuvier has separated the species into two sections, namely the Tuns (*Dolium*) and the Partridge Tuns (*Perdix* of De Montfort.)

Ex. *D. galea*, and *D. perdix*.

Shell of *Dolium galea*, and animal denuded (diminished).

Fossil Dolia.—Seven species are recorded as fossil. They are found in the Miocene Tertiary Beds.

Cassidaria.—Animal supposed to bear a general resemblance to that of *Buccinum* and *Purpura*. Shell ovoid, ventricose, with the spire but little elevated; aperture long, rather narrow, with the anterior canal recurved; right lip furnished with a bourrelet; columellar lip covered by a large callosity, often granulous or wrinkled. Operculum horny.

The seas of comparatively warm climates. Lamarck gives the Mediterranean as the locality of two species. Rang states that only one species is European. De Blainville speaks of the genus as inhabiting all seas except that of the north.

The number of living species recorded appears to be seven.

Ex. *C. echinophora*. Locality, the Mediterranean.

Cassidaria echinophora.

Fossil Cassidariæ.—Deshayes, in his Tables, gives 8 fossil (tertiary) species; and of these, two, namely *C. echinophora* and *C. Tyrrhena*, he records as both living and fossil (tertiary). The number of fossil species is about ten. They are found in the Eocene Beds of Great Britain and France.

Oniscia.—A genus separated from *Cassidaria* by Mr. G. B. Sowerby, and considered by him as having its place next to that genus in the natural system. It differs from *Cassis* in the canal not being suddenly reflected; but Mr. Sowerby states that he has seen *Cassides* which very nearly approach *Oniscia* in the form of the aperture, and in the short scarcely reflected canal. He thinks that the genus is intermediate between *Cassidaria* and *Cassis*.

Shell oblong, sub-cylindrical, apex generally rather obtuse, spire short, sometimes very short; base rather acuminated; aperture longitudinal, elongated, extending at the base into a very short canal: outer lip thickened, denticulated within, and rather contracted in the centre; inner lip expanded and covered with granules. (Sowerby.) The outside of the shell is tuberculated, cancellated, or ribbed. "Of the animal," says Mr. Sowerby, "we know nothing; but there is every reason for believing it to be related to that of *Cassis*, and that it has an operculum, though we have never seen it."

Six living species are recorded, from the West Indies, China, and the Galapagos.

Ex. *O. cancellata*.

Oniscia cancellata, adult.

Three fossil species are recorded, from the Miocene Beds of the Tertiary Strata.

Cassis.—Animal said to resemble generally that of *Purpura*. Shell inclining to oval, convex, with a spire but little projecting, nearly flat; aperture oblique, long, and narrow, with the anterior canal very short and recurved towards the back; right lip thick, furnished with an external bourrelet, and toothed within; columellar lip callous, nearly straight, and marked nearly throughout its length with transverse long teeth. Operculum horny, very rudimentary.

The species occur principally in very warm latitudes in shallow water: two or three are said to be found in the Mediterranean.

The number of living species is about thirty-four. These are divided into two groups by Lamarck; the first consisting of those species whose spire is marked by bourrelets (*C. cornuta*, for example); and the second of those whose spire is without bourrelets (*C. rufa*, for example).

De Blainville divides the species into two groups also; the first consisting of those whose aperture is long, and the external lip nearly straight (*C. tuberosa*, for example); the second of those whose aperture is suboval, and the external lip excavated (*C. flammea*, for instance).

Ex. *C. tuberosa*. Locality, West Indian Seas.

Fossil Cassides.—The number of fossil (tertiary) species is 36; of these are *C. flammea*, *C. granulosa*, *C. crumena*, *C. saburon*, *C. bisulcata*, and a new species, both living and fossil (tertiary).

Shell of *Cassis tuberosa*; and animal denuded of *Cassis sulcosa* (diminished).

The fossil species are principally found in France and Chili.

Ricinula.—Animal nearly entirely resembling those of *Buccinum* and *Purpura*. Mantle provided with a tube; foot much wider, and auriculated, as it were anteriorly; head semilunar, with conical tentacula, supporting the eyes at the middle of their external surface; excitatory organ of the male very large, recurved in the branchial cavity. Such is De Blainville's description, who made his observation on 'la Ricinule horrible,' *R. horrida*.

Shell oval or sub-globular, thick, beset with points or tubercles, with a very short spire; aperture narrow, long, with a notch (which is sometimes sub-canaliculated) anteriorly; right lip often digitated, externally and toothed within; the left lip callous and toothed or wrinkled. Operculum horny, oval, transverse, concentric. De Blainville describes the elements of the operculum as a little imbricated.

There are 29 species of this genus. They are from India, China, the Philippines, Australia, and the Pacific.

The species have been found on coral reefs and rocks.

De Blainville separates the species into three sections: the first consisting of those with an evident canal anteriorly and behind the aperture (en arrière de l'ouverture), *R. digitata*; the second of those without a canal and beset with spines, *R. horrida*; and the third of those without a canal and tuberculous, *R. morus*. He observes that this genus is evidently artificial: thus it contains one species which is a true *Murex*, whilst others are closely approximated to certain species of *Turbinella*; in fact, they have two or three plaits on the columella; finally, some of them scarcely differ, he says, from the true *Purpuræ*.

Ex. *R. horrida*.

Ricinula horrida.

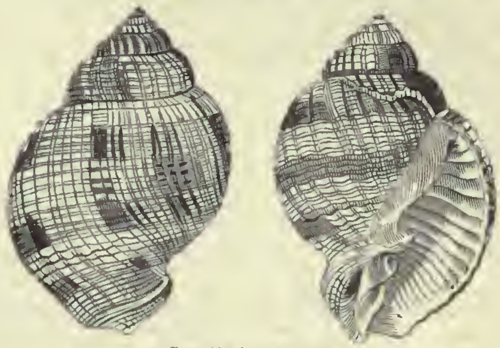
Three Fossil *Ricinulæ* have been recorded.

Cancellaria.—Animal said to resemble generally that of *Purpura*. Shell oval or globular, rather convex, reticulated, thick, with a spire slightly elevated and pointed; aperture demioval, notched or subcanaliculated anteriorly; right lip sharp-edged, striated within; columella nearly straight, with many well-defined plaits. Operculum horny.

The species are all exotic, and the inhabitants of warm seas. The localities of the bulk of those known are said by De Blainville to be inhabitants of the Indian and African seas. The species have been found on sandy bottoms, at a depth ranging from 7 to 16 fathoms.

De Blainville observes that the genus as adopted by him is not entirely the same as that of Lamarck. De Blainville withdraws from the genus the species whose aperture is evidently canaliculated, such as *C. senticosa*, which, as it appears to him, ought to remain among the *Murices* or the turriculated *Turbinellæ*. Deshayes, in his Tables, makes the number of living species 13. Mr. G. B. Sowerby ('Zool. Proc.,' 1832) describes 22 new species from the collection of Mr. Cuming, most of them from the warm latitudes of the Pacific side of South America. One of them, *C. uniplicata*, dredged in sand near Panama at a depth of 10 fathoms, is the only species known to Mr. Sowerby with a single fold on the columella. Woodward ('Manual') gives 70 recent species.

Ex. *C. reticulata*. Locality, Southern Atlantic Ocean. (Lamarck.)



Cancellaria reticulata.

Fossil Cancellariæ.—Lamarck records 7 fossil species. Rang says there are a good number. De Blainville observes that, according to Defrance, there are 20 species, two of which are identical, one from Italy, the other from Grignon, and one analogue from Italy. Deshayes makes the number of fossil (tertiary) species 42, one of which he notes as both living and fossil (tertiary). Dr. Lea describes and figures, in addition, 8 species from the Tertiary Formation of Alabama (Claiborne). He observes that the genus has been observed in England only in the London Clay, whence three species have been described; and, referring to Deshayes's Tables and his 42 species, remarks that 16 are from the Sub-Apennines (Pliocene), 12 from Bourdeaux (Miocene), and 5 from Paris (Eocene). In America, he observes, a single species only, *C. lunata* (Conrad), had been theretofore observed. It was from the Tertiary Beds of Saint Mary's. Woodward gives 60 species, all Eocene.

Purpura.—Animal rather elongated, widened in front; head large with a very short proboscis; two tentacula, generally in front and approximated, conical, and supporting the eyes on an enlargement situated at the middle of their external part; mouth below, nearly always hidden by the foot, which is rather large, very much advanced, and bilobated, as it were, anteriorly; branchial pectinations two, unequal; orifice of the oviduct at the entrance of the branchial cavity on the right side; orifice of the deferent canal at the right side of the neck, at the extremity of the exciting organ, which is generally voluminous; vent on the same side.

Shell of *Purpura Persica*, and animal of *Purpura hæmostoma*.

Shell oval, thick, unarmed or tubercular, with a short spire, the last whorl larger than all the others together; aperture very much dilated, of an oval form, terminated anteriorly by an oblique notch;

columella flattened, finishing in a point anteriorly; right lip sharp-edged, often thickened and furrowed internally, or strongly armed anteriorly with a conical point. Operculum horny, demicircular, the summit posterior.

The form is widely distributed, but the number of European species is very small; the greatest development takes place in warm seas, where the species are most abundant, particularly in South America. The larger proportion of the species of this genus are littoral. The true *Purpuræ* have been found at depths ranging from the surface to 25 fathoms, and the division which forms the genus *Monoceros*, generally on rocks, at depths ranging from the surface to 7 fathoms.

De Blainville states that there are 50 living species of ordinary *Purpuræ*, of which four only belong to the French seas. The species of *Monoceros* he states to be five, all from South America. Deshayes, in his Tables, gives 76 as the number of living species of the genus *Purpura* (Lam.), and 6 as that of the living species of *Monoceros*. Dr. Lea states that his cabinet has nine. Mr. Broderip describes two new species, and Mr. Powys one, from Mr. Cuming's collection (Port St. Elena, Valparaiso, and Maldon Island, in the Pacific), and Mr. Broderip another, *Purpura Gravesii*, figured under the name of *Murex cariniferus*, in Mr. Sowerby's 'Conchological Illustrations.' ('Zool. Proc.') Mr. Sowerby describes nine species of *Monoceros*, among them *M. punctulatum* (Gray), from Mr. Cuming's collection. Woodward puts down the species at 140.

De Blainville divides the species into four sections:—1st. Those whose right lip, near the notch, is armed with a conical horn, or tooth, which is pointed, and more or less curved. This section is the genus *Monoceros* (De Montfort), the animal of which, according to M. Rang and others, differs in nothing from that of the other *Purpuræ*. 2nd. The Buccinoid *Purpuræ*, whose lip is without a tooth, and whose aperture is moderately widened. *Purpura Lapillus* (*Buccinum Lapillus*, Linn.), for example. (See above, *Buccinum*.) 3rd. The Patulous *Purpuræ*, also without a tooth at the lip, and whose aperture is very wide: *Purpura Persica* for instance. 4th. The ventricose tuberculated species, of which he gives *P. neritoides* as the type. M. Rang divides the species into two groups only. The first, consisting of those which have the right lip simple, or only furrowed internally: the second, of those whose right lip is always thickened and armed anteriorly with a conical point.

Example of the first, *Purpura Persica*. Locality, East Indian seas.

Example of the second, *Purpura imbricata* (*Monoceros imbricatum*, Lam.). Locality, South America.

Purpura imbricata (*Monoceros imbricatum*, Lam.).

Fossil Purpuræ.—De Blainville states ('Malacologie') that no fossil species of *Monoceros* were then known. Deshayes, in his Tables, records one (tertiary) from Italy. Dr. Lea describes and figures three new fossil species from the Tertiary of Claiborne, Alabama (Eocene of Lyell). Of the ordinary *Purpuræ* De Blainville states that there are nine fossil species, one of which is the analogue of *P. Lapillus* (*Buccinum Lapillus*, Linn.), so common on our coasts, as well as those of France. Deshayes, in his Tables, gives the number of fossil (tertiary) species as four, of which he records one, *P. hæmastoma*, as both living and fossil. Woodward states the fossil species to be thirty.

**** Patelloid *Entomostoma*; that is, one whose shell is very large in its totality, very flattened, with a spire but little marked, and without a columella.

Concholepas.—De Blainville speaks of the animal as entirely unknown; but according to Lesson it resembles that of *Purpura*. Shell thick, rude, and wrinkled transversely on its external surface: spire very small, hardly projecting; aperture oval, very large, notched anteriorly, where there are two dentiform appendages; no columella; muscular impression of a horse-shoe shape, and very visible. Operculum horny, transparent, trapezoidal, concentric, with a marginal summit.

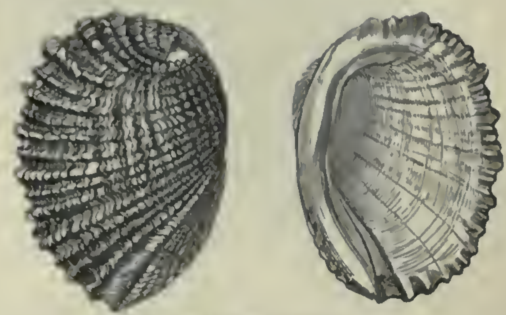
South America is the locality of *Concholepas*. It is very abundant on the coasts of Peru and Chili, and sometimes attains to a very large size.

Concholepas is only known as a littoral species.

Lamarck first placed *Concholepas* near *Purpura*. Cuvier gives it very nearly the same position. M. Rang remarks that he might have well united the genus to *Purpura*, after the example of De Férussac. In fact, he adds, M. Lesson's communication touching the animal which the latter brought home from the South Sea had proved to M. Rang that it differs in nothing from that of *Purpura*; its operculum alone affords a well-defined character.

There is but one species known; but M. Rang states that there are two distinct varieties.

Ex. *C. Peruviana*.



Concholepas Peruviana.

Concholepas is not known in a fossil state, properly so called. It occurs among other species of the coast at considerable elevations above the sea.

ENTOMO'STRACA (Müller), *Shell Insects*, for such is the meaning of the term applied to certain Aquatic Animals forming, according to Latreille and others, the second general division of the Crustaceans, and for the most part inhabiting the fresh-water. The brain, or rather the nervous knots which supply its place, consists of one or two globules merely. The heart is in the form of a long vessel. The branchiæ, composed of hair-like processes, which are either isolated or connected in a beard-like form, a pectinated shape, or one resembling aigrettes, form a portion of the feet, or of a certain number among them, and sometimes mandibles and the upper jaws. [CYPRIS; BRANCHIOPODA.] The number of the feet varies, and in some of the genera is above a hundred. These feet, ordinarily, are proper for no purpose but swimming; and are sometimes ramified or divided, and sometimes furnished with pinnules, or composed of lamellar joints. Nearly all of them have a shell, consisting of from one to two pieces, very delicate, and most frequently almost membranous and transparent, or at least a large anterior thoracic segment, often confounded with the head and appearing to replace the shell. The integuments are generally rather horny than calcareous, a condition which, as Latreille remarks, approximates the Entomostracans to the Insects and Arachnids. In those which are provided with ordinary jaws, the inferior or external ones are always uncovered, all the jaw-feet (pieds-mâchoires) performing the office of true feet, and none of them being applied upon the mouth. The second jaws, with the exception of the *Phyllopoda*, resemble those organs, and Jurine has sometimes designated them under the name of hands. These characters, says Latreille, distinguish the Masticating *Entomostraca* (Entomostraces Broyeurs) from the *Malacostraca*; the other *Entomostraca* which compose his order *Pœcilopoda* cannot, he says, be confounded with the *Malacostraca*, because they are deprived of organs fit for mastication, or because those parts which appear to perform the office of jaws are not collected anteriorly and preceded by a labrum as in the true *Crustacea* and the Masticating Insects (Insectes Broyeurs), but simply formed by the haunches of the locomotive organs, and furnished, for the purpose of enabling them to execute that office, with small spines. The *Pœcilopoda*, he observes, represent in this class those of the class of insects which are denominated Suctorial (Suceurs). They are almost all parasites, and seem to lead us by degrees (par nuances) or shades of difference to the *Lernææ*; but the presence of eyes, the property of moulting or changing the skin, or even of undergoing a metamorphosis, and the faculty of being able to transport themselves from one place to another by means of feet, appear to Latreille to establish a well-defined line of demarcation between the animals last named and the preceding. With regard to the metamorphosis, he remarks, that the young of the *Daphniæ* and of some other nearly allied genera, those probably also of *Cypris* and of *Cytherina*, differ not at all or scarcely at all from their parents, in point of form, at the time of their exclusion from the egg; but the young of *Cyclops*, of the *Phyllopoda*, and of *Argulus*, undergo in their infancy remarkable changes, as well in the form of the body as in the number of feet. These organs indeed in some (in the *Arguli* for instance) suffer transformations which modify their uses. The same author states that he has consulted, relative to these transformations, several well-informed naturalists, who have had frequent occasion to observe the *Lernææ*, and that those observers had never seen a *Lernæa* change its skin. The antennæ of the *Entomostraca*, the form and number of which vary much, serve in many for swimming. The eyes are very rarely placed upon a pedicle, and when they are so placed the pedicle is no more than a lateral prolongation of the head, and is never articulated at its base. The last-named organs are often very much approximated, and even compose one only. The tail is never terminated by a fan-shaped fin, and never presents the false feet of the *Malacostraca*. The eggs are collected under the back, or external, and under a common envelope, having the form of one or two small groups situated at the base of the tail. They possess the power of preserving their vitality for a long time in a state of desiccation. [BINOCULUS.] It would appear that not less than three moults are undergone by many of these animals before they become adult and capable of propagating their species, and it has been proved, in the case of some of them, that a single copulation will fecundate many successive generations. [BRANCHIOPODA.] Dr. Baird, in his interesting Monograph on the British *Entomostraca*, gives the following general account of this family :—

"The greater number of these little creatures are furnished with branchiæ, either to their feet or maxillæ, and when noticed in their native habitats, may be seen to have them constantly in motion, their action being seldom interrupted. One chief use therefore of them in the economy of nature may be, as Müller says, to ventilate the water day and night; and as they chiefly reside in standing pools, they may thus be of great use in preventing them from becoming soon putrid.

"As this may be considered one of the benefits conferred by these insects, it may be useful to know the evils to man they may be likely to produce.

"Though they are most abundant in stagnant water, they yet occur in considerable numbers in the purer sorts of water that serve as our common drink, and may frequently be seen even in the drinking water of London, Edinburgh, and other large towns; and Müller asserts very gravely, that as we thus drink them alive, and with their eggs, he would not be surprised were we to discover them some day in the human intestines. 'The time,' he says, 'is at hand, when the causes of disease shall not only be sought after in the air, in our method of living, &c., but in the incautious use of waters often abounding in innumerable animalcules.' According to Müller and Straus, the greater number of the *Entomostraca*, not parasitical, live upon vegetable matter, and not upon animals; and the former, in an experiment he instituted, says, that in keeping a number of species, such as the *Daphnia pennata* and *longispina*, *Cypris strigata* and *pilosa*, *Lynceus sphericus*, and *Cyclops quadricornis*, in the same water from the 24th of July to the 22nd of January, during which time the water had evaporated from a depth of five inches to that of one, he frequently subjected small quantities of this water to the microscope, and he was never able to discover any animalcules in it upon the most attentive examination, though the intestines of the *Entomostraca* themselves were seen to be full, sufficiently proving that they had not fasted during that time. This assertion however I am much inclined to call in question. The *Cyprides* particularly seem to be most voraciously carnivorous; and I have invariably found it exceedingly difficult to keep for a length of time any other *Entomostraca* alive in the same vessel with the larger species of *Cypris*. In a vessel, in which I have kept full grown *Chirocephali*, there were mixed with them many specimens of the *Cypris tristriata*. In a few days the *Chirocephali* might be seen to become languid in their movements, and assume an unhealthy appearance. The *Cyprides* had become their deadly enemy. They might be seen ever and anon to fasten themselves to the delicate feet of the poor *Chirocephali*, and wofully impede their course through the water; and when, either from these annoyances, or from any other cause, they ceased to be able to move with any degree of rapidity, hosts of these little *Carnivora* might be observed to attack them before life was extinct, anticipating as it were their victims' death. Then, when life had fairly ceased, they rioted upon their flesh, and in a few hours little but the external covering was left.

"I have no doubt that most of the *Entomostraca* are essentially carnivorous, and I have frequently seen specimens of *Cypris* in their turn, as soon as dead, attacked immediately by quantities of the *Cyclops quadricornis*, who in a few minutes had fastened themselves upon the dead animal, and were so intent upon their prey that they were scarcely frightened away from it by being touched with a brush. In a short time the *Cypris* might be seen lying at the bottom of the vessel, the valves of the shell separated and emptied of their contents. Leuwenhoek and De Geer not only maintain that the *Cyclops quadricornis* lives upon animalcules, but that it even preys upon its own young, a fact which I have also noticed myself. Jurine asserts that the *Cyclops quadricornis* is carnivorous from taste, and only herbivorous from necessity; while the *Daphnia pulex*, he distinctly affirms, lives upon animalcules. Place a few *Entomostraca*, such, for example, as the *Daphniæ*, *Chirocephali*, *Lyncei*, &c., in a vessel with clear pure water, and only some vegetable matters in it, and they gradually become languid, transparent, and finally die; but mix with this water some which contains numerous *Infusoria*, and the *Entomostraca* will then be seen speedily to assume another aspect. They become lively and active, and the opacity of their alimentary canal testifies sufficiently the cause of it. When indeed we consider the amazing quantity of animals which swarm in our ponds and ditches, and the deterioration of the surrounding atmosphere which might ensue from the putrefaction of their dead bodies, we see a decided fitness in these *Entomostraca* being carnivorous, thus helping to prevent the noxious effects of putrid air which might otherwise ensue; whilst they in their turn become a prey to other animals, which no doubt serve their purposes also in the economy of nature.

"The fresh-water *Gammari* seem to prey upon them, and the *Hydrachnæ* are their decided enemies; 'for,' says Müller, 'they seize hold of them while swimming by their feet, and daintily suck the life's blood out of their captives with their sharp beaks. The *Hydræ* also, and not a few aquatic larvæ, lay snares for them; and many *Vorticellæ* frequently greviously infest them, for they not only adhere (often in heaps) to the members projecting beyond the shell, but they overspread the whole body with their own colonies, not a little retarding the motion and agility of their host.' The larva of the *Corethra plumicornis*, known to microscopical observers as the Skeleton Larva, is exceedingly rapacious, more especially of the *Daphniæ*. They seize their prey with the rapacity of a pike, grasping it with their two strong jaws and gorging it alive. Pritchard says they are the choice food of a species of *Naia*, which he calls the *Lurco*, and which devours them in great numbers. The *Chydorus sphericus* is their especial favourite, and I have repeatedly verified Pritchard's observations, having counted at least ten individuals swallowed alive, and lodged in the different stomachs of this glutton. Those in the first and second stomachs were still alive, while those contained in the inferior ones were more or less partially decomposed.

"The marine species are also preyed upon by their different enemies, amongst which are the *Beröes*. 'The fact of *Beröes* feeding upon small *Crustacea*,' says Mr. Paterson, 'has been recorded by Fabricius, and at present appears to rest upon his authority. It was interesting to observe the fact, which I did, without knowing it was previously known. The *Crustacea* were almost as visible in the transparent body of the *Beröe* as they had previously been, and very conspicuous by the bright green of their colouring.'

"That the *Entomostraca* form a considerable portion of the food of fishes has been long observed, and it is very probable that the quality of some of our fresh-water fishes may in some degree depend upon the abundance of this portion of their food. Dr. Parnell informs us that the Loch Leven trout owes its superior sweetness and richness of taste to its food, which consists of small shells and *Entomostraca*. The colour of the Loch Leven trout, he farther informs me, is redder than the common trout of other localities. When specimens of this fish have been removed from the Loch and conveyed to lakes in other places, the colour remains, but they very soon lose that peculiar delicacy of flavour which distinguishes so remarkably the trout of Loch Leven. The experiment has been repeatedly tried, and always with the same results. The Bansticle devours them with great rapidity; and I have seen two or three individuals clear in a single night a large basin swarming with *Daphniæ*, *Cyclops*, &c."

The following is the arrangement of this family adopted by Dr. Baird :—

Sub-Kingdom ANNULOSA.

Class CRUSTACEA. Division ENTOMOSTRACA.

Legion I. BRANCHIOPODA. [BRANCHIOPODA.]

Order I. PHILLOPODA.

Family 1, APODIDÆ, containing one genus	*Apus*.
Family 2, NEBALIADÆ, containing one genus	*Nebalia*.
Family 3, BRANCHIPODIDÆ, containing two genera	*Chirocephalus*. [CHIROCEPHALUS.] *Artemia*. [ARTEMIA.]

Order II. CLADOCERA.

Family 1, DAPHNIADÆ, containing six genera	*Daphnia*. [DAPHNIA.] *Moina*. *Bosmina*. *Macrothrix*. *Sida*. *Daphnella*.
Family 2, POLYPHEMIDÆ, containing two genera	*Polyphemus*. *Evadne*.
Family 3, LYNCEIDÆ, containing seven genera	*Eurycercus*. *Chydorus*. [CHYDORUS.] *Camptocercus*. *Acroperus*. *Alona*. *Pleuroxus*. *Peracantha*.

Legion II. LOPHYROPODA.

Order I. OSTRACODA.

Family 1, CYPRIDIDÆ, containing five genera	*Cypris*. *Candona*. *Cythere*. [CYTHERE.] *Cythereis*. *Cypridina*.

Order II. COPEPODA.

Family 1, CYCLOPIDÆ, containing four genera	*Cyclops.* *Canthocamptus.* *Arpacticus.* *Alteutha.*
Family 2, DIAPTOMIDÆ, containing three genera	*Diaptomus.* *Temora.* *Anomalocera.*
Family 3, CETOCHILIDÆ, containing one genus	*Cetochilus.*
Placed here provisionally, genus .	*Notodelphys.*

Legion III. PŒCILOPODA. [PŒCILOPODA.]

Order I. SIPHONOSTOMA.

Tribe 1. PELTOCEPHALA.

Family 1, ARGULIDÆ, containing one genus	*Argulus.* [ARGULUS.]
Family 2, CALIGIDÆ, containing four genera	*Caligus.* [CALIGUS.] *Lepeoptheirus.* *Chalimus.* *Trebius.*
Family 3, PANDARIDÆ, containing two genera	*Dinemoura.* *Pandarus.*
Family 4, CECROPIDÆ, containing two genera	*Cecrops.* *Læmargus.*

Tribe 2. PACHYCEPHALA.

Family 1, ANTHOSOMADÆ, containing one genus	*Anthosoma.*
Family 2, ERGASILIDÆ, containing one genus	*Nicothoë.*

Order II. LERNEADÆ. [LERNEADÆ.]

Tribe 1. ANCHORASTOMACEA.

Family 1, CHONDRACANTHIDÆ, containing two genera . .	*Chondracanthus.* *Lernentoma.*

Tribe 2. ANCHORACARPACEA.

Family 1, LERNEOPODODÆ, containing one genus . . .	*Lerneopoda.*
Family 2, ANCHORELLADÆ, containing one genus . . .	*Anchorella.*

Tribe 3. ANCHORACERACEA.

Family 1, PENELLADÆ, containing one genus	*Lerneonema.*
Family 2, LERNEOCERADÆ, containing two genera	*Lerneocera.* *Lernea.*

In M. Latreille's second method, the *Entomostraca* were treated as a sub-class, with the following characters :—Mandibles naked or none; mouth formed of two rows of pieces; antennæ and feet of a branchial form; tarsi without a horny nail at the end; shell clypeaceous or shield-like, univalve or bivalve, or with annular horny or membranous segments of the body; eyes sessile, often united so as to form one.

1st Section. (Operculés, shell univalve or bivalve.)

*

Shell Univalve. (Clypeacés.)
1st Order, Xyphosures. (Ex. *Limulus.*)
2nd Order, Pneumonures. (Ex. *Ozolus.*)
3rd Order, Phyllopodes. (Ex. *Apus.*)

**

Shell Bivalve. (Ostrachodes.)
4th Order, Ostrachodes. (Ex. *Cypris.*)

2nd Section. (Nues, body annulated throughout its length.)
5th Order, Pseudopodes. (Ex. *Cyclops.*)
6th Order, Cephalotes. (Ex. *Polyphemus.*)

In the last edition of Cuvier's 'Règne Animal,' M. Latreille divides the *Entomostraca* into two orders :—

I. BRANCHIOPODA.

II. PŒCILOPODA.

The PŒCILOPODA he divides into two families :—

1st. *Xyphosura.*

This family consists but of one genus, namely, *Limulus.*

2nd. *Siphonostoma.*

This family he separates into two tribes :—

1. *Caligides.*

This tribe contains the genera *Argulus*, *Caligus*, and its sub-genera *Pandarus*, *Dinemoura*, &c., and *Cecrops.*

2. *Lernæiformes.*

This tribe consists of *Dichelestium* and *Nicothoë.*

M. Milne-Edwards remarks, that at the first glance the branchial feet of *Apus* and of many other *Entomostraca* would appear to have hardly anything in common with the ambulatory feet or buccal members of the Decapods; but, nevertheless, the same parts are found among the former. In fact, he observes, in the great foliaceous laminæ or blades, the structure of which seems as complicated as it is anomalous, the analogues of the flagrum (fouet), palp, and stem (tige) are easily traced. The first of these appendages constitutes the flattened vesicle which occupies the basilary and external part of the foot: its form is the same as among the Stomapods, and its structure further confirms the approximation.

The last-named author proposes the following method, differing from that of Latreille not only in the number of the orders under which the different *Crustacea* are arranged, but also in the limits assigned to many of these divisions :—

A. Mouth deprived of special organs of mastication.

Orders.
Xyphosures.
Siphonostomes.

B. Mouth armed with special organs of mastication, namely, with one pair of mandibles, and with one or more pairs of jaws.

Orders.

Ostrapodes.	Isopodes.
Cladoceres.	Amphipodes.
Phyllopodes.	Stomapodes.
Copépodes.	Decapodes.
Læmipodes.	

M. Milne-Edwards further states that Latreille, a little before his death, was again occupied with the subject, and introduced into his method many modifications, which made it approach nearly to that proposed by M. Milne-Edwards. The latter says that Latreille in fact admitted into the class *Crustacea* 12 orders, namely, the Decapods, the Stomapods, the Læmipods, the Amphipods, the Isopods, the Dicladopods, the Lophyropes, the Ostrapods, the Xyphosures, and the Siphonostomes; and that the Dicladopods very nearly correspond to the Copepods of M. Milne-Edwards. The last-named author, when speaking of Latreille's classification in the first edition of the 'Règne Animal,' speaks of Latreille's not attaching to the distinction of *Malacostraca* and *Entomostraca* an importance which those divisions do not deserve; but M. Milne-Edwards still retains the term *Entomostraca;* for we find in his synoptical table ('Histoire Naturelle des Crustacés—Suites à Buffon'), under the sub-class of Maxillated Crustaceans, the legion of Branchiopods, containing the orders *Ostrapoda* and *Phyllopoda*, and the legion of *Entomostraca*, consisting of the orders *Copepoda* and *Cladocera.*

The reader who wishes to study the classification, economy, and anatomy of the *Entomostraca*, should more particularly consult, besides the works above alluded to, those of Swammerdam, Needham, Leuwenhoek, De Geer, Ramdhor, Schöffer, Straus, Hermann, the younger Fabricius, the Jurines, father and son, Adolphe Brongniart, Slabber, Desmarest, De Blainville, Thompson, and Audouin.

Fossil Entomostraca.

The remains of small *Crustacea* evidently referrible to this family have been found in many strata. Setting aside the *Trilobites*, whose affinities are evidently with the *Entomostraca* [TRILOBITES], and which abounded in the earliest Palæozoic Rocks, species belonging to the group *Ostracoda* have been described as occuring in the older Secondary Rocks. M. Hitsinger has figured and described two species from the Silurian Rocks of Sweden; Count Münster has given short descriptions of eight species from the Bergkalk of Regnitztorae near Hof; Professor M'Coy has figured and described twenty-two species from the Carboniferous Limestone of Ireland; M. de Koninck six species from the Carboniferous System of Belgium, and Mr. Bean one species from the Newcastle Coal-Beds. Species have also been described by Portlock, Horner, Hibbert, and Murchison, making altogether about thirty-seven distinct forms belonging to the Silurian and Carboniferous Rocks. Ten species have been described from the Magnesian Limestone of North Britain, and Mr. Rupert Jones has described twenty-six species from the Chalk. The fossil species mostly belong to the genus *Cythere.* [CYTHERE.] Species have also been found in the Wealden Beds of Great Britain and in the Tertiaries of Europe. The forms of the *Entomostraca* have at present been only partially examined, but the results already obtained lead to the conviction that in all strata there are deposits of these animals which, when properly examined into, will lead to the discovery of many new and instructive forms.

(Jones, *On the Entomostraca of the Cretaceous Formations of England*, and *On Permian Fossils*, in *Palæontographical Society's Works.*)

ENTOPHYTA (from ἔντον and φυτόν), a term applied to plants found living within animal bodies. The term *Epiphyta* has been applied to those forms of plants which live upon the external parts of organised beings whether plants or animals. It is however difficult to draw the line between these two classes, because it frequently happens that a plant whose spores are deposited in the interior of an animal body, in the course of growth find their way to the surface. The term Epiphyte has also been employed to designate those higher forms of plants, more especially the *Orchidaceæ* which are found growing on other plants, so that the term Entophyte is more especially used to designate those cryptogamic plants which grow on the skin or mucous membranes of animals. These will be more particularly referred to here. At the same time it should be observed that a large number of cryptogamic plants are found in the living tissues of other plants, and claim to be regarded as Entophytes in relation to the vegetable kingdom.

The study of *Entophyta* has been invested with considerable interest, since by the aid of the microscope so many of these plants have been detected accompanying various diseased conditions of the animal body. Although they have been perhaps more carefully investigated in the human body, it has been for a long time a familiar fact that many of the lower animals are attacked by these plants in states of disease. Thus the cultivators of the silk-worm have observed the growth of a species of *Botrytis* in the organs of that animal, producing great destruction amongst them, and the occurrence of this fungus is known by the name of Muscardine. [MUSCARDINE.] Caterpillars have been brought to this country from New Zealand, Australia, and China, as curiosities, from the bodies of which a species of *Clavaria* or *Sphæria* of considerable size is found to project. A species of *Polistes*, a kind of wasp, has been observed in the West Indies to be subjected to the attacks of a fungus which appeared on the surface of its body in the form of a growth as large as itself. The common house-fly is often seen in the autumn of the year adhering helplessly to a pane of window-glass from the growth of a fungus on its body, which has not been free from the suspicion of producing even so formidable a disease as cholera. Gold-fish, when kept in confinement, as well as water-salamanders and sticklebacks, have been observed to be covered with a fungus (*Achlya prolifera*) before death.

These facts, and many others, have from time to time attracted attention, which, having been followed up by diligent observations with the microscope, have led to the discovery of a very large class of vegetable bodies taking up their ordinary residence within or upon animal surfaces.

A question has been raised as to whether these plants are the natural products of the bodies on which they are found, as other plants are of the soil in which they grow, or are introduced from some foreign and extraneous source. From the observations that have been made up to the present time, it appears that these plants are truly in their natural positions in the localities in which they are found, and that they only multiply or become sources of disease when the bodies on which they grow get into a disordered state. In the same manner the ova of animalcules seem constantly present in the air and water, only awaiting the proper combination of circumstances to be developed in prodigious numbers. The circumstances which predispose to the growth of these Entophytes upon the body, are not better known than those which predispose the body to receive certain contagions. A failure of the ordinary vital powers to carry on the healthy processes of life seem ordinarily to be the inviting cause of such a development of these plants as would constitute a disease.

All the observations that have been made on this important subject have been brought together by M. Robin in his work on the 'Natural History of the Parasitic Vegetables which Grow on Man and on Living Animals' (Paris, 1853). The following is a classification of these plants:—

I. ALGÆ.

Class *Isocarpeæ*.
 Sub-Class I. *Diatomeæ*.
  Genus *Psorospermia*, 11 species.
 Sub-Class II. *Malacophyceæ*.
  Tribe *Gymnospermeæ*.
   Order I. *Eremospermeæ*.
    Sub-Order I. *Mycophyceæ*.
     Family *Cryptococceæ*.
      Genus *Cryptococcus*, 2 species.
  Tribe *Palmelleæ*.
      Genus *Merismopædia ventriculi*. [SARCINA.]
     Family *Leptothriceæ*.
      Genus *Leptothrix*, 2 species.
      Genus *Cladophytum comatum*.
      Genus *Arthromitus*, 2 species.
  Tribe *Leptomiteæ*.
      Genus *Leptomitus*, 6 species.
      Genus *Moulinica*, 3 species.
  Tribe *Laprolegnieæ*.
      Genus *Saprolegnia ferax*.
      Genus *Enterobryus*, 4 species.
      Genus *Eccrina*, 2 species.
    Sub-Order III. *Tiloblasteæ*.
     Family *Oscillarieæ*.
      Genus *Oscillaria*.
      Genus *Zygnæma cruciatum*.
   Order II. *Cryptospermeæ*.
     Family *Chætophoreæ*.
      Genus *Chætophora meteorica*.

II. FUNGI.

Division I. *Arthrosporei*.
  Tribe *Torulacei*.
      Genus *Trichophyton*, 3 species.
      Genus *Microsporon*, 3 species.
      Genus *Sporendonema musca*.
  Tribe *Oidiei*.
      Genus *Achorion Schœnleinii*.
      Genus *Oidium*, 3 species.
  Tribe *Aspergillei*.
      Genus *Aspergillus*, 8 species.
Division II. *Trichosporei*.
  Tribe *Oxycladei*.
      Genus *Dactylium oogenum*.
      Genus *Botrytis Bassiana*.
  Tribe *Sporotrichei*.
      Genus *Sporotrichum*.
  Tribe *Isariei*.
      Genus *Isaria*, 12 species.
Division III. *Cystoporei*.
  Tribe *Columellati*.
   Section *Ascophorei*.
      Genus *Mucor Mucedo*.
Division IV. *Chirosporei*.
  Tribe *Coniopsidei*.
   Section *Phragmidiei*.
      Genus *Puccinia favi*.
 Sub-Division *Endoclivei*.
   Section *Spheronomei*.
      Genus *Laboulbenia*, 2 species.
  Tribe *Sarcopsidei*.
      Genus *Stilbum Buquetii*.
Division V. *Thecasporei*.
  Tribe *Sphæriacei*.
      Genus *Sphæria*, 8 species.
      Genus *Kentrosporium*, 2 species.

The following is a list of the distribution of the species of the above genera in the various localities of the animal body.

I. Man and the *Mammalia*.
 A. The Skin.
  Trichophyton tonsurans. Malmsten. (On Hairs.)
  T. sporuloides. Ch. Robin.
  T. ulcerum. Ch. Robin. (On Ulcerated Skin.)
  Microsporon Audouini. Gruby. (Hair Follicles.)
  M. mentagrophytes. Ch. Robin. (Roots of the Hair.)
  M. furfur. Ch. Robin. (Skin.)
  Mucor mucedo. Linnæus.
  Achorion Schœnleinii. Remak. (The Hair and the Hair Follicles.)
  Aspergilli species. Pacini et Meyer. (Auditory Passage.)
  Puccinia favi. Ardsten.
 B. On the Mucous Membrane.
  Cryptococcus cerevisiæ. Kützing. (Intestines.)
  C. guttulatus. Ch. Robin. (Rabbit.)
  Merismopædia ventriculi. Ch. Robin. [SARCINA.]
  Leptothrix buccalis. Ch. Robin. [SARCINA.]
  Oscillaire (?) of the Intestines. Farre.
  Leptomitus urophilus. Mont. (Bladder.)
  Leptomitus of Hannover. Ch. Robin. (Pharynx and Œsophagus.)
  Leptomitus of the Epidermis.
  Leptomitus of the Uterus.
  Leptomitus of Uterine Mucus.
  Leptomitus of the Eye.
  Oidium albicans. Ch. Robin. (In Thrush.)
  Fungus of the Lungs. Bennett. [OIDIUM.]
  Fungus of the Nasal Mucus.
II. Birds.
 A. Of the Respiratory Organs.
  Aspergillus candidus. Michele. (The Air-Cells and the Lungs.)
  A. glaucus. Fries.
  A. nigrescens. Ch. Robin. [MOULD.]
  A. Strix nyctea. J. Müller and Retzius.
  Mouldiness of the Lungs of the Jackdaw. Meyer.
 B. The Eggs.
  Dactylium oogenum. Montague.
  Sporotrichum (*Nematogonum*) *brunneum*. Schenk.
III. Reptiles.
 A. The Eggs.
IV. Batrachians.
 A. The Skin. *Saprolegnia ferax*. Kützing (*Achlya*, Nees von Esenbeck). [ACHLYA.]
V. Fishes.
 A. The Skin.
  Zygnema cruciatum. Agardh.
  Chætophora (*Tremella*) *meteorica*. Ehrenberg.
  Saprolegnia ferax. Kützing.
  Trichotraunia dermale. E. Germain of St. Pierre.
  Confervæ of Gold-Fish. Bennett.

Algæ of the Stickleback. Manicus.

B. The Gills and the Cellular Tissue.

Psorospermia of the Pike. J. Müller.

P. of the *Synodontis Schal.* J. Müller.

P. of the Sandre. (*Lucioperca sandra*). J. Müller.

P. of the Roach. (*Cyprinus rutilus*). J. Müller.

P. of the *Labeo niloticus.* J. Müller.

P. of the *Pimelodus Blochii.* J. Müller.

P. of the *Pimelodus Sebæ*, and of *Platystoma fasciatum.* J. Müller.

P. of the *Catastomus tuberculatus.* J. Müller.

P. of the *Gadus callarias.* J. Müller.

P. of the *Acerina vulgaris* of Grenville. Creplin.

P. of the *Sciæna umbra.* Ch. Robin.

C. The Eggs. *Saprolegnia ferax.* Kützing.

VI. Insects.

A. On the Elytra, and on the Articulations.

Botrytis Bassiana. Balsamo. Montagne.

Laboulbenia Rougelii. Ch. Robin. Montagne.

L. Guerinii. Ch. Robin.

Stilbum Buquetii. J. Müller and Ch. Robin.

B. On the Caterpillars and Chrysalises in the Tissues.

Botrytis Bassiana. Balsamo. Montagne.

Genus *Sphæria.* Haller. [SPHÆRIA.]

Section *Cordyceps.* Fries.

Sphæria militaris. Ehrenberg.

S. sphærocephala. Klein.

S. entomorhiza. Dickson.

S. sobolifera. Hill.

S. Sinensis. Berkeley.

S. Robertsii. Hooker.

S. Taylori. Berkeley.

S. Gunnii. Berkeley.

Kentrosporium microcephalum. Wallroth.

K. mitratum. Wallroth.

Isaria eleuteratorum. Nees. [ISARIA.]

I. floccosa. Fries.

I. strigosa. Fries.

I. arachnophila. Dittmar.

I. leprosa. Fries.

I. Tartarica. Wallroth.

I. crassa. Persoon.

I. sphecophila. Dittmar.

I. exotcla. Fries.

I. aranearum. Schweinitz.

I. sphyngum. Schweinitz.

I. gigantea. Montagne.

C. In the Intestines.

Mouliniea chrysomelæ. Ch. Robin.

M. cetoniæ. Ch. Robin.

M. gyrini. Ch. Robin.

Leptothrix insectorum. Ch. Robin.

Genus *Eccrina.* Leidy.

E. longa. Leidy.

E. moniliformia.

Cladophytum comatum. Leidy.

Anthromitus cristatus. Leidy.

A. nitidus. Leidy.

VII. The Myriapoda.

A. In the Intestines.

Enterobryus elegans. Leidy.

E. spiralis. Leidy.

E. attenuatus. Leidy.

E. Juli-terrestris. Ch. Robin.

VIII. The Mollusca.

A. On the Vesicle of Slugs. (Algue indéterminée, Lebert.)

B. The Eggs. *Saprolegnia ferax.* Kützing.

The most interesting of these species are undoubtedly those which attack man or the animals which he domesticates and employs. With the exception of the *Botrytis* of the silk-worm, the latter have not been much investigated. Those which attack man, and accompany diseased conditions of his body are better known. They may be divided into those which are found on the skin, and those which are attached to or found in the secretions of the mucous membrane.

I. *Entophyta* of the Skin.—Ten species have been noted in this locality. We shall enumerate them in the order in which they are given by M. Robin.

1. *Trichophyton tonsurans* (Malmsten); *Trichomyces tonsurans; Mycoderma* of the *Plica Polonica;* fungus of the hairs in *Herpes tonsurans*, fungus of *Porrigo scutulata, Achorion Lebertii;* fungus of the *Teigne tondante*, Bazin; *Rhizophyte*, Gruby. This fungus was discovered and described in 1844 by Gruby in the disease called by the brothers Mahon *Teigne tondante*, by Cazenave *Herpes tonsurans*, by Erasmus Wilson *Trichosis furfuracea* (one of the diseases called Ringworm and *Porrigo scutulata* in this country). It exists also, as pointed out by Gunsberg, in the *Plica Polonica*, although the two plants were formerly described as different. The *Trichophyton* is formed by oval transparent spores; which give rise to articulated filaments. Its anatomical seat is in the interior of the roots of the hairs. The hairs and fungi simultaneously increase. The former seem larger than usual, are paler in colour, lose their elasticity, soften, and break off when they have risen some one or two lines above the surface of the scalp. In the short cylinder then left the fungus grows still more rapidly, so that the normal structure of the small stump of hair soon becomes indistinguishable. Sometimes the hair breaks off before emerging from the skin, and the fungus, epidermis, and sebaceous matter, fill the ends of the piliferous conduits, and form the little prominencies which can be seen by the naked eye in this disease, and give the skin a rough anserine appearance. The sporules and mycelium of the plants can sometimes be seen, in the form of a white powder, on the roots of the broken hairs. Sometimes the cutis becomes congested and thickened, and then the plant is mixed up with scales of epidermis, with fatty and albumenoid granules, with pus, &c., and crusts are formed of greater or less thickness in which the growth of the fungus can go on. Messrs. Robin and Bazin adopt unreservedly the opinion that the *Trichophyton* is the cause of the disease known under the various names above given, and each has given examples of the contagion of the disease by the transmission of the spores. Bazin has made the very important observation that the same disease will attack horses, and can be communicated from them to men. Both Robin and Bazin however admit that there is some condition of the hairs (dependent no doubt on constitutional causes) which is essential for the growth of the plant, as sometimes the disease disappears, that is, the fungus dies, without treatment. With respect to the name of the most common disease in which the *Trichophyton tonsurans* appears, the term used by Cazenave (*Herpes tondens*) is extremely unfortunate. No doubt vesicles are sometimes seen, and sometimes the cryptogamic disease succeeds to true *Herpes circinata* of the scalp, but in many cases there are no vesicles at all throughout the whole course of the disease. The term used in this country *Porrigo scutulata* is inconvenient as it is applied with greater justice to *Favus.* The old term of *Tinea* is after all by far the best, and the specific affix *tondens* expresses well one feature of the disease, the baldness arising from the brittleness of the hairs.

2. *Trichophyton* (?) *sporuloides* (Robin). (*Mycoderme* of the *Plica Polonica*). In addition to the former species, Walther describes in the *Plica Polonica* oval or circular flattened sporules, which have been too little studied at present to permit their exact characters to be stated.

3. *Trichophyton* (?) *ulcerum* (Robin). Lebert has described a fungus in the crusts covering an atonic ulcer of the leg.

4. *Microsporon Audouini* (Gruby). This plant has been studied by Gruby, and its existence, though denied by Cazenave, has been confirmed by Robin. It is present in the disease commonly called after Willan, *Porrigo decalvans* or *Alopecia circumscripta*, or by Bazin, *Tinea achromatosa.* It differs from the *Trichophyton* of *Tinea tondens*, by its numerous waved filaments, and by the extremely small size of its sporules. It is not found, like the *Trichophyton*, in the interior of the root, but forms round each hair a little tube; the hair then becomes opaque, softens, and breaks off. The Alopecia is rapid, with or without vitiligo of the skin. The dermis is not congested, and the epidermis is thin and smooth. There is an affection which should probably be distinguished from the *Porrigo decalvans*, or *Alopecia circumscripta*, and which is characterised by a rapid disappearance of pigment from both skin and hair, with or without Alopecia. M. Bazin includes it in his *Tinea achromatosa*, but does not mention the fact that Alopecia is not constant. He states that a parasitic plant is present, but does not describe it. There must however be something more than a fungus to cause the total disappearance of pigment from a considerable portion of dermis. Besides, when the hairs return they are at first white, and only gradually regain colour; but if the vitiligo were owing to a plant it is probable they would not grow at all. The disease appears to be allied to those obscure pigmentary changes which have a much deeper seat than the surface of the body.

5. *Microsporon mentagrophyta* (Robin), (*Mentagrophyte*, Gruby). This is a plant resembling the preceding, but possessing larger spores and filaments. It was discovered by Gruby in a case of mentagra, and has been since described by Bazin. Its seat differs from that of the preceding, and from that of the *Trichophyton.* It is between the bulb of the hair and the follicle in which the bulb is seated, and never extends beyond the surface of the skin.

6. *Microsporon furfur* (Robin). In 1846 Eichstedt discovered a cryptogamic plant in the disease called by Willan *Pityriasis versicolor*, and more lately *Chloasma.* Soon afterwards Sluyter described the same fungus, and lately Sprengler has described and figured it. It forms with the epidermic scales the yellowish-brown scurf seen in *Pityriasis.*

7. *Achorion Schœnleinii* (Remak), (*Oidium Schœnleinii; Mycoderma* of *Tinea favosa; Porrigophyte* (Gruby); Fungus of *Favus.* Schœnlein was the first to suggest that the honeycomb, or yellow favous crusts in the so-called *Porrigo lupinosa* (Willan) and *P. scutulata* were constituted by a vegetable growth. This has been repeatedly confirmed, and many excellent descriptions have been given of the disease now called indifferently *Favus, Tinea favosa*, or *Porrigo scutulata.*

M. Robin believes he has discovered that the primary seat of the

Achorion is in the depth of the hair follicle, against the hair, and, as well as we can understand the description, outside the layer of epithelium which covers the root of the hair, and which forms the 'inner root-sheath' of Kölliker. In this observation however he has been anticipated by Wedl, who has pointed out that by using a concentrated solution of liquor potassæ to make the parts transparent, the fungus is found in the follicle round the hair at the place where it passes through the epidermis. In addition to this, the plant is found in depressions on the surface of the skin, forming the yellow honeycomb-like masses which give the specific name *Favus* to the disease, and which from their frequent buckler-like shape suggested the term *scutulata*. The development of the *Achorion* in this situation is described by Robin after Remak and Lebert. A cuticular elevation is seen, beneath which is a small favus. When the cuticle is raised, a drop of pus sometimes issues: hence the error of those who have considered this disease always pustular. Generally however there is no pus or liquid of any kind. The plant grows, and the cuticle over it (supposing it has not been forcibly detached) finally separates, leaving the favus exposed to the air.

M. Bazin describes the *Favus* under three heads, which are fundamentally identical, and different only in respect of form:—

1. *Favus urceolaria dissemina*: this corresponds to the *Porrigo favosa*, *Favus dispersus*, and *Teigne alveolaire* of other authors.
2. *F. scutiformis*: this is the *Porrigo scutulata*, or *F. confertus*.
3. *F. squamosa*, a form usually called *scutulata*, but distinguished chiefly by the irregular distribution of the achorion, and by the furrowed masses formed by the fungus, the hairs, epidermis, and exudation.

8. *Puccinia Favi.* The achorion constitutes, with epithelium and a little exudation, the mass of the *Favus*; but it has been lately (1850) observed by Ardsten, of Christiania, that a different fungus, a species of *Puccinia*, is occasionally also present. Robin considers it to be only an epiphenomenon, and that it is certainly not present in all cases. The *Puccinia* is easily recognized. It has one extremity (the body) rounded, and composed of two cells of unequal size, a superior and an inferior. The other extremity is prolonged into a pointed stem or trunk.

There are still three other plants found upon the skin which need merely be enumerated.

9. *Mucor.* In senile gangrene, an ill-described fungus, supposed to be the *Mucor mucedo* of Linnæus, has been seen on the sloughing mass.

10. *Aspergillus.* In the wax in the external meatus of the ear, Mayer many years ago described a fungus, and Paccini has lately made a similar observation—*Leptomitus* (?) of the epidermis. An *Alga* has been seen by M. Gubler in the epidermis of an arm which was irrigated for a long time to keep down inflammation after a gunshot wound. No one else has noticed it. Not only Messrs. Robin and Bazin, but Simon and others of the best dermatologists of Europe, have adopted the opinion that the plants are the actual causes of the diseases in which they are found. The contrary opinion is generally held in this country, on the grounds that fungi are generally the proofs and consequences of decay, but not its causes; that in the various forms of *Tinea* a special condition of the skin and hairs appears necessary for the growth of the plant; and that in *Tinea favosa* (*Favus*) in particular, a marked feature of the disease occasionally is an hyper-secretion of epithelium and exudation, owing to an hyperæmic cutis, before any trace of fungus can be found.

Nevertheless, these arguments, strong as they are, seem to be overborne by the two grand facts that *Tinea tondens* and *Tinea favosa* can be communicated by transfer of the plant, and that the disease can be cured with the greatest readiness by the chemical agents which are most destructive to vegetable life. That a special nidus is necessary may very well be admitted by the partisans of this view, since even in the case of epidemic agents a predisposition is necessary; yet no one dreams of confounding the co-operating cause with the special and peculiar poison.

It may be desirable to recapitulate the diseases of the skin in which parasitic plants are found:—

1. *Tinea tondens*, in which the *Trichophyton tonsurans* is present.
2. *Tinea favosa*, in which are present the *Achorion Schœnleinii*, and the *Puccinia Favi* in some cases.
3. *Mentaga*, or *Tinea mentagra*, which exhibits the *Microsporon mentagrophyta*.
4. *Pityriasis versicolor* (*Chloasma*), in which the *Microsporon furfur* occurs.
5. *Porrigo decalvans* (*Tinea achromatosa*) in which the *Microsporon Audouini* is found.
6. *Plica Polonica*, in which the *Trichophyton tonsurans* and *Trichophyton sporuloides* are present.

II. *Entophyta* on the Mucous Membrane.—The plants forming on mucous membranes, or in the contents of cavities lined by mucous membrane, are of less interest than those which grow on the skin, as in most cases they are decidedly only secondary. We shall merely enumerate them:—

1. *Cryptococcus Cerevisiæ*, Kützing (*Torula Cerevisiæ*), the Yeast-Plant in the bladder, stomach, intestines, &c.
2. *Merismopœdia ventriculi*, Robin (*Sarcina*), in the stomach, intestines, &c.
3. *Leptothrix buccalis*, Robin (*Alga*), of the mouth.
4. *Oscillaria* of the intestines. (Farre.)
5. *Leptomitus urophilus*, Montague; an *Alga* described as forming in the urine. It has as yet been scarcely studied.
6. *Leptomitus* (?), Hannover, Robin; *Alga* found by Hannover in the pharynx and œsophagus.
7. *Leptomitus* of the uterus.
8. *Leptomitus* of the uterine mucous.
9. *Leptomitus* of the eye.
10. *Oidium albicans*, Robin (*Cryptogamiæ*), of diptheritis and aptha; Aptophyte. (Gruby.)
11. Fungus of the lungs. (Bennett.)
12. Fungus in the discharge of glanders.

To this list from M. Robin may be added the so-called Cholera Fungus of Brittan and Budd. It should however be added that no confirmation of the view originally taken by the discoverers, that the fungus discovered in the dejections of those affected with cholera was the cause of the disease, has been afforded. The only explanation that can be given of the occasional occurrence of the spores of fungi or spore-like bodies on the mucous membrane of the stomach and intestines, is their introduction with the food. It has been stated above that the spores of certain species of fungi are found naturally on grains of wheat, and only await favourable conditions for development. Such fungi may be constantly introduced into the stomach with the flour of wheat in the form of bread or other kinds of food.

"In the study of the vegetable parasites of animals, particularly those of the intestinal canals, it is necessary to be careful not to confound the tissues of certain well-known cryptogamic plants, which may serve as food or adhere to the ordinary food of such animals, with true *Entophyta*. Thus, fragments of fungi, confervæ, lichens, and the spores of these, used as food, or adhering as foreign matter to food of an ordinary kind, are liable within the intestine to be mistaken for parasites.

"In mid-winter I found beneath an old fence-rail an individual of *Achela nigra*, or large black cricket, within the proventriculus of which were large quantities of what I supposed at the time to be a free floating Entophyte, resembling in general appearance the ordinary Yeast Fungus, *Torula*, but which I now suspect to be an ergot upon which the animal had fed. The plant consisted of oblong or oval vesicular bodies, apparently thickened at the poles, and filled with a colourless liquid; but this appearance more probably arose from the cells being distended with a single large, transparent, colourless, amorphous globule, which pressed a small existing amount of protoplasma to each end of the cavity. The cells were single, or in rows, to eighteen in number. Frequently a single cell of comparatively large size had an attached pair of cells, or rows of cells, at one or both ends. Occasionally they are met with containing one or two small round hyaline amorphous nuclei. The isolated cellules, measured from the $\frac{1}{2500}$th to the $\frac{1}{1800}$th of an inch in length by the $\frac{1}{8000}$th to the $\frac{1}{5000}$th of an inch in breadth. The rows measured up to the $\frac{1}{300}$th of an inch in length." (Leidy.)

(Leidy, *A Flora and Fauna within Animals*; Robin, *Histoire Naturelle des Végétaux Parasites*; Bazin, *Recherches sur la Nature des Teignes, &c.*; Parkes, *Epiphytes and Entophytes*; *Brit. and For. Medico-Chirurgical Review*, 1853; *Journal of Microscopical Science*, vol. ii.)

ENTOZO'A, from ἐντὸς, within, and ζῷον, an animal. Under this name are designated the different living beings which are produced and developed within other living beings. It comprehends a series of animals differing greatly from one another in form and organisation, and having but one character in common, which is, that they are all parasitic, or have their exclusive habitation in, and live at the expense of, the bodies of other animals. They can scarcely be said to form a distinct class in the animal kingdom, some of the species being closely resembled, both in external appearances and internal structure, by individuals placed in other classes, and only differing from them in the localities where they are found; thus, the zoosperms, or seminal animalcules, which are enumerated by some zoologists with the *Entozoa*, closely resemble the true *Cercariæ* of vegetable infusions.

Entozoa are found in most animals. They have been discovered in all the *Mammalia*, from man down to the *Cetacea*; they also occur in the other classes of the *Vertebrata*; indeed, it seems that a greater number reside in birds, reptiles, and fishes, than in mammals. The *Invertebrata* have also their peculiar parasites; and they have been ascertained to exist in all the Insect tribes, and in beings still lower in the scale. The best known species are those which inhabit the intestines of the human subject, and vulgarly go by the denomination of Worms, which term was probably derived from the resemblance which the *Ascaris lumbricoides* bears to the common earth-worm, as this species is most frequently met with, and was the first described of the human *Entozoa*, being mentioned by Hippocrates, who called it the ἕλμινς στρογγύλος, or round worm. The origin of *Entozoa* is involved in some obscurity, as well as the circumstances under which they are developed.

"Within living beings," says Dr. Leidy, "that is, within their cavities or the parenchyma of the organs, of course all the indisputable conditions of life exist, and consequently we cannot wonder at their being infested with other living beings adapted to their parasitic position. Nevertheless, although the conditions of life are necessarily ever present in living beings, yet these frequently do not contain parasites. There are many circumstances, besides those essential to life in general, which influence the existence or non-existence of such forms. One of the most important of these circumstances is the convenience or ease of access or of entrance to the living body infested. Within the living closed organic cell parasites very rarely if ever exist, because it is liquid matter only which can endosmose through cell membrane, and therefore solid germs cannot enter, and hence the unfrequency of true *Entozoa* in vegetables. *Entozoa* may and do penetrate through living tissues, but it is entirely by the mechanical process of boring.

"The intestinal canal of animals is most frequently infested by entoparasites on account of the ease with which their germs enter with the food.

"Aquatic animals are more troubled by *Entozoa* than those which are terrestrial, because the water affords a better medium of access than the air.

"Terrestrial animals, on the other hand, are more infested by ectoparasites because their covering of hair, wool, and feathers, is more favourable to their protection and reproduction. A low degree of organic activity and slowly digestible food favour the development of entoparasites, and hence they are more frequent in the relatively sluggish *Herbivora* than in the *Carnivora*. Comparatively indigestible food, and such as contains but a small proportion of nutritive matter, from its long retention in the alimentary canal, favours the development of entozoic and entophytic germs more than that in which the contrary conditions prevail. Animals subsisting upon endosmosed pieces of the tissues of other animals and of plants are rarely infested by parasites, as in the case of the hemipterous insects, aphides, &c., because such food is necessarily free from parasites or their germs. *Entozoa* themselves, on this account, are not infested.

"On the other hand, if the liquid food be open to the air, parasitic germs may be readily introduced into the animal, as in the case of the common house-fly, which often contains myriads of a species of *Bodo*. Food swallowed in large morsels favours the introduction of attached parasites; hence these are frequently found in reptiles, and even in birds, which are among the *Vertebrata* of the highest organic activity.

"Animals of feeble organic activity, using solid food, which is very slowly digested and contains little nutriment, are rarely free from parasites. This is the case with the coleopterous insect *Papalus* and myriapod *Julus*. Cooking food is of advantage in destroying the germs of parasites, and hence man, notwithstanding his liability to the latter, is less infested than most other *Mammalia*. Did instinct originally lead him to cook his food to avoid the introduction of parasites?

"*Entozoa* are more abundant than *Entophyta* [ENTOPHYTA], because the power of voluntary movement favours them in their transmigrations, and renders them less liable to expulsion from the intestinal canal."

Although it is now a general opinion that the *Entozoa* are introduced from without, it is very certain that with some it cannot be in their adult form. From some recent researches it appears that, like many of the Radiate Animals, the *Entozoa* assume various forms after escaping the egg before they attain their final condition. Steenstrup, in his 'Alternation of Generations,' has shown that *Entozoa* belonging to the Trematode forms, pass through various conditions of existence. Thus he has traced the species of *Distoma* in the higher animals to the various forms of *Cercariæ*. Mr. Busk has also pointed out ('Transactions of Microscopical Society,' vol. ii.) the probability that one of the Nematoid Worms, the *Filaria Medinensis*, the Guinea-Worm, passes through other forms before it penetrates the human body, and assumes its characteristic form in the human skin. With regard to the *Entozoa* of the higher animals, their eggs seem to be produced in that position, but not to be perfected where they have been generated. It has been shown that the ova of the *Bothriocephalus*, an entozoon found in birds, never come to perfection unless the ova are first swallowed by the Stickleback, which being eaten by the bird, the entozoon takes the opportunity of assuming its proper form. The *Gordius*, or Hair-Worm, deposits its eggs in water, but the eggs are not developed in this position; they are first swallowed by insects, and in this position the egg is hatched, producing the *Gordius*, which becomes impregnated, and escapes from the insect into waters where it deposits its eggs. The ova of a species of *Tænia*, Tape-Worm, when swallowed by the rat or mouse, will not produce perfect tape-worms in the inside of these creatures, but if they are eaten by the cat or dog, then the perfect tape-worm is produced. [GENERATION, ALTERNATIONS OF.]

According to the derivation of the word *Entozoa* and the definition which we have given of it, this term should include every living creature found in the body of another (which has not been introduced from without): therefore the small microscopic animalcules detected in the semen of animals, called *Spermatozoa*, come under this head; and in a very able paper on the 'Entozoa' by Professor Owen, we find them placed accordingly in this class, only situated in a separate group, denominated *Protelmintha*, and divided from the animals forming the class *Entozoa* of Rudolphi. These minute beings, which, from their size and organisation, rank with the assemblage of animalcules which are collected under the head *Infusoria* in the 'Règne Animal,' have been detected in the secretion of the testicles of various mammiferous animals arrived at maturity. When a drop of the secretion is expressed from a divided vas deferens shortly after death, and examined with a microscope, after being diluted with water, it is seen to be filled with minute beings resembling tadpoles, and swimming about in various directions, with different degrees of velocity, guided by the inflection of a slender tail. It has been doubted whether these are animated beings at all, or are to be considered as analogous to the moving filaments of the pollen of plants; but leaving this undecided, we may proceed to state that the body is always of a compressed form, which will distinguish these animalcules from the vegetable *Infusoria*, in which the body is always ovoid or rounded. With regard to their organisation, no alimentary canal or gastric cavities have been detected, nor organs of generation; they are said to be fissiparous, the body and tail spontaneously dividing, and forming two independent beings. The shape of these zoosperms differs in different animals, the large end, or body, being bigger in proportion to the tail in some than in others, and their size not being always in relation to that of the animal to which they belong: thus those of the rabbit are nearly as large as those from the bull.

In the present group are also included those minute internal parasites which have been detected in the bodies of many of the *Entozoa* themselves, and which, from their external form, are referrible to the *Infusoria*.

The *Trichina spiralis*, an entozoon found inhabiting the muscles of the human subject, has been placed by Professor Owen, who first described it, with the preceding animalcules; but further observations on its organisation have discovered a complexity of structure which qualifies it to occupy a place in the highest instead of the lowest group into which the present class of animals is divided.

Cuvier divided the true *Entozoa* into the 'cavitaires,' or those which have an abdominal cavity, and a distinct intestinal canal within it, and the 'parenchymateux,' or those in which no intestinal tube is traceable, and which for the most part consist throughout of an homogeneous structure; but this classification is anything but a natural one, as worms the most dissimilar in their general appearance are here promiscuously congregated together. Professor Owen, in the article which we have before alluded to (in the 'Cyclopæd. of Anat.'), has adopted the arrangement of Cuvier, only inventing new Latin names derived from the Greek, instead of the French terms: thus he denominates the 'parenchymateux' Sterelmintha, from *elmins*, 'a worm,' and *stereos*, 'solid;' and the 'cavitaires' Cœlelmintha, from *elmins*, and *cœlos*, 'hollow.' Zeder laid the first foundation of a good classification of these animals, dividing them into five classes, afterwards called families, at Rudolphi's suggestion; and these were again subdivided into genera and species. Rudolphi himself doubted the possibility of ever reducing all the species of *Entozoa* to absolutely natural and well-defined families, but as Zeder's system seemed the most perfect, he has adopted it for his own; and it does not seem that we can do better than follow the arrangement of this great entozoologist in the present article.

According to this classification the *Entozoa* are divided into five orders, or families, the *Nematoidea*, *Acanthocephala*, *Trematoda*, *Cestoidea*, and *Cystica*. The only point in which we shall depart from this arrangement will be, that, instead of commencing with the most perfect, and descending to the most simple, we shall begin with the lowest in the scale of organisation, and ascend to those possessing the most complicated structure, as this is most in accordance with the laws of the animal kingdom.

Order I. *Cystica* (from κύστις, a bladder), Hydatids. The characters are:—Body flattish, or roundish, and terminating posteriorly in a transparent cyst filled with pellucid fluid, which is sometimes common to many individuals; the head is retractile, and provided with pits two to four in number, or four suckers and a circle of hooklets, or with four unarmed or uncinated tentacles. The organs of generation and nutrition are unknown. This is not a very natural family, the species being closely allied to those of the next order in the structure of the heads; and the *Echinococcus*, or Granular Hydatid, though referred to it, is not hollow.

Order II. *Cestoidea* (from κεστὸς, a band; and εἶδος, form), Tape-Worms. Characters:—Body elongated, flattened, soft, continuous, or articulated, furnished with lateral or marginal pores, and erectile papillæ passing through them, supposed to be the male organs of generation. Head generally provided with two or four pits, or suctorial orifices, and sometimes with four retractile, unarmed, or uncinated tentacles; but the head is so dissimilar in different genera, and their shape varies so much, that they do not form a very natural family. There is no trace of intestinal canal; unless the vessels proceeding from the suckers be considered as such. In some species nutrient vessels and ovaries are to be seen. They are all androgynous.

Order III. *Trematoda* (from τρῆμα, a foramen), Fluke-Worms. Characters:—Body soft, rounded, or flattened. Head indistinct, with a suctorial foramen; one or more suctorial pores on the under surface of the body, which furnish the grounds for their subdivision into genera: they have no intestinal canal, and the organs of generatiou of the two sexes co-exist in the same individual. This is a very natural order.

Order IV. *Acanthocephala* (from ἄκανθα, a thorn; and κεφαλή, the head), Hooked-Worms. Characters:—Body elongated, round, sub-elastic; the anterior extremity or head has a retractile proboscis, furnished with hooks or spicula, arranged in rows. They have uo intestinal canal, but distinct genital organs, and a separation of the sexes. This is a very natural group, and includes the most noxious of the internal parasites; there is only one genus, and fortunately no species is known to infect the human body.

Order V. *Nematoidea* (from νῆμα, a thread, and ειδὸς, form), Round-Worms. Characters:—Body cylindrical, elongated, and elastic; structure very complicated, there being a true intestinal canal, terminated by a distinct anus. The mouth, by its varieties, affords generic characters; the sexes are distinct; the females, which are longer than the males, being for the most part oviparous. They constitute a very natnral order.

Having given the above brief view of the orders into which the class *Entozoa* is divided, with the leading or characteristic differences in their form and organisation, we will now enumerate the principal genera contained in each group, and make a few observations on some of the most interesting species. Following the order of classification, we must commence with the most simple group, the *Cystica;* and here the first parasite which attracts our attention is the common Hydatid, which consists of a globular bag, composed of condensed albuminous matter of a laminated texture, and contains a limpid colourless fluid. No head or appendices of any sort being attached to it, it is appropriately denominated an acephalocyst, that is, a headless cyst. This genus was established by Linnæus, who regarded as animals those productions which before his time had been considered simply as cysts. Considerable diversity of opinion still exists as to their natnre, and it is impossible to determine whether an hydatid is an animal or not, till we can agree what is the definition of an animal: if an animal must have sensation and motion, this is not one, as the best observers agree that the acephalocyst is impassive under the application of stimuli of any kind, and manifests no contractile power, either partial or general. If an animal is characterised on the other hand by independent existence merely, the hydatid is one; and as such we shall regard it, for it is certainly an independent organised being, growing by intrinsic power of imbibition, and reproducing its species by gemmation; the young are developed between the layers of the parent cyst, and thrown off internally or externally, according to the species. It is a being certainly far inferior in the scale to the *Cysticercus*, but still not the less an independent creature. Its structure is very similar to that of some of the lowest forms of *Algæ* in the vegetable kingdom, as the *Protococcus nivalis*, or Red Snow, of the arctic regions, which consists of simple and minute vesicles, which propagate their kind by gemmules developed from the external surface of the parent. Acephalocysts have been found in almost every structure and cavity of the human body, but particularly in the liver, uterus, kidneys, and cellular tissue. The species which resides in man is called *A. endogena*, the Pill-Box Hydatid of Hunter, from the gemmules being detached from the internal surface of the cyst; and it is thus distinguished from those of the ox and other ruminating animals, which are exogenous, or have the gemmules excluded from the external surface.

2. The next genus is *Ecchinococcus*, which, as the name implies, is a round body covered with asperities. The *E. hominis*, or Many-Headed Hydatid, of the Germans, occurs in cysts in the liver, spleen, omentum, and mesentery; tho cyst, which is externally yellow and coriaceous, is unprovided with head or mouth, and contains minute bodies, which are described as possessing the armed and suctorious head characteristic of the *Cœnuri* and *Cysticerci*. From observations made on another species, the *E. veterinorum*, found in animals, the particles adhering to the internal surface of the cyst being examined with a microscope, appeared to be minute animalcules, moving about by means of external vibratile cilia, having an orifice at each extremity of the body, and the centre occupied by large globular stomachs. These little animals are the *Echinococcus*. The following account of these bodies is from the abstract of a paper read by Mr. T. H. Huxley before the Zoological Society. After describing the cysts he says:—

"The contents of the large cysts were free *Echinococci* and secondary *Echinococcus* cysts, contained in a clear fluid. The former were alive, and exhibited distinct contractile motions. Attention was drawn to two important points in their structure; firstly, that the well-known oval corpuscles were not calcareous, inasmuch as they were rapidly dissolved by acetic acid without effervescence, and were considerably acted upon by ammonia. The author supposed that they were albuminous, and that both in these and the *Tæniæ* the conversion into calcareous substances is an effect of degradation; and he pointed out their relations with the solid bodies in the integument of the *Turbellaria*, and with the so-called thread-cells of these and the *Polypes;* secondly, that the peculiar wavy cilia characteristic of a water vascular system could be seen in motion in the living *Echinococci*. The cilia were described by Lebert in 1843, but tho discovery seems to have been forgotten. It is however a point of great importance now that the existence of similar cilia in a definite water vascular system has been demonstrated in the other Cestoid Worms. The proper wall of the cyst (as distinguished from the laminated capsule) was traversed by a network of anastomosing vessels, to the points of union of which the fixed *Echinococci* were attached, the cavity of the pedicle of the latter appearing to be continuous with that of the vessels. It is in the cavity of the pedicle that Virchow observed cilia. The secondary cysts varied in size from 1-100th to 1-30th of an inch. The contained *Echinococci* were always of about the same size, and all the smaller secondary cysts possessed from one to four *Echinococcus* heads attached to their outer surface. The wall of the secondary cysts contains vessels like those of the primary one. In the larger cysts the external heads were found gradually disappearing until they were quite smooth externally. When the secondary cysts were burst, their membrane continued to connect the heads and formed the pedicle described by various authors. The formation of secondary cysts takes place thus:—*Echinococcus* heads are formed over the whole inner surface of the cyst; this then becomes raised up at one spot by the development of *Echinococcus* heads outside it also, and gradually projecting inwards, and acquiring a narrower and narrower pedicle it eventually falls into the cavity of the cyst as a free secondary cyst. The external heads of the secondary cyst (internal of the primary cyst) then gradually disappear, the internal ones (external of the primary cyst) remaining entire and in a normal state. The process is not essentially different from the ordinary germination of a *Tænia*, or *Cysticercus*. The author then endeavoured to show that the *Echinococcus* is nothing but the 'Scolex-form'—to use Van Beneden's term—of a *Tænia* retracted within itself, then greatly dilated, and developing *Echinococcus* heads from its inner and outer surfaces, which are however, like those of a serous sac, in reality both outer. It is the extreme result of modifications similar to those already undergone by the Tænioid type in *Cœnurus* and *Cysticercus*. The conclusion thus drawn on anatomical grounds is strikingly confirmed by the result of the recent experiments of Von Siebold, who fed young puppies on milk containing *Echinococci*, and after a short time discovered *Tænia* in their intestines."

3. *Anthocephalus* is the next genus.—It occurs in fish, in the liver, mesentery, and peritoneum, and within hydatids in the viscera. Each animal exists solitarily in a double bladder, of which the outer layer is hard and elastic, the iuner more thin and delicate. The body is long, flat, terminated behind by a caudal vesicle, and in front by a head with two or four fossæ, and four probosces furnished with spicular processes.

4. *Cœnurus.*—This has the terminal cyst common to many bodies and heads; the former are elongated, flattish, and wrinkled; the latter are furnished with a rostrum, on which there are hooks and suckers adhering in greater or less number to the surface of a bladder filled with fluid. The best known species is the *C. cerebralis*, commonly developed in the brain of sheep, and giving rise to the disease called the Staggers.

5. *Cysticercus.*—Here there is a dilated cyst forming the termination of a single entozoon: the head has four suckers, and a rostrum furnished with recurved processes or hooks. Of this genus one species is known to infest the human subject, the *C. cellulosæ*. It is developed in the interfascicular cellular tissue of the muscles, aud is invariably surrounded by an adventitious capsule of condensed surrounding substance. This entozoon occurs much more rarely in this country than on the Continent. It is not confined to the muscular structures, for several individuals have been detected in the anterior chamber of the eye, where they may occasion so much irritation and inflammation of the organ as to require extraction, which occurred some years ago in a case in the Glasgow Ophthalmic Infirmary. These parasites also occur in quadrupeds, particularly the hog, giving rise to that state of the muscles which is called Measly Pork.

Of the Cestoid order of *Entozoa* Rudolphi has described 8 genera, two only of which contain each a single species that infest the human body:—

1. *Bothriocephalus*, the species of which occur frequently in fishes aud birds, in the branchiæ, œsophagus, pyloric appendices, intestines, and abdominal cavity. The one which affects the human subject, *B. latus*, or *Tænia lata*, rarely falls under the observation of the English entozoologist, but is common in the intestines of man in Switzerland, Russia, parts of France, &c. It may be distinguished from the *Tænia solium* by the form of the segments, which are broader than they are long, and by the position of the genital pores, which are on the under surfaco of the body, instead of at the sides; the head is also very different, for instead of having four round oscula, characteristic of the true *Tæniæ*, there are two lateral longitudinal fossæ or bothria.

2. *Tænia.*—This genus has the body flat, long, articulated, with four suckers on the head. It occurs in the intestines, biliary ducts, gall-bladder, and liver of vertebrate animals. The *T. solium*, commou Tape-Worm, inhabits the humau intestines, but not with equal frequency in all countries, though its distributiou seems to be much more extensive than that of the *Bothriocephalus latus*. It occurs in England, Holland, Germany, Swedeu, Italy, Greece, and most countries in Europe, and also in Egypt and the East; and in all these situations the other genus is comparatively rare.

Tho delicacy of their structure, and their so seldom being obtained entire, has thrown great obstacles in the way of their investigation. The head was for a long while unknown, and it was disputed whether nourishment was taken in by the lateral pores of the several joints or by the mouth alone. Rudolphi says the latter, and it seems now pretty clearly determined that the former are mere outlets of the generative organs. The length to which the *T. solium* is capable of attaining is very considerable, but quite indefinite. Those passed now-a-days seldom exceed twenty feet, but in former times we read of much more gigantic specimens; but whatever may be thought of some of the accounts which are quite improbable, it indubitably has occasionally attained a very great length, having been found extending from the pylorus to within a few inches of the anus, and then by no means fully stretched out. Such cases are however very rare.

The determination of the species in this genus is very difficult: they may be divided for greater convenience into three sections:—The first are without a proboscis, the *Tæniæ inermes;* the second have one, but unarmed, *T. rostellatæ;* the third are furnished with an uncinated proboscis, *T. armatæ.*

3. *Caryophyllæus* has the body flat, continuous; the head dilated, and divided into flattish processes; it is furnished with an upper and under lip. The species of this genus occur in the intestines of fishes (carp, &c.).

4. *Scolex.*—The body is flat and continuous; the head has four fossæ on it. It occurs also in the intestines and abdomen of fishes, sepiæ, &c.

5. *Gymnorhynchus.*—This genus has the body very long, with a globular receptacle at the neck; head with two opposite fossæ, and four naked retractile proboscces. The species occur in the muscular substance of many fish.

6. *Tetrarhynchus.*—Body flat, continuous, head with four fossæ and four retractile probosces, furnished with recurvated spicular processes. It occurs in reptiles, fishes, *Mollusca,* in the muscles, branchiæ, stomach, and its membranes, the liver, and peritoneum.

7. *Ligula.*—In its first stage of development the body is elongated with a longitudinal fissure, without any appearance of head, or organs of generation. In its perfect state there is a simple fossa on each side of the head, and the ovaries and processes form a single or double row along the median line. The species occur very frequently in birds and fishes, but very rarely in *Mammalia.*

8. *Triænophorus* has the body elongated, flat, sub-articulated; mouth bilabiate, and furnished on each side with two tricuspid acicular processes. It is found in fishes.

The *Trematode* order is divided into six genera, which also include only two species infesting the human body.

1. The first genus is *Monostoma,* which has only a single anterior pore. It occurs in *Mammalia,* birds, reptiles, and fishes.

2. *Amphistoma* is furnished with two pores, one anterior and one posterior. Found in the stomach, intestines, and abdomen, and in the hydatids of the viscera of mammals, birds, and reptiles.

3. *Distoma.*—In this genus there are two pores: an anterior and a ventral. An immense number of species are known, occurring in *Mammalia,* birds, fishes, &c. The *D. hepaticum,* or Fluke-Worm, frequents the gall-bladder and ducts very frequently in some animals, as the ruminating, and is particularly common in the sheep in the disease called the Rot. It has been discovered in the gall-bladder of the human subject, though very rarely. It bears a considerable resemblance in its shape to a melon-seed, being flat, and appearing lanceolate at each end, as seen with the naked eye, though, when magnified, the extremities are found to be obtuse, the tail being the broader of the two. The anterior pore, or true mouth, is round and small; the posterior cavity is imperforate, and only subservient to adhesion and locomotion; it is situated in the ventral aspect of the body in the anterior half. Between these there is a third orifice, destined to the generative system, and from which a small cylindrical process is generally protruded. The Fluke is hermaphrodite and oviparous: it lives upon the bile, which is absorbed by the mouth, and is at once so digested or modified by the vessels which go off from thence, as to become immediately fitting nourishment for the animal.

4. *Tristoma* has three pores, the anterior simple, and the posterior radiated. It is found in the gills of one or two species of fish.

5. *Pentastoma.*—The mouth is here situated between two pores on each side, through which a spicular process comes out. It occurs in the frontal sinuses, lungs, and surface of the liver of the *Mammalia* (dog, horse, wolf), and in reptiles.

6. *Polystoma.*—This genus has six anterior pores, besides a ventral and posterior one. It mostly occurs in the throat and branchiæ of fishes, and the bladder of frogs; but one species, the *P. pinguicola,* was discovered by Treutler in the cavity of an indurated adipose tubercle, in the left ovarium of a female aged 20, who had died in child-bed. The tumour, which was apparently formed entirely of indurated fat, was of a reddish colour, and hollow within; the cavity was nearly filled by the above-named worm, which was about half an inch in length, and between one and two lines in width.

The 4th order, *Acanthocephala,* contains but one genus, *Echinorhynchus,* to which belong numerous species occurring in all classes of vetebrate animals except man. They are generally found in the intestinal canal, fixed between its membranes, and occasionally even in the peritoneal cavity; they have also been found in the neck under the skin.

We now come to the last and most highly-organised group of the *Entozoa,* the *Nematoidea,* which contains a greater number of genera, and includes more species inhabiting the human body than any of the preceding. It has been divided into 11 genera, namely:—

1. *Filaria.*—These are of nearly equal thickness throughout their whole length. They occur in all parts of the *Vertebrata,* though principally in the cellular membrane; they are also even found in insects and their larvæ.

2. *Trichosoma.*—On its anterior extremity, which is very thin, is the mouth, resembling a minute point. It is found in *Mammalia* birds, and *Amphibia,* between the coats of the stomach, in the intestines, and the urinary bladder.

3. *Trichocephalus.*—This genus differs from *Filaria* in the capillary form of the anterior part of the body, and in its swelling out behind. It occurs principally in the cæcum of the *Mammalia.*

4. *Oxyuris* is characterised by being subulate posteriorly, having the mouth orbicular, and the penis in a sheath. The *Ascaris vermicularis* is included in this genus by Bremser.

5. *Cucullanus* is attenuated posteriorly. It occurs in the intestines and abdomen of reptiles and fishes.

6. *Spiroptera* is attenuated at each end. It occurs under the nictitating membrane of birds, in various parts of fish, and is said to have been found in the urinary bladder of man.

7. *Physaloptera* is attenuated at both extremities; the tail of the male is bent downwards, winged, and furnished below with a sort of bladder. The species are found in the stomach of *Mammalia,* birds, and reptiles.

8. *Strongylus.*—This has both ends attenuated: the tail of the male termintes in what Rudolphi calls a bursa, and through this the penis passes out. It occurs frequently in various situations in the three first classes of vertebrate animals.

9. *Ascaris.*—This genus, which is the most numerous of the intestinal worms, 80 species having been already described, has the extremities attenuated, the mouth furnished with three valves or tubercles, and the penis double. The species occur in almost every part of the bodies of vertebrate animals.

10. *Ophiostoma* is attenuated at the extremities, and has the mouth furnished with two lips. It is found in the intestines of *Mammalia* and fishes.

11. *Liorhynchus* has the mouth at the end of a sort of erectile and polished tube. It occurs in the stomach and intestines of some of the *Mammalia* and of many fishes.

In the above list of the genera of the cavitary, intestinal, or round worms, we have not made any particular mention of the species parasitic in man, and as several of them possess considerable interest, we need no apology for giving a short description of them. We may begin with the genus *Filaria,* three species of which are enumerated as human inhabitants, though two of them have been only once detected. The Guinea-Worm (*Filaria Medinensis*) frequently occurs in hot climates, but the countries where it most abounds are Arabia, Upper Egypt, Abyssinia, and Guinea. Its general habitation is the subcutaneous cellular tissue, particularly of the lower extremities; but it is also found in the scrotum, and very rarely beneath the tunica conjunctiva of the eye. The length of this worm varies from six inches to twelve feet: it is about as thick as the string of a violin. Its colour is generally white, but occasionally brown; it is round, and of nearly equal dimensions in its whole length, but becomes a little attenuated towards the anterior extremity. The tail of the male is obtuse, and armed with a spiculum; in the female it is acute and bent. The mode of development of this entozoon is unknown. It seems that it may exist for many months without being detected, cases occurring where it has not been discovered till more than a twelvemonth after leaving the country where it was contracted. After a time it produces irritation; in some point of the skin a vesicle, pustule, or small abscess forms, breaks, and then the end of the worm makes it appearance, which may be taken hold of, and cautiously and gradually extracted. If the *Filaria* is broken, the portion remaining beneath the skin dies, and produces inflammation, sinuous abscesses, and often great constitutional disturbance, requiring amputation of the limb. It seems to be capable of slowly shifting its situation in the cellular membrane. According to Rudolphi, its coming out through the skin is not to be attributed to perforation of that membrane, which it is not at all capable of effecting, but only to the irritation which it excites in approaching the integuments. It seems sometimes to affect people within the tropics in an endemic or even epidemic form, nearly half the men in a regiment having been attacked at the same time by it. This species has been mentioned as having been found occasionally beneath the conjunctiva of the eye; but another, and much smaller kind, has been detected within the eyeball itself, namely the *F. Oculi Humani,* which Nordman met with in the liquor Morgagnii of the capsule of the crystalline lens of a man who had had the operation of extraction for cataract performed. Two minute worms were discovered coiled up together. This species differs from the large *Filaria* found in the eye of the horse. The third species is the *F. bronchialis,* which was once detected in the enlarged bronchial glands of a man by Treutler; its length was about an inch.

Recently species of *Filaria* with *Monostomata*, *Distomata*, and *Infusoria*, have been found in the blood of animals. Gruby and Delafond have found *Filaria* in the blood of dogs. The results at which they arrived may be shortly stated in their own words as follows:—

1. The number of microscopic *Filariæ* inhabiting the blood of certain dogs may be estimated approximately at from 11,000 to about 224,000. The mean number, deduced from 20 dogs, was more than 52,000.

2. The microscopic *Filariæ*, having a diameter less than that of the blood discs, circulate in the most minute capillaries where the blood discs can find entrance. A drop of blood taken from these vessels, it does not signify at what part of the body, nor at what season of the year, contains these minute *Hematozoa.*

3. The chyle and the lymph of dogs, whose blood contains microscopic *Filariæ*, present none.

4. Nor do any of the secretions or excretions.

5. Nor in the dissection of 28 dogs of different sorts and ages, and whose blood was known to have been verminous for periods varying from several months to more than five years, and made with the utmost care, were any *Filariæ* ever discovered in any of the tissues. Their proper habitat seems to be exclusively in the blood-vessels.

6. The authors calculate, from the examination of 480 dogs, that the blood in about four or five per cent. is verminous.

7. It is so more frequently in old and adult dogs than in young ones.

8. The verminons condition seems to be irrespective of racc, sex, or geueral habit of body.

9. Even when most abundant, this condition of the blood does not seem to interfero with the instincts or muscular force of the animal.

10. Nor is the constitution of the blood itself altered.

11. Transfusion of verminous blood, dcprived of fibrin, into sound animals, was not followed by any result. But,

12. When unaltered verminous blood was thus injected, *Filariæ* were found living in the animals experimented on, for more than three years, or until their natural death.

13. *Filariæ*, transfused with defibriuated blood into two rabbits, lived in the blood of those animals for 89 days; after which time none could be found.

14. In a similar experiment with six frogs, two of which already had *Filariæ* in their blood, the canine *Filariæ* lived for eight days, during the whole of which time the blood-discs of the dog appeared unaltered among those of the frog. On the ninth and tenth days the dog's blood-discs having become changed, the *Filariæ* had disappeared, and the frogs died of a scorbutic malady (!).

15. Injected together with the blood into the serous cavities or cellular tissue of dogs, in good health, the *Filariæ* could not live in their new domicile.

16. A verminous dog, of one race, with a female not so affected, of another, had offspring of which those belonging to the paternal race were verminous, and the others not.

17. When the conditions were reversed, so was the result.

18. But the *Filariæ* in the blood of the descendants could not be detected till the dogs were five or six months old.

The authors have also succeeded in finding in the verminous blood of a dog which died in consequenco of its being fed exclusively on food composed of gelatine, large worms, visible to the naked eye. They found six, of which four were fcmales and two males, and they were lodged in a large clot occupying the right ventricle of the heart. The worms were white, from 0·5 to 0·75 inch long, and from 0·039 to 0·058 inch in diameter. They propose for this hematozoon, the name of *Filaria papillosa hæmatica Canis domestici.*

The *Trichocephalus dispar*, or Long Thread-Worm, is about an inch and a half or two inches in length, the male being smaller than the female. The capillary portion makes about two-thirds of the whole length of this species. This worm is very common in the cæcum and large intestines, but does not seem to occasion any inconvenience, though inflammation of the intestinal follicles and fever has been erroneously ascribed to it. The existence and history of the following entozoon are involved in a good deal of mystery. *Spiroptera Hominis* is the name given to some small intestinal worms which were sent to Rudolphi, together with some other vermiform bodies of an elongated form and solid homogeneous texture, which were passed from the bladder of a poor woman then living in St. Sepulchre's workhouse, London. There were also discharged, together with these substances, numerous small granular bodies, considered by Rudolphi as mere morbid concretions, but which subsequent examinations have caused to be regarded as ova. The small nematoid worms, which were six in number, and of different sexes, are supposed to have been expelled from the woman at the same time; they were from eight to ten lines in length, slender, white, and elastic; the other elongated bodies varied in length from four to eight inches. Some of the latter substances and ova are preserved in the Museum of the College of Surgeons; but none of the former *Entozoa*, denominated *Spiroptera Hominis*, are to be found among them.

The *Strongylus gigas* also inhabits the urinary apparatus. Before Rudolphi's time it was generally confounded with the *Ascaris lumbricoides*, to which it bears some resemblance. It occurs, though rarely, in the substance of the kidneys, where it sometimes attains an enormous size, having been met with three feet long, and half an inch in diameter. The more ordinary dimensions however are about fifteen inches in length and two lines in thickness. The common colour is blood-red, arising from the nature of their food, as they obtain their nourishment from the contents of the renal vessels: they occasionally find their way into the bladder, and are discharged with the urine. This entozoon occurs much more frequently in some animals, as the dog, horse, &c., than in man. Their presence in the kidneys does not seem to give rise to any peculiar symptoms differing from those of other renal diseases.

The *Ascaris lumbricoides*, the Common Round Worm so frequently met with in children, is so well known as to require a very brief notice here. It occurs in the hog and the ox, as well as in man, and chiefly inhabits the small intestines. The male is smaller than the female, and much more rare; it may be distinguished by the end of the tail being curved, and terminating in an obtuse point, at the apex of which a small black speck may be frequently observed. In the female this extremity is straighter and thicker. The anus is situated in both sexes close to the tail. In the female there is generally a constriction in the centre of the body where the organs of generation are placed. This worm, when minutely examined, will be found to consist of integuments, muscles, digestive organs, genital apparatus, and a nervous system consisting of an œsophageal ring and a dorsal and ventral cord. It has been supposed to feed on the chyle or mucus in the intestines, and to adhere to the coats of the bowels, but on these points there is considerable doubt. They are often found in great numbers.

The last human species in this group is the *Ascaris vermicularis*, the Maw-Worm, Thread-Worm, or Ascarides. It is very minute, the male seldom exceeding two lines, and the female five lines in length, and being proportionally slender. Their colour is white; they are so small that there is great difficulty in detecting their structure, but Rudolphi says that he has repeatedly observed the three tubercles round the mouth characteristic of the genus. Their abode is the large intestines, particularly the rectum, where they sometimes occur in immense numbers, and occasion great irritation.

We have now enumerated all the genera of *Entozoa* described by Rudolphi and other entozoologists, but before we conclude our subject we will say a few words on the *Trichina spiralis* which we have before mentioned. It is a microscopic parasite, infesting the muscles of the human subject belonging to the voluntary class, and found in greater numbers in those that are superficial than in the deep seated. Their nidus seems to be in the inter-fascicular cellular tissue. A portion of muscle affected by these animals appears beset with whitish specks, which, if examined with a microscope, are found to be little cysts containing a minute worm coiled up. The cysts are of au elliptical shape, and attenuated towards the extremities: their length is about $\frac{1}{50}$th of an inch, and breadth $\frac{1}{100}$th. By cutting off one extremity of the cyst, the *Trichina* may be extracted entire, when it is generally found rolled up in two or two and a half spiral coils. Being straightened out, it will be found to measure $\frac{1}{30}$th of an inch in length and $\frac{1}{700}$th of an inch in diameter. From the minuteness of the object it is necessary to employ a magnifying power of considerable intensity to examine it satisfactorily, and from the difficulty of managing the investigation, and the deceptive appearances produced under the microscope, it is not easy to detect its organisation. Professor Owen never succeeded in discovering an intestinal tube, or cavity, and therefore, as we have stated, placed this entozoou in his first group along with the seminal animalcules. ('Zool. Trans.,' vol. i.; and 'Zool. Proceedings,' February, 1835.) Dr. Arthur Farre observed, by very patient and minute observation with the microscope, under favourable circumstances, that it possesses an intestinal canal with distinct parietes ('Med. Gazette,' Dec. 1835), and upon this ground it ought to occupy a higher station among the nematoid or intestinal worms; but further researches are necessary before it can be stated with confidence in which group this entozoou should be placed. It seems that this parasitical affection of the humau body is unconnected with age, sex, or any particular form of disease, aud it appears that it may exist without giving rise to any debility of the vital powers, or even without interfering with the enjoyment of robust health.

For an account of the diseases produced by *Entozoa*, and their remedies, see ANTHELMINTICS, in ARTS AND SC. DIV.

EOCENE. The lowest of three great divisions of Tertiary Strata is thus termed by Sir Charles Lyell. [TERTIARY STRATA.]

EOLIDÆ. [NUDIBRANCHIATA.]

EOLIS. [NUDIBRANCHIATA.]

EPACRIDA'CEÆ, *Epacrids*, a natural order of Monopetalous Exogenous Plants, very closely allied to *Ericaceæ*, with the small-leaved genera of which they entirely agree in habit, and from which they are scarcely distinguishable by any character beyond their anthers being in all cases one-celled. Dr. Brown, in founding the order in the year 1810, explained his motives for doing so as follows:—"The family of *Ericeæ* is now so vast that it seems to constitute a class rather than an order, of which one part, although not a very natural one, has been already separated by Jussieu under the separate name of *Rhododendra*, on account of some diversity in the structure of the fruit. I therefore may be allowed to propose another order (*Epacrideæ*), which is truly natural, although it depends upon the single character of the unusual simplicity of the anthers; a character however which is of the greater value as opposed to the 2-celled anthers of *Ericeæ*, which are generally divided and furnished with appendages. The propriety of the measure is moreover confirmed not only by the number of *Epacrideæ*, large as it is, but also by their geographical disposition; for all, as far as we at present know them, are inhabitants of Australasia or Polynesia, countries in which not more than one or two species of *Ericeæ* are found." ('Prodr.' p. 536.)

Sprengelia incarnata.

1, a flower with a calyx as long as the 5-parted corolla, and several bracts imbricating the base; 2, an anther; 3, the stamens and ovary.

The species consists of shrubs with alternate or occasionally opposite leaves, which are either articulated with the stem, like those of *Ericeæ*, or broad at the base and half-surrounding the stem in a kind of hood or sheath. Their flowers are usually monopetalous, but as in the order *Ericaceæ*, it is not unfrequent to find them with their corolla divided or divisible into several pieces, and therefore truly polypetalous. The size and colour of the corolla are often striking, and the species then become exceedingly showy, and are favourites with gardeners. None of them are of any particular use, unless those are considered an exception whose succulent fruit is eatable, like *Lissanthe sapida* and others, which constitute the Australian cranberries.

Dr. Brown mentions 24 genera and 144 species of this order in his work upon the 'New Holland Flora.' Dr. Lindley, in his 'Vegetable Kingdom,' gives 30 genera and 320 species.

EPENDYMA. [EPITHELIUM.]

EPERVA, a genus of Plants belonging to the natural order *Fabaceæ*. It has four thick and concave sepals connected together into a permanent urceolate tube at the base, with the sides incumbent, the upper one the broadest. It has but one petal, which is roundish, fringed, and inserted in the middle of the calyx. There are 10 stamens, which are long thickened filaments, rather villous at the base, and joined into a short monadelphous ring. The ovary is stipitate. The style long and filiform. The legume compressed, dry, coriaceous, falciform, 2-valved, 1- to 4-seeded. When young it is tomentose.

E. falcata is a tree with abruptly pinnate leaves, bearing 2 or 3 pairs of ovate acuminated shining leaflets. The panicle is pendulous on a long peduncle, constantly composed of numerous distant racemes. It is the Wallaba-Tree of Guyana according to Sir Robert Schomburgk, who informs us that its wood is deep red, frequently variegated with whitish streaks, hard, heavy, and shining, and impregnated with an oily resin which renders it very durable. The bark is bitter, and is used by the Arawaak Indians as an emetic.

(Lindley, *Vegetable Kingdom*; Don, *Dichlamydeous Plants*.)

EPHEDRA (the Greek name of the *Equisetum*, which this genus closely resembles), a genus of Plants belonging to the natural order *Gnetaceæ*. The species are diœcious; the male flowers are arranged in the form of a catkin, having a bifid calyx, and 7 stamens, 4 of the anthers of which are inferior, 2 superior; the female flowers have a quintuple calyx 2-parted, 2 ovaries, and 2 seeds covered over by the berried calyx. The species are not numerous, and are found in Europe, Asia, Africa, and America. The branches and flowers of the Asiatic species of this genus were formerly kept in the shops as styptics. The fruit is mucilaginous, eatable, subacid, and slightly pungent.

E. distachya has the sheaths of the joints 2-toothed, blunt, the catkins 2, opposite, stalked, the peduncles shorter than the catkins. It is a native of France and some parts of Germany, and abounds in the southern parts of Europe, and thence eastward to Persia and India. The berries, which consist of the fleshy calyx covering the ovarium, ripen in July and August. They have a sweetish taste, and contain a mucilaginous juice.

E. monostachya has the sheaths of the joints the same as the last, but the catkins either solitary or opposite, and the peduncles longer than the catkins. This plant is found in Hungary and Siberia, and in these countries the fruit is eaten as a great luxury.

E. altissima has clustered catkins and spreading branches, and is a native of Barbary.

There is an American species found on the borders of Lake Michigan in the country of the Chippeway Indians. It bears a large fruit.

(Burnett, *Outlines of Botany*; London, *Encyclopædia of Plants*.)

EPHE'MERA (ἐφήμερα, living for a day), a genus of Neuropterous Insects belonging to the family of *Subulicornes* of Latreille. They have long soft tapering bodies, terminating in two or three long setæ. Their wings are placed nearly or quite perpendicularly. Their antennæ are very small, and 3-pointed. In the larva state they live in wet places or under water, and enjoy an existence of two or three years; but when they attain their final stage of metamorphosis and perfect form, they are among the most fleeting of living creatures, existing often only a few hours, and propagating their species before they die. In this state they sometimes appear suddenly in myriads, during fine summer evenings, by the water-side, where they may be seen flitting about and balancing themselves in the air, in the manner of gad-flies. (Westwood, *Introduction to Entomology*.)

EPHIALTUS. [MAIADÆ.]

EPHIPPUS. [CHÆTODON.]

EPHYRA. [ACALEPHÆ.]

EPIDENDRUM, an old name for all the Orchidaceous Plants which grow upon the branches of trees, and which are now called Epiphytes. [EPIPHYTES.] In its modern sense it is restricted to a considerable genus of the order with the labellum united to the column, and four pollen-masses adhering to as many little straps bent back upon them. Some of them are showy and interesting, particularly *E. Skinneri*, *E. oncidioides*, *E. cochleatum*, *E. aromaticum*, *E. bifidum*, and *E. auropurpureum*; but many are inconspicuous, and of no importance except to botanists. According to Sir R. Schomburgk the expressed juice of *E. bifidum* is a purgative, taken in doses of a table-spoonful at a time; it is also reckoned in Tortola an anthelmintic and diuretic.

EPIDERMIS (in Animals). [SKIN.]

EPIDERMIS (in Plants). [BARK; TISSUES, VEGETABLE.]

EPIDOTE, a Mineral consisting of silica, alumina, lime, iron, and manganese. It crystallises in right rhomboidal prisms, more or less modified, often with six or more sides. It is of a yellowish-green colour, with ash- and hair-brown. It is translucent to opaque. Lustre vitreous, a little pearly; often brilliant on the faces of the crystals.

There are three prominent varieties of this species: one of a yellowish-green colour; another called *Zoisite*, of a grayish-brown or hair-brown; and a third of dark reddish shades, which contains 14 per cent. of oxide of manganese, and is called *Manganese Epidote*. Another variety of a red colour is called *Thulite*. The yellowish-green variety is often called *Pistacite*. *Bucklandite* is an iron *Epidote*. The green Epidote has a composition as follows:—

Silica	37·0
Alumina	26·6

Epidote occurs in crystalline rocks, and also in some sedimentary rocks that have been heated by the passage of dykes of trap or basalt. It has been found principally in the United States of America.

(Dana, *Mineralogy*.)

EPILOBIUM, an extensive genus of Plants belonging to the natural order *Onagraceæ*. It is composed of herbs with opposite or alternate leaves; axillary or solitary flowers, or disposed in terminal spikes, each flower furnished with a bractea; the corollas purple, rose-coloured, or flesh-coloured. The calyx has four sepals connected in a long tube; the petals 4; stamens 8; the capsule linear, bluntly tetragonal, 4-celled, 4-valved, many-seeded, and inseparable from the calyx; the seeds pendulous and covered with pappus. About 45 species of this genus have been described: they are natives of the cooler parts and mountainous districts of Europe, Asia, and America.

E. angustifolium, Narrow-Leaved Willow-Herb, or French Willow, has a creeping root; erect nearly simple stem; sub-sessile lanceolate undulated glabrous leaves, with pellucid veins; the flowers bracteated in spicate racemes; the style reflexed, pilose at the base, and shorter than the stamens. It is found in mountains, woods, and meadows, in Europe and Siberia. In Great Britain it is found in moist shady places in the north of England and in the south of Scotland. It has crimson inodorous flowers, with blue pollen. It is a very ornamental plant, and is often introduced into gardens; but it requires great attention, as its roots spread very rapidly, and are got rid of with great difficulty. In Kamtchatka the pith of this plant is dried and boiled, and on being fermented is converted into ale and vinegar. The young shoots are said to be eatable, but the matured plant possesses narcotic properties. As this plant is very common in some places, two or three varieties have been observed and described.

E. hirsutum, Hairy Willow-Herb, or Codlings-and-Cream, has creeping roots; branched hairy stems; lower leaves opposite, upper ones alternate, ovato-lanceolate, hairy, toothed, half stem-clasping; stigma 4-cleft, the segments deflexed. This plant is found in wet places in Europe and Siberia. In Great Britain it is a common plant in ditches, on the margins of rivers, amongst reeds and coarse grasses. The whole plant is downy and clammy. It exhales a peculiar acidulous scent, which, from its resemblance to that dish, has procured it the name of Codlings-and-Cream. This scent is not unlike that of hot apple-pie.

The other British species of this genus are *E. parviflorum*, *E. lanceolatum*, *E. montanum*, *E. palustre*, *E. variegatum*, *E. tetragonum*, *E. roseum*, *E. alsinifolium*, and *E. alpinum*.

Although this genus is numerous, the species offer no great variety of character. None of them possess active medicinal properties, which is a character of the family to which they belong; nor do they yield secretions which render them available as food for man or beast. All of them are ornamental plants, and may be introduced into gardens. They require little care in their cultivation, as they will grow in any common garden soil, and may be easily propagated by sowing the seed or by dividing the roots.

EPIMEDIUM, a genus of Plants belonging to the natural order *Berberaceæ*, or *Berberideæ*. It has a calyx of 4 deciduous sepals; 4 petals; 4 cup-shaped nectaries; the capsule pod-like, many-seeded. The species are herbs with creeping perennial roots and annual stems.

E. alpinum, Alpine Barrenwort, has no root-leaves, and the leaves of the stem twice ternate. It is a native of France and other parts of Europe in sub-alpine coppices and woods. It has been found growing in Great Britain in Cumberland and Yorkshire, but Mr. Babington remarks that it has very slender claims to be considered a native of England or Scotland. The flowers are red, with yellow nectaries. The stem is about four inches high. Its somewhat bitter leaves were formerly regarded as sudorific and alexipharmic.

E. pinnatum is a native of Persia, and *E. hexandrum* of the north-west of America. The first species is easily cultivated, and will grow in any common garden soil, and may be propagated by dividing the root.

(Babington, *Manual of British Botany.*)

EPIPACTIS, a genus of Plants belonging to the natural order *Orchidaceæ* or *Orchideæ*, and to the tribe *Limodoreæ* or *Arethuseæ*. It has the perianth patent, the lip interrupted, the basal division concave, the terminal one larger, with two projecting plates at its base above; the stigma nearly square; the rostellum short, terminated by a globose appendage; the anthers terminal, erect, sessile, 2-celled, the cells without septa; the column short; the germen straight on a twisted stalk. There are two species of this genus found wild in Great Britain.

E. latifolia has ovate clasping leaves, the lower bracts longer than the flowers, the terminal division of the lip entire, with a minute point. Babington observes that there are four or more very different plants included under this species inhabiting various parts of Great Britain. These are:—1. *E. latifolia*, with the terminal division of the lip roundish, cordate, obtuse, with a small recurved point. 2. *E. media*, with the terminal division of the lip triangular-cordate, acute, as long as the lanceolate sepals and petals. 3. *E. purpurata*, with the terminal division of the lip triangular-cordate, acute, shorter than the ovate-lanceolate sepals and petals. 4. *E. ovalis*, with the terminal division of the lip transversely oval and acute.

E. palustris has lanceolate leaves, bracts shorter than the somewhat drooping flowers, the terminal division of the lip roundish, obtuse, crenate, as long as the perianth. It is found in Great Britain in moist places, and is not a rare plant.

These plants will thrive in the borders on common garden soil, and will also grow in pots with a mixture of loam and peat; they require but little water when not vegetating, and may be propagated by division of the roots.

(Babington, *Manual of British Botany;* Loudon, *Encyclopædia of Plants.*)

EPIPHE'GUS (from ἐπί, upon, and φηγός, the beech, because the plant is parasitical on the roots of the beech), a genus of Plants belonging to the natural order *Orobanchaceæ*. It has the sterile flowers perfect, and the fertile flowers imperfect; the calyx short, 4-toothed; the perfect corolla 2-lipped; the upper lip emarginate, the lower 3-toothed; the imperfect corolla slender, 4-toothed, deciduous; the stamens as long as the corolla; the filaments smooth; the anthers 2-lobed, acute at the base, valveless, dehiscent in the middle; the stigma capitate, and somewhat emarginate; the capsule gibbous compressed, half 2-valved with four diverging placentæ. There is but one species, *E. Virginiana*. It is found parasitical on the roots of beech-trees in the southern states of the American Union, where it is called Beech-Drops. It is the *Orobanche Virginiana* of Linnæus. It is a smooth fleshy branching plant, growing from 6 to 18 inches high, and clothed with small scales instead of leaves. The corolla is purple streaked with white. The capsule dilates after it opens into the shape of a cup. There is in North America a quack medicine called 'Martin's Cancer Powder,' which consists of equal parts of this plant and white arsenic. It is said by some writers to have a beneficial effect. (Lindley, *Flora Medica;* Don, *Dichlamydeous Plants.*)

EPIPHLEUM. [BARK.]

EPIPHYLLOSPERMOUS PLANTS, so called by the old botanists because they bore their seed upon the back of their leaves. They are what have more recently been called Dorsiferous Ferns. [FILICES.]

EPIPHYTES are plants found growing upon other vegetables, adhering to their bark, and rooting among the scanty soil that occupies their surface, in which respect they are distinguished from parasitical plants, which, like Mistletoe and the various species of *Loranthus*, strike their abortive roots into the wood, and flourish upon the blood of the individual to which they attach themselves. In this sense of the word, Mosses, Lichens, Ferns, and plants of many other families, are Epiphytes; but as in this country at the present day the word is principally employed with reference to those *Orchidaceæ* which grow upon trees, it is to plants of that description that we propose to devote the present article.

It had long been known, from the reports of travellers, that Orchidaceous Epiphytes were plants of extremely curious organisation, and that great numbers were also remarkable for the singular beauty and fragrance of their flowers; but when imported into this country, their habits were found to be so unlike those of other plants, that no gardener could succeed in keeping them even alive for any considerable time, except in a very few instances; and it was not till about the year 1820 that the real method of managing them successfully began to be understood. About that time Mr. Cattley and Dr. Lindley began to direct their attention to the subject with some success. Since that period the difficulties of cultivating Orchidaceous Plants have been gradually disappearing, and at the present day they may be said to be almost entirely overcome; so that in the gardens of the Duke of Devonshire at Chatsworth, of Mr. Bateman at Knypersley, of Lord Fitzwilliam at Wentworth, of Mr. Harrison of Liverpool, and of many other amateurs, they have acquired a beauty quite unknown to them in a wild state. Species which in their native woods yield no more than two or three of their curious blossoms in a cluster have been found to produce from nine to between twenty and thirty, and the whole order has in short been found willing to submit to domestication with as much advantage as has ever attended roses, hyacinths, tulips, or dahlias—those well-known flowers which we have from time to time reclaimed from their wild habits, and by the arts of cultivation invested with a splendour of appearance that never could have been anticipated from their original appearance in a savage state. Previously to the year 1820 it is doubtful whether any garden in England could at any one time have produced twenty species of these plants, but since that period more than a thousand have been successfully preserved in the collections of the Messrs. Loddiges, Rollisson, Knight, and other nurserymen near London.

We do not propose in this place to give any botanical account of these curious plants. For such particulars we refer to the article on ORCHIDACEÆ. Upon the present occasion we shall confine ourselves to an account of their natural habits, and of those methods of cultivation which appear to have met with so much success. In preparing the following account, we depend in part upon our own experience, in part upon the information contained in the writings of botanical travellers, and in part upon the useful communications which within the few last years have been made to the current horticultural publications, especially the 'Transactions of the Horticultural Society' and the 'Gardeners' Chronicle.'

Orchidaceous Epiphytes grow naturally upon trees in the recesses of tropical forests. They establish themselves upon the branches, and either vegetate amidst masses of decayed vegetable and animal matter, or cling by their long succulent grasping roots to the naked branches of trees, from which and the humid atmosphere together they exclusively derive their food. It appears from the testimony of Mr. Henchman that they are never found upon dead erect trees in forests; but if upon dead wood at all, then only upon fallen trunks, which, from their situation near the ground, are constantly damp. Such situations are however said to be by no means favourable to their growth. They will also flourish upon rocks and stones in hot and damp climates. Mr. W. Harrison of Rio Janeiro is said, by one of the Horticultural Society's collectors who visited him, to have cultivated with the most perfect success above seventy species upon a wall in his garden at Boto Fogo.

We even see some of them germinate and grow most luxuriently in damp places, in the stove, upon the sides of the garden-pots, and among gravel; some genera, such as *Brasavola*, are even reported to prefer stones; and Dr. Wallich found them in all cases growing equally well in Nepaul upon trees and stones, provided the latter had a certain quantity of mould and moss adhering to them. In the botanic garden at Calcutta they are said to be cultivated with success in raised beds of solid brickwork, so contrived as to insure a perfect drainage; the soil being rich vegetable matter mixed with at least two-thirds small pebbles, and covered with a dense layer of moss. A certain quantity of shade seems, in many cases, essential to them, their natural situation being in forests, or among the branches of growing trees. In Brazil numbers of them occupy damp woods and rich valleys, among vegetation of the most luxuriant description, by which they are embowered. Reinwardt describes others as inhabiting in great abundance those deep shady gloomy forests which form the lower zone of vegetation in Java, where the air is heavy and damp with vapours that cannot ascend, and where the thickness of the vegetation is really frightful; where, in short, heat, moisture, and a most extraordinarily deep and rich vegetable soil combine to produce wood of a fungus-like softness and an inconceivable abundance of Twining Plants and Epiphytes. In those forests more especially where huge fig-trees constitute the principal part of the timber, intermingled with the most tropical forms of vegetation, such as *Sterculiaceæ*, *Sapindaceæ*, and *Artocarpaceæ*, tufts of Orchidaceous Plants abound, in company with *Araceæ*, *Acanthaceæ*, and *Zingiberaceæ*.

In Nepaul Dr. Wallich states that Orchidaceous Epiphytes grow in company with Ferns; and the thicker the forest, the more stately the trees, the richer and blacker the natural soil, the more profuse the *Orchidaceæ* and Ferns upon them. There they flourish by the sides of dripping springs, in deep shady recesses, in inconceivable quantity, and with an astonishing degree of luxuriance. It would however be a great error to suppose that it is only in very shady places that Orchidaceous Epiphytes appear. On the contrary, it is probable that the cases just cited are extreme, and that they more commonly prefer situations where the broken rays of the sun can readily reach them. Mr. John Henchman states ('Gardeners' Mag.,' ii. 139) that he has observed in Demerara "That *Orchidaceæ* appear to rejoice in a light situation and a free circulation of the atmosphere; but are decidedly adverse, with few exceptions, to exposure to the intense rays of the sun. We may except from this remark *Oncidium luridum*, the Catasetums, and a fine pseudo-bulb found on the Spanish Main (which I suppose to be an *Epidendrum*), which seem not only to exist, but to rejoice, in exposure to the sun." Mr. Bateman also found, from the report of his collector, Colley, that the situations in which they are most usually seen are those parts of a forest where old and broken wood occurs, or on the skirts of savannas. These savannas are large open breaks in the woods, covered with fine white sand, which has at night the appearance of snow. They contain also many low and stunted bushes. The *Orchidaceæ* seem to like an airy and exposed dwelling-place; being found on the more prominent parts of a tree, and not in the shade, as is generally supposed. Mr. Colley only found in one instance an Orchidaceous Plant in the heart of a forest, and this was growing on the prostrate trunk of a tree so rotten as to fall to pieces when pressed with the foot. ('Gard. Mag.,' ii. 4.)

This quite corresponds with the statements of travellers in Brazil, who speak of their occuring most abundantly in open glades of the forests, and on the faces of naked rocks, or on shaded banks, although they are also met with "in sombre glades where heated vapours are incessantly circulating."

Where the climate suits them, they are sometimes prodigiously numerous. Descourtilz, in his manuscripts, speaks of a whole tree being overrun with a single species; and Henchman also assures us that in Demerara masses of *Oncidium altissimum* and *Maxillaria Parkeri* are to be seen, which would defy any attempt at intrusion; on the Spanish Main he saw the Epiphyte commonly called the Spread-Eagle, clasping enormous trees, and covering them from top to bottom; and he also met with two or three species, supposed to be Maxillarias, which were growing with uncommon vigour. "But," he adds, "with the above exceptions, I have not found *Orchidaceæ* growing in such quantities as it has been reported they do; often, as Mr. Bateman justly observes, single specimens only are to be obtained. This cannot be more strongly illustrated than in the case of a beautiful *Oncidium*, which I was happy enough to meet with on the Spanish Main; its leaves are nearly six inches in width, of a very firm texture, and possessing an uncommonly strong nerve; and though the plant, judging from the remains of the original stem, which had gradually decayed as the plant progressed, must have occupied its station for nearly half a century, yet I searched the neighbourhood in vain for another specimen, nor did I see another plant of it on the Main."

This altogether corresponds with what we know of such plants in other countries, and with the general habit of the whole order, which is extremely local in the majority of cases. Upon comparing the Orchidaceous Plants of Java, of Ceylon, and of the Birmese country, it is quite extraordinary how few species those countries possess in common; and the quantities of species found exclusively in every large collection are a corroboration of the same fact. Mr. Bateman assures us that in Guyana "a river may be ascended for twenty miles without an Orchidaceous Plant being seen; while, on a sudden turn of the stream, every tree becomes covered with them: yet they do not appear to have a favourite aspect; for on some of the rivers which Mr. Colley visited he found them exclusively on the northern exposure, while on others they occupied the southern." The part of the tree on which they are principally found is as uncertain as their station. It is said that they love the loftiest branches, and are hardly found near the bottom, and M. Descourtilz confirms this statement by describing some of them as swinging in the air from the top of the old patriarchs of the forest, or exposed to all the violence of storms in the most exposed situations. But Mr. Henchman asserts that in Demerara at least they "do not grow in such high situations upon trees as is generally supposed. Twenty or twenty-five feet is the greatest height, with few exceptions, at which I have seen them growing. Some of the bulbless Epidendrums, the Spread-Eagle Plant, and *Oncidium papilio*, attain a much greater height. The other Oncidiums I have not seen growing above seven feet or eight feet from the ground, and generally on some of the small closely interwoven branches, and not on the stem or main branches of the tree. The various species of *Gongora*, *Coryanthes*, and *Rodriguezia*, are, almost without exception, found in the same position; while, again, the genera *Maxillaria*, *Fernandesia*, *Epidendrum*, *Ceratochilus*, *Cattleya*, *Zygopetalon*, *Brassavola*, *Ornithidium*, *Camaridium Pleurothallis*, *Brassia*, *Ornithocephalus*, *Trizeuxis*, *Catasetum*, and many other genera supposed to be new, I have found always attached to the trunk or strong limbs of the tree, which they clasp with surprising tenacity. It may be also observed that rough and soft barked trees are favourite habitats of *Orchidaceæ*. The Calabash-Tree, which has a peculiarly soft and woolly bark, often possesses many of the more minute species. Indeed, I sent home pieces of the Calabash-Tree, about a foot long, on some of which were six and on others seven distinct species of *Orchidaceæ*."

A high mean temperature throughout the year, and a climate either constantly humid or at least periodically so, are also atmospheric elements eminently favourable to the production of these plants. All those species which simply exist clinging by their roots to the branches of growing trees, and probably others also, must necessarily derive their nourishment in a great measure, if not entirely, from the moisture, in a very elastic state, that surrounds them. And although nature seems in general to have provided for the scantiness of their food by the construction of them with a cuticle only capable of parting by slow degrees with the fluid they receive by their roots, yet it is obviously requisite that they should be so situated as to be within reach of an abundant supply, not only at the time when they are growing, but also at all other times to a certain extent. Hence we find that the hottest countries if dry, and the dampest if cold, are destitute of them; while there is no instance of a country both hot and damp in which they are not plentiful. For example, in Africa they are unknown in its sandy deserts and parched atmosphere, notwithstanding the high temperature of that part of the world; yet they abound in Sierra Leone, where the climate is damp; and even at the Cape of Good Hope they occur not unsparingly in all that jungly district to the eastward of the Cape Town to which the name of Outniqualand is applied.

In the West India Islands they exist in great quantities, particularly in Jamaica and Trinidad; not however so much on the coast as upon the lower ranges of hills. This is in conformity with their habits elsewhere: in these islands the air of the level of the sea is dry, while that of the mountains is humid. Captain Sabine found the air of the level of the sea at Trinidad indicate 5° of dryness, and that of Jamaica 7°; while the atmosphere was saturated with humidity in the first of these islands at 1060 feet above the level of the sea, and in the second at an elevation of 4080 feet. At Rio Janeiro the mean temperature is 74° 3′, and much higher inland; the woods are so damp that it is difficult to dry plants; and in such situations multitudes of Orchidaceous Epiphytes spring up. But in the immediate vicinity of Buenos Ayres, where the mean temperature is 67° 6′ and the air dry, they are unknown; and in the high dry land of Mendoza, where the aridity is still greater, the whole order disappears, with the exception of a single species. On the west coast of South America, as high as Lower Peru, Orchidaceous Epiphytes are unknown; a circumstance which is not surprising when we consider the effect of the currents setting round Cape Horn, which bring the mean temperature of even Lower Peru itself down to 60° at night, and how arid the whole of that region is with the exception of a few valleys. No country however exhibits in a more striking manner than India the necessity of a hot and damp climate for the production of Orchidaceous Epiphytes. In the Malayan Archipelago, the mean temperature of which is estimated at between 77° and 78° and is very damp, they are found in profusion. In Nepaul it is upon the sides of the lower mountains that they occur, where they vegetate amongst clouds and constant showers; while on the continent of India they are almost unknown, their place being occupied by parasitical *Loranthi*. The traveller finds himself in the morning on the dry plains of Hindustan, where the mean temperature is 80°, and where all the trees are destitute of *Orchidaceæ*; and at noon he is at the foot of the first range of the Nepaulese hills, where every tree teems with that class of plants. There are however places on the continent of India where they are not less numerous than in Nepaul; at the æstuaries of the Ganges, the Brahmaputra, the Irawaddi, and the rivers of Martaban, they exist in vast quantities; but all these stations are excessively damp. In the Botanic Garden at Calcutta they grow most vigorously during the rainy season, but in the fiercely hot season, which begins in March and lasts till the 10th of June, they perish notwithstanding all the care they receive. Madagascar and Mauritius offer similar evidence to the same effect.

While however these statements are applicable to a very large part of Orchidaceous Epiphytes, there are some striking exceptions that require to be pointed out, both with regard to atmospheric moisture and to the temperature requisite for their production.

Mr. Allan Cunningham has shown in the 'Botanical Register,' fol. 1699, that in Australia there are three of these plants which require a very dry atmosphere, and it is probable that others exist in other countries. "These are *Dendrobium æmulum*, Brown, an Epiphyte uniformly found upon the rugged trunk of *Eucalyptus resinifera*, or Iron-Bark, in the open very dry forest grounds of the older colony at Port Jackson; *Cymbidium canaliculatum*, Brown, which of late years has been observed beyond the tropic both at Moreton Bay and still farther to the southward at Hunter's River, growing upon the principal limbs of several of the *Eucalypti* in the dry open shadeless forest. These two Epiphytes flourish most luxuriantly in an extremely dry atmosphere, and flower usually in the summer season in their native wilds, the high temperature of which is oftentimes greatly increased by the blighting hot winds which not unfrequently prevail at that period from the north-west. The third is *Dendrobium undulatum* of Mr. Brown, a handsome species, originally discovered by Sir Joseph Banks at Bustard Bay, and which has been lately found on barren hills naturally clear of timber upon the banks of the Brisbane River at Moreton Bay, where the plant forms tufts on bare rocks exposed to the full heat of the sun, which during nine months of the year is very considerable on that part of the coast."

In many cases a much lower temperature than that hitherto spoken of is natural to these plants, and there are some instances where they are naturally accustomed to rigorous weather. In America their favourite station, according to Humboldt, is in the gorges of the Andes of Mexico, New Granada, Quito, and Peru, where the air is mild and humid, and the mean temperature is 63° to 67° Fahr. (17° to 19° Cent.). In these localities they are so abundant that, according to the authors of the 'Flora Peruviana,' above 1000 species might be found in Tarma, Huanuco, and Xauxa alone. It is therefore not surprising that one species, *Epidendrum conopseum*, should advance as far to the northward as the rice climate of Florida, where it grows on the bark of *Magnolia glauca;* nor that others should be found in the damp maritime parts of the government of Buenos Ayres. But it is more remarkable that an *Oncidium nubigenum* should occur at the height of 14,000 feet on the mountains of Peru, and that other species should, upon the authority of M. Descourtilz, be able to bear without difficulty the cold glacial winds of the high serras of Brazil. The same peculiarities occur in the eastern world. Reinwardt speaks of great quantities of *Orchidaceæ* in the Storax and Laurel woods of Java, growing along with *Nepenthes*, Rhododendrons, Magnolias, and Oaks, in a zone of vegetation whose lower limit is 3000 feet above the sea. *Dendrobium nobile, Renanthera coccinea*, and some others, bear the periodical cold of Canton, where it occasionally freezes; *Dendrobium catenatum* and *D. moniliforme* occur in Japan as far north as 37° or 38°, or the parallel of Lisbon, and are periodically subject to a very low temperature; and Dr. Royle met with the deciduous *Cœlogynes* and *Dendrobium alpestre* on the Himalaya Mountains at the height of 7500 feet, where snow sometimes lies in winter for a week or more. To the southward they not only occur in the latitude of Port Jackson, where the mean temperature does not exceed 66° 6′, but even in much higher latitudes. The beautiful little *Gunnia Australis* grows on the branches of shrubs in Emu Bay, in Van Diemen's Land, in about 41° S. lat.; and *Earina mucronata* extends to 45° 45′ S. lat., in "the very permanently damp woods which clothe the shores of Dusky Bay in New Zealand," where it was originally observed by Forster in Cook's second voyage, and where it has since been met with by Mr. Cunningham, whose words we quote.

Such are the more important data that we possess to guide us in the cultivation of Orchidaceous Epiphytes; the result of which is, that they are kept in this country in stoves the air of which is maintained in a state of constant moisture, and at a temperature varying from 56° to 90° or more. The requisite uniformity of their atmosphere is provided for by keeping the houses but little ventilated, and the glass of the roof well puttied at the junction of the squares. Shade is secured either by moveable laths or by a screen of netting or coarse canvass, or by some such contrivance; some even grow their plants in a house exposed only to the north, but it does not appear that this plan is a good one; for it is an object not only to exclude excessive light, but also to be able to admit it if requisite, and this cannot happen in a hothouse with a northern aspect.

The soil in which the plants are made to grow is peat or some other kind of decayed vegetable matter, thoroughly drained, and yet so compact as not to be liable to become dry by excessive loss of water. In many cases it is found advantageous to make the plants grow upon the apex of a truncated cone of earth rising several inches above the rim of the pot. Certain kinds are suspended in baskets, or in frames so contrived as to be filled with moss and decayed vegetable mould rammed in very tight; and provided that precaution is attended to, the caulescent drooping species, especially Dendrobiums and Vanda-like plants, thrive admirably; but in general it is found most advisable to plant in earth in common garden-pots. Attempts have been made to grow some species on decayed dead wood, but they are generally abandoned now; nor have the trials to cultivate them on the branches of living trees hitherto proved more successful. The orange-tree was employed for this purpose by Mr. Lance with great success in Surinam, but in the hothouse it does not appear to suit them.

By attending to the natural habits of these plants, and observing the precautions just pointed out, the management of Orchidaceous Epiphytes has been brought quite within the skill of any good gardener. There are however two or three capital points about which cultivators entertain great difference of opinion.

The first is temperature. Some allow the thermometer to rise to 100° and higher in a summer's day, and never suffer it to fall below 65°; the consequence of which is, that their houses are so unpleasant that few persons can visit them to inspect the beautiful objects they contain. Others keep the temperature of even midsummer down to 80° at the most, and permit the minimum heat to be low in proportion; their houses are consequently cool and pleasant at all times. If we must admit that the first practice is eminently successful with some, so is the other most assuredly so with others; and we entertain no doubt that in the end it will be the only method followed.

The second question is the amount of moisture. Some form water-tanks in their houses, the evaporation from the surface of which keeps the air continually at the point of saturation; others simply keep the air sensibly moist by syringing or similar devices: the first is accompanied by a high, the latter by a moderate, temperature; in this case also we incline to believe that the latter practice is the best. The fact is that it may be reasonably doubted whether it is right always to follow nature literally in what we suppose to be her practice, and whether we ought not rather to adapt the management of our plants to the new and artificial condition under which they are placed. Keeping plants in a state of constant excitement by exposure to an excessive climate is a certain means of weakening them in the long run, and may be compared to keeping an animal always awake. It may be very true that this may seem to happen in nature; but does it really happen? Is it not probable that the long diurnal darkness of a tropical situation may be intended as a compensation for the high excitement of daylight? and are not we, with eighteen hours' daylight in summer, in an essentially different position from what Orchidaceous Epiphytes from equinoctial regions are exposed to in a wild state? Moreover, it can hardly be doubted that a moderate temperature is sufficient for them, even if they can be made to bear an excessive climate.

The third unsettled point is of another nature. In our hothouses we often maintain a high temperature all the year round, keeping our stove-plants growing from January to December. In nature this hardly ever happens. If a country has no winter it has its dry season, during which plants become more or less torpid. This is quite the case in all the countries inhabited by Orchidaceous Epiphytes, with the exception of some of the temperate parts of Mexico, where the climate is equal and mild. Should we not therefore give such plants, when cultivated, a similar period of repose? About this the opinions of cultivators are so much divided that we cannot say on which side the majority of votes would go. Mr. Bateman calls attention to the fact, in his account of Colley's mission to Guyana. "In consequence," he says, "of the unexampled length of the dry season, scarcely an orchidaceous plant was seen in flower, or a pseudo-bulb which had not lost its leaves. When however the rains had commenced, that is, in the month of July, the *Orchidaceæ* were pushing rapidly into flower, as were also some of those collected by Mr. Colley, which reached this country in as dry and shrivelled a state as Dutch bulbs usually come over in. This may afford a hint for their cultivation."

And Henchman, in like manner, urges the circumstance upon the consideration of gardeners.:—

"The atmospheric changes," he says, "are very great in tropical climates; and as I consider that *Orchidaceæ* derive their main support directly from the atmosphere, I think too much attention cannot be paid to the various changes by which they are in their natural state liable to be affected. One of the principal objects kept in view by growers of *Orchidaceæ* appears to be the keeping up a regular heat in the stove. Nothing can be more contrary to nature; for in the tropics, to a sultry day, with the thermometer standing at from 85° to 95°, succeeds a cool night and a cold morning, the thermometer falling to 60° or 55°; effecting in twenty-four hours a change of temperature of from 20 to 30 degrees. During the dry season, periods of two, three, and often extending to five or six months, the whole nourishment derived by the *Orchidaceæ* must be communicated through the agency of the tree to which they are attached, or from the atmospheric moisture which is the effect of the action of the sun upon the dew which has fallen during the night and morning; for the situations generally occupied by *Orchidaceæ* preclude the possibility of the dew reaching them in its descent; and slight though the moisture be which is communicated through these channels to *Orchidaceæ*, it is nevertheless sufficient to retain the vital principle in the pseudo-bulb, though not sufficient to rouse it into action. The dry season then appears to act upon *Orchidaceæ* on much the same principle as our winter acts upon our trees, &c. It is for them a period of rest; and the pseudo-bulbs having been well ripened are ready, when the wet season has given them a sufficient stimulus, to push forth luxuriantly both leaves and flowers." Nevertheless some of our best gardeners object to the plan of periodical resting; and, it must be added, appear to succeed without attending to it.

So far as the opinion of the writer of this article is of any value, it is rather in favour of the system of resting these plants for three or four months annually by lowering the temperature to 60° or thereabouts, and diminishing the moisture very considerably; indeed in regard to *Catasetum*, *Cycnoches*, *Phaius*, *Bletia*, *Geodorum*, and some others with deciduous leaves, there is no doubt that the plan is indispensable; and it would probably be equally advantageous with respect to all the kinds with fleshy stems or pseudo-bulbs; but how far it may suit caulescent species with the habit of *Vanda* and *Aerides* can only be ascertained by direct experiment.

EPISTILBITE, a Mineral occurring massive with attached crystals. The primary form is a right rhombic prism. The cleavage parallel to the short diagonal of the prism. Colour white. Streak white. Fracture uneven. Hardness 4·0 to 4·5. Lustre vitreous. Transparent, translucent. Specific gravity 2·20 to 2·25. It is found on Faroe Islands and in Iceland. The analysis of the Iceland mineral by Rose is as follows:—Silica, 58·59; alumina, 17·52; lime, 7·56; soda, 1·78; water, 14·98.

EPITHELIUM. As on the external surface of the animal body there is covering over all a delicate layer of cells which is called Epidermis, so over the internal surface of the body there is found a layer of cells which are called Epithelial Cells, or Epithelium. The epidermal and epithelial cells are homologues, and are so many modifications of a similar general arrangement.

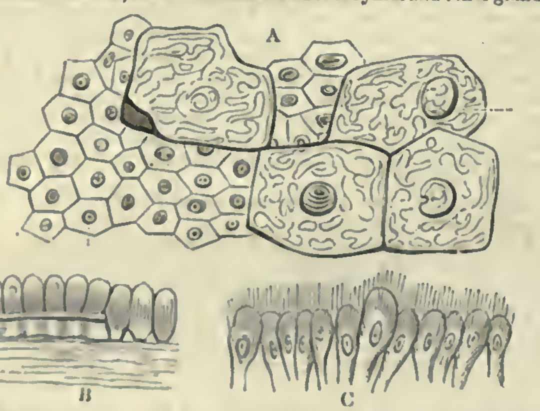
The functions of the epithelial cells vary according to the surfaces on which they are placed. They differ from the epidermal cells in being generally moist from the positions in which they are placed. The cells of the epithelium performing, as they do, the most remarkable part of the functions of the organs of which they form a part, vary much in form and size. In all cases they are soft, contain a nucleus, and are in shape rounded, polygonal, fusiform, or conical. Sometimes they occur in one layer, sometimes in several. In some instances they are supplied with cilia. The following is Kölliker's arrangement of the epithelial cells:—

a. Epithelium in a single Stratum.

1. With rounded polygonal cells. This, called Pavement Epithelium (*Fig.* A), presents only a single layer. It exists as an investment of the true serous membranes, of most synovial membranes, of the cerebral ventricles (ependyma), of the membrane of Demours, of the back of the iris, and of the inner surface of the choroid (pigment layer) of the capsule of the lens and of the retina, of the internal ear, of the endocardium of the veins, of many glandular vesicles and canals, and of the interlobular ducts of the liver.

2. With fusiform superficially united cells. This is called Fusiform Epithelium, and is found in the arteries and many veins.

3. With cylindrical cells. This is the Cylindrical Epithelium. (*Fig.* B.) It is found in the intestinal tubes in Lieberkühn's glands, in the excretory ducts of the gastric glands, as well as of all the other glands which open into the intestine, also of the lacteal and lachrymal and other glands.



4. With cylindrical or conical ciliated cells. This is the Ciliated Cylinder Epithelium. (*Fig.* C.) It is found on the finest bronchiæ, in the nasal cavities, on the inner surface of the membrana tympani, in the Eustachian tube, in the uterus, and in the Fallopian tubes.

5. With rounded ciliated cells. This is simple Ciliated Pavement Epithelium, and occurs in the cerebral cavity of the embryo.

b. Epithelium in many Layers.

1. With cylindrical or rounded cells below, rounded polygonal, more or less flattened cells above. This is called Laminated Pavement Epithelium. It occurs in the mouth, the lower half of the pharynx, the œsophagus, the lachrymal canals, the conjunctiva, the tympanic cavity, the bladder, the reproductive passages, the kidneys, and certain synovial membranes.

2. With rounded cells below, more elongated ones in the middle, and ciliated conical ones above. This is called Laminated Ciliary Epithelium. It occurs in the larynx, trachea, and larger bronchiæ, in the nasal cavity, in the lachrymal sac and duct, and the upper half of the pharynx.

In many instances these forms of Epithelium pass into each other, where they are placed upon the same surface.

The functions performed by the Epithelium are various. In the instances where the cells are supplied with cilia, their object seems to be to give movement to the fluids secreted upon their surfaces. [CILIA.] Those placed on mucous membranes elaborate the protective mucus which covers these organs. In the case of those cells which are prolonged into the follicles and tubuli of which glandular structure is essentially composed, they are the real organs of secretion. [SECRETION.] They separate from the blood, as the materials of their nutrition, the peculiar products elaborated by the gland of which they form a part, and by their death and decay these products are set free to perform their work in the system. Even the cells in which the spermatozoa are developed for the fertilisation of the ova are produced upon the surfaces of the tubes or follicles of the spermatic glands.

(Kölliker, *Manual of Human Histology*, translated by Busk and Huxley; Carpenter, *Principles of Physiology*.)

EPITHEMIA. [DIATOMACEÆ.]

EPOMIS. [CHLÆNIUS.]

EPOMOPHORUS. [CHEIROPTERA.]

EPSOMITE, Native Sulphate of Magnesia. It occurs massive, botryoidal, and reniform, on the surface of other bodies, and in solution in sea and mineral waters. Colour white. Streak white. Structure fibrous, sometimes earthy. Brittle. Taste bitter and saline. Found originally in a spring at Epsom. It forms a large bed near Arequipa in Peru, and is often in fine crystals and silky fibres.

EQUIDÆ, a family of Animals to which the Horse belongs. They have but a single finger or toe terminating each extremity; and this finger or toe is incased in a horny-hoof, or shoe. But though the *Equidæ* possess but one well-developed toe, there are on each side of the metacarpus and metatarsus two small rudimentary processes which represent two lateral toes. The following is the form of dentition:—

$$\text{Incisors, } \frac{6}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{7-7}{6-6} = 42.$$

Various fabulous species of these animals are recorded in the descriptions and figures of some authors; such as the Bisulcated Horse with a mane extending the whole length of the animal from head to tail, and figured by Jonston as the Æthiopisch Pferd (*Equus Æthiopicus*). The Wald-Esel is figured by the same author with a unicorn-like horn in the midst of its forehead. These may be classed with the figures of monstrous horses collected by Aldrovandus, a horse with a human head and face for example, and another with hands by way of anterior extremities, which as he says, according to Suetonius, belonged to Julius Cæsar, and would suffer no one else to mount him:—"Caius Julius Cæsar utebatur equo insigni pedibus prope humanis, et in modum digitorum ungulis fissis," &c. This last was probably a case of malformation of the hoof; but the painter has given the animal two human hands, with four fingers and a thumb on each, and nails to match.

Linnæus, in his last edition of the 'Systema Naturæ' (12th), left the Horse (*Equus*) among his *Belluæ* (the sixth order of *Mammalia* in his arrangement), in company with the genera *Hippopotamus*, *Sus*, and *Rhinoceros*. His genus *Equus* consists of the following species: *E. Caballus*, *E. Asinus*, and *E. Zebra*, and is thus defined by him:—Incisor teeth (dentes primores) six above erecto-parallel, six below more prominent; canines (laniarii) solitary, included, remote on each side. Feet with an undivided hoof.

Gmelin, in his edition of the 'Systema Naturæ' (13th), added to the above definition, 'Teats two, inguinal,' and divided the genus into two sections—1, species with bisulcated feet; 2, species with solidungulous feet. The first section consists of one species only, *E. bisculus*, the 'Equus pedibus bisulcis,' Molin., 'Hist. Nat. Chil.' This was most probably a Llama. The second section embraces the following species:—*Equus Caballus*, *E. Hemionus*, *E. Asinus*, *E. Zebra*, and *E. Quagga*.

Cuvier places the Solipèdes at the end of his Mammiferous Pachyderms, and makes this family to consist of only one genus, *Equus*, with the following species:—*Caballus*, *Hemionus*, *Asinus*, *Zebra*, *Quagga*, and *Montanus*.

Dr. Gray, in his 'Revision of the Family Equidæ' ('Zool. Journ.,' vol. i), observes that the older authors speak of the Horse, Mule, Onager, Ass, and Zebra, the last of which they generally describe as having the body (corpus) striped with black, brown, and white bands, three inches broad, but take no notice of the colour of its legs; but in Jonston's figure they are distinctly banded. After referring to the other figures in Jonston and to Molina's Guemel, or Huemul, *Equus bisulcus* of Gmelin, which, if it exists, Dr. Gray considers to be probably a species of Llama (*Auchenia*), he notices the figures in Edwards's 'Gleanings'—the species recorded by Linnæus, Pallas, and Burchell,—the Quagga sent by Captain Gordon from the Cape to Amsterdam, where it was first described and figured from his drawing in the Dutch edition of Buffon, and afterwards in the supplement of the French editions; and L'Ane Isabelle of Le Vaillant. With regard to the last, which is described as being of a plain Isabella colour without any band, Dr. Gray observes, that nobody since Le

Vaillant's time, as far as he can learn, has mentioned it, and he asks whether it may not be an albino variety of the Zebra or Quagga, as the ass is sometimes found of yellowish-white, without any cross, in its domesticated state.

Dr. Gray thus defines the family of *Equidæ*:—"This family (which is distinguished from all other animals by its undivided hoof, formed of the two anterior toes soldered together, its simple stomach, and its female having the teat placed on the pubes) may be divided into two very distinct types of form; the one, the Asses and the Zebras, which are always whitish and more or less banded with blackish-brown, and always have a distinct dorsal line, the tail only bristly at the end, and have warts only on the arms and none on the hind legs; and the true Horses which are not banded, have no dorsal line, are furnished with warts on their arms and legs, and have long hair on the tail, from its insertion to its extremity." He further proceeds with his definition thus: "*Equidæ; Solidungulæ* Antiquorum, Cuvier, &c. Genus *Equus*, Linnæus:—

Dentes incisores, $\frac{6}{6}$; canine (mares), $\frac{1-1}{1-1}$; molars, $\frac{6-6}{6-6} = 40$.

Pedes ungulâ indivisâ." Dr. Gray then divides the family into two genera, namely: 1. *Equus*, consisting of the Common Horse and its varieties, *Equus Caballus*; 2. *Asinus*, embracing the following species: 1. *E. Hemionus*; 2. *E. vulgaris* (and its varieties); 3. *E. Quagga*; 4. *E. Burchellii*; 5. *E. Zebra*.

M. Lesson states that the Solipèdes, or *Equidæ*, of Gray, comprise only the genus *Equus*, which Dr. Gray has proposed to advance to the rank of a family under that name, comprising the genera *Equus* and *Asinus*; but, adds M. Lesson, there is nothing to induce us to admit a division which reposes only on superficial characters.

Mr. Bell is of a different opinion, and in his 'British Quadrupeds' follows Dr. Gray in considering the Ass as belonging to a distinct genus from the Horse, and he adopts Dr. Gray's family-name *Equidæ*. Mr. Bell makes the following remarks on the character of the Ass and its nearest congeners as compared with those of the Horse, upon which it had been thought necessary to establish them as distinct genera in the family. After admitting the truth of the observation that, in the absence of any knowledge of the original condition of the Horse, the question can only be considered with reference to the characters of a domesticated and probably much altered race, he reminds the reader, nevertheless, that as the distinctions upon which the division in question is founded are structural, there is less danger of error than if they had been only those of colour or of general form, and thus proceeds: "The character of the tail is one of the most striking points upon which this distinction rests. In the horse, the whole of this part is covered with long hair, totally concealing its actual form; whilst in the whole of the others, the ass, the zebra, the quagga, the dzigtai, &c., it is only clothed with long hair towards the extremity. The mane of the horse also is long and flowing; that of all the other species is short and upright. In the former animal, the hinder as well as the fore legs are furnished with those warty collosities, which in the others, without exception, are found only on the fore legs. Waiving some other particulars of minor importance, there is one character which, if not in itself to be considered of primary value, is yet interesting, and not unimportant as a collateral distinction: I mean the general tendency of the coloration and marking in the two forms. In the horse's coat there is an obvious disposition to the formation of small round spots of a different shade or hue from that of the ground, and this is the case whether the general colour be black, chestnut, or gray; in the genus *Asinus*, on the contrary, the markings are invariably disposed in stripes. The zebra, the quagga, and the mountain zebra are examples too familiar to require more than this allusion; and in the common ass, not only is the same tendency evinced by the cross-mark on the shoulders, but in the young ass there are frequently observed some obscure darkish bands on the legs. These tendencies to a peculiar character of coloration and marking are well worthy of especial notice in the *Mammalia*, among which will be found numerous instances bearing upon the distinction of approximating forms. In birds and insects it is still more general and striking, and has always attracted the attention of naturalists; but in the present class it has certainly been too much overlooked."

Geographical Distribution of the *Equidæ*.—Although the Horse, the Ass, and the Mule, are now spread over the whole face of the civilised earth, and although the Horse is found wild, or rather has reverted to a wild state, in both the New and the Old World, there can be no doubt that the form which we are now considering was originally entirely confined to the latter portion of the globe, where the truly wild species of the family, the Zebra, the Quagga, &c. are still to be found in all their native freedom. And this leads us to consider the time and the place where the Horse was first subdued by the powerful hand of man. Mr. Bell, who appeals to the sacred scriptures in proof that the Horse is of eastern origin, is of opinion, from the same authority, that the Egyptians were probably the first who broke the proud spirit of this noble animal, and reduced it to obedience and servitude. The books of Genesis and Exodus abound with passages which prove that the Horse had been long under the dominion of man at the date of the events then recorded. It was expressly prohibited (Deut., xvii. 16) that the king should multiply horses to himself, or should cause the people to return to Egypt, to the end that he should multiply horses. Solomon however does not seem to have regarded this prohibition, for his stables were filled with these noble animals; he had 40,000 stalls of horses for his chariots, and 12,000 horsemen. (1 Kings, iv. 26.)

The grand description in Job (xxxix. 19-25) is familiar to most, but Egypt (1 Kings, x. 28), and not Arabia, seems to have been the source whence Solomon's supplies were obtained. In very early Egyptian monuments the horse is seen in battle, and under circumstances which denote long subjugation and experienced training.

It seems to be quite clear that the wild horses of Tartary are as much the descendants of a domesticated race as the wild horses of America, whose ancestors were introduced by the Spaniards; nor have we any evidence to show the time when the horse existed in a primitive state of nature.

The *Equidæ* form two genera—*Equus* and *Asinus*; the species however freely breed together in confinement, but the produce is almost always, if not always, barren.

Equus has the tail covered with long hair to the base, the fore and hind legs with a wart (sallenders) on the inner side. The fur is dappled, that is, marked with round pale spots, having a dark net-like ground.

E. Caballus, the Horse, is brown, gray, or black, with roundish pale spots.

The following are the synonyms and varieties of this species given by Dr. Gray in the 'Catalogue of the British Museum:'—*Equus antiquorum* (Gesner). *Equus Caballus* (Linnæus; F. Cuvier; Fischer; Gray). *Equus, Equa* (Pliny). Horse (Pennant). Generous Horse (Pennant). Cheval (Buffon; Cuvier). Pferd (Redinger). Ross (Schrank). The Horse (Youatt). The Tarpan Wild Horse, primeval bay stock (H. Smith). The Andalusian Horse (H. Smith). South American Horse (H. Smith). The Parameros of Peru (H. Smith). Mexican Horse and Seminole Horse (H. Smith). Feral Horses of America (H. Smith). The Arabian Horse (Bewick; Low; Smith). The Race-Horse (Bewick; Low). English Race-Horse (Smith). Hunter (Bewick). The Old Irish Hunter (Low). The Connamara Horse (Low). Black Horse (Bewick). The Old English Black Horse (Low). The Cleveland Bay Horse (Low). The Suffolk Punch (Low). The Clydesdale Breed (Low). Old English Road-Horse (Bewick). Common Cart-Horse (Bewick). Improved Cart-Horse (Bewick). The Barb of Morocco (H. Smith). The Bornou (white) Race of Africa (H. Smith). The Dongola (black) Race (H. Smith). The Turkish Race (H. Smith). The Persian Race (H. Smith). The Toorkee Races (H. Smith). The East Indian Races (H. Smith). The New Holland Horse (H. Smith). The Transylvanian Horse (H. Smith). The Moldavian Horse (H. Smith). The Greek Horse (H. Smith). The Spanish Horse (H. Smith). Cheval d'Islande—var., *Islandicus* (Quoy and Gaim.; Lesson). *Equus Mongolicus* (Lesson). Thibet Horse (Hodgson). Cheval à Port Frisses—*E. frisius* (F. Cuvier). *Equus Caballus frisius* (Lesson). Villous Horse—primeval of the white stock (H. Smith). The White or Gray Horse (H. Smith); Marengo,—'Bonaparte's Arab.' The Crisp-Haired Horse—primeval of the black stock (H. Smith). The Black Horse—the English Draught-Horse (H. Smith). The Dun or Tau Horse (H. Smith). The Decussated Horse, or the Eelback Dun Horse of Ukraine (H. Smith). The Myautzee, or the Pied Horse of China (H. Smith). The Bhooteahs Ponies (H. Smith). The Pickarrow Ponies (H. Smith). The Yaboos of Affghanistan Ponies (H. Smith). The Hungarian Horse, with slit nostrils (H. Smith). The Common Bashkir Horse (H. Smith). The Morea Ponies (H. Smith). The Swedish and Norwegian Ponies (H. Smith). The Shetland Ponies (H. Smith). The Galloway (H. Smith). The Dartmoor and Exmoor Pony (H. Smith). Sardinian Wild Horse (H. Smith). The Tatto, or the East Indian Pony (H. Smith). Tuttoo, or Mahratta Pony (Sykes); sedulously propagated in the Deccan: much used to transport luggage, and very vicious.—Sykes. Tattoo, or Hack Pony of Calcutta (Hardwick). The Taugum Piebald or Skewbald Horse—*Equus varius* (H. Smith). The Tangum, or Tanghans—primeval Piebald Stock of Thibet (H. Smith). Skewbald of Achin in Sumatra (H. Smith). Tangham of China (Hodgson). Tangham of Lhassa (Hodgson). Tangham of Gyanche (Hodgson). Hubstee of Deo Dharma (Hodgson). The Koomrah, or *Equus hippargus* (H. Smith). The Koomrah—*Equus Lalisi* (H. Smith). Hippargus (Oppian). Boryes (Herodotus). Bourra of Koldagi (Rüppell); Northern Africa: not gregarious. The Kuda or Saran Horse (H. Smith). The Javan Horse (H. Smith). The Tamboro or Birma Horse (H. Smith). Horse with a curled moustache on the upper lip, of Asiatic Russia (Pallas). Horse covered with curled woolly hair, of Asiatic Russia (Falk.; Pallas). Naked Horse of a beautiful form, of Asiatic Russia (Pallas). The Argamaki of Bocharia—a white horse with very close, minute, orbicular, brown spots, of Asiatic Russia (Pallas).

It is questionable as to whether there exist at the present day any truly wild horses or descendants of an originally wild stock. Dr. Gray observes that the figure of the Wild Horse, as given by Gmelin, very much resembles the ponies left at liberty on the commons of Cornwall and mountains of Scotland; and it appears very doubtful if these animals are not rather to be considered as domestic horses which have escaped and become deteriorated. This is not the case with the wild horses which are found on the rich prairies of America, which retain the size and form of the well-bred horse. In many parts of the world the Horse is found in a semi-wild condition. It was introduced by the French into the Falkland Islands in 1764, and since that time they have greatly increased. The horses in these islands are always found on the eastern side of East Falkland, although there is no natural boundary; and that part of the island is not more fertile than the rest. The predominant colours of these horses are roan and iron-gray. Mr. Darwin says they are rather small-sized, but are generally in good condition. In South America the Horse was first landed at Buenos Ayres in 1537, and the colony being for a time deserted, it ran wild. In 1580, forty-three years after, they were found wild at the Straits of Magellan. On the Pampas they now abound in prodigious numbers. The Guachos, a semi-civilised race of men, live amidst these horses. They early learn to capture and ride them, and a Guacho is seldom off the back of his horse. It is said that they can capture and break in one of these wild horses in the course of an hour. The flesh serves them also as an article of food. The hides are preserved and sold. With the horses are also herds of wild oxen. The numbers of these animals may be judged of from the fact that in a period of five years, from 1838 to 1842, Monte Video and Buenos Ayres yielded annually about 90,000,000 lbs. of oxen and horses' hides, and 9,500,000 lbs. of horse-hair. The Horse is now found over the whole continent of America. Darwin says the natives of Tierra del Fuego are well stocked with horses, each man having six or seven, and all the women and even the children have their own horse. In his 'Fauna Boreali-Americana,' Sir John Richardson tells us that the Horse is found amongst the wandering Indians who frequent the prairies of the Saskatchewan and the Missouri. They use it for chasing the buffalo, as well as a beast of burden. Amongst the Indians, as well as the Guachos, the Horse is eaten. It is also eaten by the Calmuck Tartars, and in many parts of Asia mare's-milk is taken as an article of diet. It is also converted into butter and cheese, and a favourite beverage amongst the Tartars is made by fermenting it.

Everywhere the horse is recognised as the most useful of the servants of man, and he yields in intelligence to the dog alone. In the earlier ages of the world he seems to have been devoted to the purposes of war or of pleasure, while the ox was our agricultural servant; but his beauty, and strength, and tractability have now connected him, directly or indirectly, with almost all the purposes of life. If he differs in different countries in form and in size it is from the influence of climate and cultivation; but otherwise, from the war-horse, as he is depicted on the friezes of ancient temples, to the stately charger of Holstein and of Spain, or from the fleet and beautiful Arabian to the diminutive Shetlander, there is an evident similarity of form and destination which clearly stamps his common origin.

He is naturally and of choice an herbivorous animal. His thin and muscular lips, his firm and compressed mouth, and his sharp incisor teeth are admirably adapted to seize and to crop the grass; and although we know nothing of him in his natural state, yet when he has escaped from the bondage of man, and follows his own propensities, the grass is his chosen food. In his domesticated state however he was destined to live partially or chiefly on other aliment, and that of a much harder kind—the various species of corn; therefore while man and the carnivorous animals can only champ and crush their food, a provision is given to the horse, in the structure of some of the bones of the face, by means of which he can comminute and grind down his food as perfectly as in the best contrived mill.

The teeth of the horse require some lengthened consideration, not only from their admirable adaptation to this purpose, but as indicating, by the various changes which they undergo, almost beyond the possibility of error, the age of the animal. He may, when young in years, be reduced nearly to the decrepitude of age by the barbarous usage of those who ought to be his most zealous protectors; the cavity above the eye may be deepened, the under lip may fall, the limbs may be bowed, and the feet may be battered and distorted,—but it is not easy to alter the character of the teeth.

The colt is generally dropped with the first and second molar and grinding teeth having forced their way through the gum. When he is about seven or eight days old the two central front or incisor teeth, above and below, appear. At the expiration of five or six weeks the next two incisors may be seen. At three months they will have overtaken the central ones, and both pairs will have nearly attained their natural level. A third grinder will then have appeared; and a little before or after the eighth month the third nipper, above and below and on each side, will be seen. The colt will now have his full complement of front or cutting teeth.

These teeth are beautifully adapted to their purpose. They have in front an elevated cutting edge of considerable sharpness. It is formed of enamel, a polished substance almost too hard to be acted upon by the file, which covers the tooth. This elevated edge is bent somewhat inwards and over the tooth, so that there is a depression behind it which gradually becomes stained by the food and constitutes what is called 'the mark' in the mouth of the colt or horse.

This elevated edge of enamel, hard as it is, is gradually worn down in the act of nipping and cutting the grass; and as it wears away the hollow behind becomes diminished, and is at length totally obliterated. By the degree in which this mark is effaced, the horseman, not only with regard to the first, but the permanent teeth, judges of the age of the animal. This obliteration begins to be manifest at a very early age. At six months it is sufficiently evident in the four central nippers. At a year and a half the mark will be very faint in the central nippers, diminished in the other two, and the surface of all of them will be flattened.

At twelve months a fourth grinder protrudes, and a fifth at the expiration of two years.

These are all temporary teeth. They were only to last during a very early period of the life of the animal; and when his jaws were considerably expanded they were destined to give way to another set, larger, firmer, and that would probably last during life. The permanent teeth had been long growing in the socket beneath the temporary ones, and had been pressing upon their roots, and that pressure had caused an absorption of these roots, until at length they lost all hold and were displaced.

When the animal is about three years old the central pair of nippers, above and below, are thus removed, and two fresh teeth, easily distinguishable from the first by their increased size, make their appearance, so that a three-year-old colt is easily recognised by these two new and enlarged central nippers.

A three-year-old colt has his form and energies much more developed than a two-year-old one, and is considerably more valuable; therefore some dishonest breeders endeavour to pass him upon the unwary as being a year older than he really is, and they accomplish this in an ingenious but cruel manner. This cannot however be effected until a portion of the second year is past, when the permanent teeth below are beginning to press upon the roots of their predecessors, and then the breeder extracts the central milk-teeth. Those below having no longer anything to resist their progress, grow far more rapidly than they otherwise would do, and the scoundrel gains four or five months in the apparent age of his colt.

Can this trickery be detected? Not always, except by him who is well accustomed to horses. The comparatively slow wasting of the other nippers, the difference of the development of these nippers in the upper and under jaw—for the breeder usually confines his roguery to the lower jaw, the upper one being comparatively seldom examined—these circumstances, together with a deficiency of general development in the colt, will alone enable the purchaser to detect the attempted cheat.

The honest mouth of a three-year-old horse should be thus formed: —the central teeth are palpably larger than the others, and have the mark on their upper surface evident and well defined. They will however be lower than the other teeth. The mark in the next pair of nippers will be nearly worn away, and that in the corner nippers will begin to wear.

At three years and a half the second nippers will be pushed from their sockets, and their place gradually supplied by a new pair; and at four and a half the corner nippers will be undergoing the same process. Thus at four years old the central nippers will be fully grown; the next pair will be up, but will not have attained their full height; and the corner nippers will be small, with their mark nearly effaced. At five years old the mark will begin to be effaced from the central teeth, the next pair will be fully grown and the blackness of the mark a little taken off, and the corner pair will be protruding or partly grown.

At this period, or between the fourth and fifth year, another change will have taken place in the mouth; the tushes will have begun to appear. There will be two of them in each jaw, between the nippers and the grinders, considerably nearer to the former than the latter, and particularly so in the lower jaw. The use of these tushes in the domesticated state of the horse is not evident; but they were probably designed as weapons of offence in the wild state of the animal. Attempts are too frequently made to hasten the appearance of the second and the corner teeth in the same manner as described with regard to the first, and the gum is often deeply lanced in order to hasten the appearance of the tush.

At six years old the mark on the central nippers will be diminished, if not obliterated. A depression and a mark of rather brown hue may remain, but the deep blackened hole in the centre will no longer be found. The other incisors will also be somewhat worn, and the tush fully developed.

At seven the mark on the next pair of incisors will have nearly disappeared, and the tush will be rounded at the point and the edges.

At eight the mark will have disappeared from all the incisor teeth, and the tush will be evidently rounder and blunter.

At this period another piece of trickery is occasionally practised. The breeder had, till the animal was five years old, been endeavouring to give him an older appearance than his years entitled him to, because in proportion as he approached the period when his powers were most perfectly developed his value increased; but now he endeavours to conceal the ravages of age. The horse is cast, and with a sharp-pointed steel instrument a little hole is dug on the surface of the corner incisor, to which a red-hot iron is afterwards applied. An indelible black mark is thus left on the tooth. Sometimes the roguery is carried further; the next tooth is slightly touched with the engraver and the cautery; but here the dishonest dealer generally overreaches himself, for the form and general appearance of a six-year-old horse can rarely be given to one who has passed his eighth year. The eighth year having passed, it is difficult to decide on the exact age of the horse. The incisors of the upper jaw are then the best guides. At nine years the mark is said to be worn away from the central teeth; at eleven, from the next pair; and at twelve, from the corner ones. The tush likewise becomes shorter and blunter.

There are many circumstances which render a decision as to the age of the horse very difficult after the marks are effaced from the lower incisors, and even before that period. Horses always kept in the stable have the mark much sooner worn out than those that are at grass, and it is impossible to form any calculation at all as to crib-biters.

Of the age to which the horse would naturally arrive it is impossible to say anything satisfactory. Many have exceeded thirty, and some of them even forty years; but, from ill usage and over exertion, the majority come to their end before they have seen nine or ten years.

The Proper Conformation of the Horse.—A very general account only can be given of this, for it varies essentially with the breed and destination of the animal. There are some points however which are valuable in horses of every description. The head should not be disproportially large, and should be well set on, that is, the lower jawbones should be sufficiently far apart to enable the head to form that angle with the neck which gives free motion and a graceful carriage to it, and prevents its bearing too heavily on the hand. The eye should be large and a little prominent, and the eyelid fine and thin. The ear should be small and erect, and quick in motion. The lop-ear indicates dulness or stubborness; and when it is habitually laid too far back upon the neck, there is too frequently a disposition to mischief. The nostril in every breed should be somewhat expanded: it can hardly be too much so in the Racer, the Hunter, the Roadster, and the Coach-Horse, for these animals breathe only through the nostril, and would be dangerously distressed when much speed is required of them, if the nostril could not dilate to admit and to return the air. The neck should be long rather than short. It then enables the animal to graze with more ease, and to throw his weight more forward, whether he is in harness or galloping at the top of his speed. It should be muscular at its base, and gradually become fine as it approaches the head. The withers should be somewhat high in every horse, except perhaps that of heavy draught, and it does not harm him, for there is larger surface for the attachment of the muscles of the back, and they act at greater mechanical advantage. A slanting direction of the shoulder gives also much mechanical advantage, as well as an easy and pleasant action, and a greater degree of safety. It must not however exist in any considerable degree in the horse of draught, and particularly of heavy draught. The chest must be capacious, for it contains the heart and the lungs, the organs on which the speed and endurance of the horse depend. Capacity of chest is indispensable in every horse; but the form of the chest admits of variation. In the Waggon-Horse the circular chest may be admitted, because he seldom goes at any great speed, and there is comparatively little variation in the quantity of air required; but in other horses the variation is often fearful. The quantity of air expended in the gallop is many times that required in hard work. Here we must have depth of chest, not only as giving more room for the insertion of the muscles on the action of which the expansion of the chest depends, but a conformation of the chest which admits of that expansion. That which is somewhat straight may be easily bent into a circle when greater capacity is required; that which is already circular admits of no expansion. A few words more are all that our limits permit us to add, and they contain almost all that is necessary to be added on the conformation of the Horse:—"The loins should be broad, the quarters long, the thighs muscular, and the hocks well bent and well under the horse."

General Management of the Horse.—The foal, as soon as it is dropped, should be turned with its dam into a sheltered and good pasture, in which there is a hovel for occasional retreat from the wind and rain. Some hay or corn, or both, should be allowed, if it is early in the season, or the grass has scarcely begun to shoot. There is nothing so detrimental to the colt as insufficient food. It should be regarded as a fundamental principle in breeding, that if the growth is checked by starvation, beauty and energy and stoutness will rarely be displayed in after-years.

In five or six months, according to the growth of the foal or the convenience of the farmer, the weaning may take place. The colt should be removed from his former haunts to some distant rick-yard, or confined to a stable until he becomes a little reconciled to the loss of his dam.

In the ensuing spring the breaking may commence; a process on which will materially depend the temper and value of the horse, and the pleasure of the rider. The foal should be handled and haltered, and led about by the servant who has the chief care of him, and whose conduct towards him should always be kind. "The principle," says the author of 'The Horse,' "on which the after-usefulness of the animal is founded, is early attachment to and confidence in man, and obedience, resulting principally from these."

With regard to the Racing Colt, the processes of breaking and training are injuriously and cruelly completed in the second year, and thousands of horses are irreparably injured by this early exaction of labour and speed; but in the Hunter, the Hackney, the Agricultural and the Carriage-Horse, the serious part of this business is not entered upon until the third year.

A horse is well broken when he has been taught implicit and cheerful obedience to his rider or driver, and dexterity in the performance of his work. A dogged, sullen, spiritless submission may be enforced by the cruel and brutal usage to which the breaker so frequently has recourse; but that prompt and eager response to the slightest intimation of the rider's will—that manifest aim to anticipate every wish, that gives to the horse so much of his value—must be built on habitual confidence and attachment. The education of the horse should be that of the child. Pleasure should be as much as possible associated with the early lessons; while firmness, or, if need be, coercion must establish the habit of obedience.

The breaking being accomplished, the management of the Horse will vary according to his breed and destination; but the good usage of our domesticated slaves should be regarded as a principle that ought never to be violated. The Agricultural Horse is seldom overworked, and on large farms is generally well fed; perhaps in many cases too much above his work. This however is an error on the right side. A very slight inspection of the animal will always enable the owner to determine whether he is too well or not sufficiently fed. The size of the horse, and the nature of the work, and the season of the year, will make considerable difference in the quantity and the quality of the food. The following accounts will sufficiently elucidate the general custom:—"Mr. Harper, of Bank Hall, Lancashire, ploughs seven acres per week, the year through, on strong land with a team of three horses, and allows to each weekly two bushels of oats, with hay, during the winter six months, and during the remainder of the year one bushel of oats per week, with green food. Mr. Ellman, of Glynde in Sussex, allows two bushels of oats, with peas-haulm or straw, with but very little hay, during thirty winter weeks. He gives one bushel of oats, with green food, during the summer."* There is very little difference in the management of these two gentlemen, and that probably arising from circumstances peculiar to their respective farms. The grand principles of feeding with reference to agricultural horses are, to keep the animal rather above his work, to give him good and wholesome food, and, by the use of the nose-bag or other means, never to let him be worked more than four or five hours without being baited.

The horse of quick work, the Stage-Coach Horse and the Poster, should be allowed as much as he will eat, care being taken that no more is put in the manger than he will readily dispose of. The quantity actually eaten will depend on the degree of work and the natural appetite of the horse, but it may be averaged at about 66lbs. of chaff, 17½lbs. of beans, and 77lbs. of oats per week. When the work is unusually hard, the quantity of oats may be diminished, that of beans increased, and a portion of barley added.

During the sporting season the Hunter is well fed, and with that kind of food which contains a great proportion of nutriment in little compass. A small quantity of hay, rarely more than 8lbs. or 10lbs. per day, is allowed, and less than that on the day before work. The quantity of corn may vary from 14lbs. to 16lbs. daily. There is a prejudice in most hunting stables, and probably well founded, against chaff, and it is seldom that the beans and oats are bruised. A bran-mash is given after a day of more than usual fatigue, and is serviceable at other times, when there has not been more than ordinary work, provided that at least two days are suffered to elapse before the horse is again taken into the field.

No horse should be urged on after he has exhibited unequivocal symptoms of distress, such as a drooping pace, a staggering gait, a heavy bearing on the hand, a rapid inspiration like a hurried sigh, and a peculiar convulsive action of the diaphragm, as though the heart were violently beating against the side. The loss of blood, the administration of some cordial medicine, and slow leading to the nearest stable, are the best restoratives at the moment of distress; although the cordial would be absolutely destructive a few hours afterwards, when inflammation had commenced.

The hunting season having passed, the horse used to be turned into the field as soon as the grass had begun fairly to sprout, and there, with his feed or two feeds of corn daily, and his hovel, into which he might retreat from the sun or the storm, he remained until the middle of June, or the flies began to be troublesome. It was delightful to see how much he enjoyed this short period of liberty; and well had he earned it. Of late years however it has become the fashion to confine him to his box, whence he stirs not except for an hour's walking exercise on the road, until he is taken into training for the next winter's business.

Nothing can be so erroneous or cruel as this. There are few horses that have not materially suffered in their legs and feet before the close of the hunting season. There cannot be anything so refreshing to their feet as the damp coolness of the herbage which they tread at that period, and there is no physic which so safely and effectually as

* 'Agricultural Survey of Sussex,' pp. 378, 381.

the spring grass carries off every humour that may be lurking in their frame.

The training of the Hunter for his work is a simple affair. It is, by means of exercise and of physic, getting rid of all superfluous fat and flesh, without debilitating him. The physic is useful; it is indispensable; but the chief thing is gradually to accustom him to the exertion of every power that he possesses, without too much hurrying his breathing or overstraining or injuring him.

The training of the Race-Horse is of a similar character, but it is far more severe, for his strength, his speed, and his endurance must be tested to the utmost. The hunter has to carry his rider gallantly and well through perhaps a long burst, and if he tires, and the sportsman has the good sense and humanity to cease to urge him on, the greatest evil is some temporary suffering to him, and disappointment to his master; but if the race-horse breaks down, or if his capabilities have not been accurately calculated, the most serious loss may be sustained. Thence arises the necessity of straining and of testing every power in the preparation of the turf horse; and thence too it happens, from the strange and impolitic sacrifice of the endurance of the modern racer to speed during short distances, that so many young horses break down and become perfectly useless in their training.

The watering of the horse is a very important but disregarded portion of his general management. The kind of water has not been sufficiently considered. The difference between what is termed hard and soft water is a circumstance of general observation. The former contains certain saline principles which decompose some bodies, as in the curdling of soap, and prevent the solution of others, as in the making of tea, the boiling of vegetables, and the process of brewing. It is natural to suppose that these different kinds of water would produce somewhat different effects on the animal frame, and such is the fact. Hard water, freshly drawn from the well, will frequently roughen the coat of the horse unaccustomed to it, or cause griping pains, or materially lessen the animal's power of exertion. The racing and the hunting groom are perfectly aware of this; and so is the horse, for he will refuse the purest water from the well if he can obtain access to the running stream, or even the turbid pool. Where there is the power of choice the softer water should undoubtedly be preferred.

The temperature of the water is of far more consequence than its hardness. It will rarely harm if taken from the pond or the running stream, but its coldness when recently drawn from the well has often been injurious. It has produced colic, spasm, and even death. It should therefore be exposed for some hours, either in the stable or in some tank.

There is often considerable prejudice against the horse being fairly supplied with water. It is supposed to chill him; to injure his wind, or to incapacitate him for hard work. It certainly would do so, if, immediately after drinking his fill, he were galloped hard, but not if he were suffered to quench his thirst more frequently when at rest in the stable. The horse that has free access to water will not drink so much in the course of a day as another who, to cool his parched mouth, swallows as fast as he can, and knows not when to stop.

When on a journey a horse may with perfect safety be far more liberally supplied with water than he generally is. An hour before his work commences he should be permitted to drink a couple of quarts. A greater quantity might be probably objected to. He will perform his task far more pleasantly and effectively than with a parched mouth and tormenting thirst. The prejudice both of the hunting and the training groom on this point is cruel as well as injurious. The task or the journey being accomplished, and the horse having breathed a few minutes, another quart, or even two, will be delightfully refreshing to him, and will never do him harm. His corn may then be offered to him, which he will readily take; and before he has eaten the whole of it two or three more quarts of water may be given.

Towards the close of the day the speed of the traveller should somewhat abate, and the horse should arrive at his resting-place as dry and as cool as circumstances will permit. If he is hot he must be walked about awhile, or the perspiration will return in the stable. If he is wet he must be carefully rubbed dry. The sooner this is done the better; and after he is clothed, watered, fed, and bedded, he should as soon as possible be left to his repose.

In travelling the horse should undergo some degree of training as to the pace, the distance, and the burden. When there has been no preparation, the stages must at first be short, and the pace gentle. For a journey of 300 miles the horse may travel from 20 to 25 miles a day, resting on the Sunday, and doing the work in two stages, at the pace of six miles an hour. This requires a seasoned horse, and the number of working hours per day is about four.

Hunting requires speed and stoutness. The pace seldom exceeds twelve miles an hour, and the run is short, soon over, or interrupted; yet soft sinking ground, hills, and leaps make this pace severe even on the best horses. The time for preparation varies from two to four months. On the day before work the horse should have exercise enough to empty the bowels. If he is a good feeder he should have no hay within eight hours of starting, nor water within four hours, nor corn within three hours; but if he has five or six miles to go to cover, these restrictions are less necessary. The working days will vary according to his condition and the hardness of the running. He may be able to go out every second day, and sometimes not more than once in six or seven. His spirits and appetite, and the state of his legs, will decide this. Even on the blank days some exercise should be taken in order to evacuate the bowels and create an appetite.

Horses are best prepared for coaching by good feeding and gradual increase of speed and distance. The ordinary length of a stage is eight miles; so that a horse is required for every mile, or a coach running between two places forty miles distant, employs forty horses to take it away and bring it back. The pace being calculated at from nine to eleven miles an hour, no horse works quite an hour in the day, and some not more than three-quarters of an hour, except that, occasionally, an able horse may perform a double journey in order to relieve a sick companion. No horse therefore leads so easy a life as an English coach-horse in a well-regulated establishment. The muscular exertion is severe while it lasts, but it is soon over. The excitement however of high keep and excessive exertion gradually wears the horse down, and it is rarely that he continues in a fast coach more than four years. (Nimrod, 'On the Road.')

Cart-Horses usually work from eight to ten hours, six days in the week. The pace varies from two miles to three and a half miles per hour, and the weight rarely exceeds 24 cwt., besides the cart, which probably is seven or eight more. All beyond this in weight or in time of work is cruel.

The average work done by a horse in ploughing is about eight hours in the day. The severity of it depends on the pace, the nature of the soil, and the breadth of the furrow-slice. The pace is from a mile and a half to two miles per hour; the furrow varies from eight inches to eleven, and the distance travelled is from 12 to 16 miles. The horse and the man can well support this as long as the ploughing season continues.

Asinus.—The species of this genus have the upper part of the tail covered with short hair, and the lower part covered with longer hair forming a tuft; the fur marked with darker stripes; the fore legs only furnished with hard horny warts in a similar situation to those in the front legs of the horse, but there are none in the lower part of the hinder legs. We shall follow in our arrangement of the species that adopted by Dr. J. E. Gray in the 'British Museum Catalogue.'

* Colour nearly uniform, with a dark longitudinal dorsal stripe; some have a black stripe across the shoulders.—The Asses of Asia.

† Ears elongated, acute.—The Tame or Domestic Asses.

These animals vary greatly in size and appearance, according to the climate. They are large and smooth-haired in the warmer climates; small and shaggy in the colder countries.

It is very doubtful if the Domestic Ass is found in a truly wild state; the asses which have been described as wild appear rather to be domestic animals which have escaped, or mules between the Domestic Ass and the allied wild species; for when caught they, after a short time, submit themselves to man, which is not the case with what Dr. Gray has here considered as the wild kinds.

Pallas justly observes, "In extensis Asiæ desertis primam patriam esse quærendam *Equi feri* et *Onagri* a nomadibus in domesticos usus domatorum, æque ac Hemioni hactenus indomiti." ('Zool. Ross.,' A. i. 255.) This is equally applicable to the African species. [Ass.]

A. vulgaris, the Domestic Ass. Gray, with a longitudinal dorsal streak and a dark streak across the shoulders; ears elongate; facial line arched. Skull with suborbital foramen as in *E. Hemionus.*

The following are some of the synonyms of this animal:—

Equus Asinus (Linn.); *Asinus vulgaris* (Gray); *Equus Asina* (Fleming); *Asinus* (Plin.); Ass (Penn., Bewick); Asne (Buffon); Ane (Cuvier); *Asinus Onager* (Gray, Bonap. 'Index Mam. Eur.'); *Asinus domesticus*, Domestic Ass (H. Smith).

Var. Without any cross.

Var. Legs and body more or less banded.

Domestic Varieties.

Gudha of the Mahrattas, very little larger than a good mastiff or Newfoundland dog (Sykes). Domestic Ass of Ispahan (H. Smith). Domestic Ass of Beloochistan (H. Smith). Domestic Ass of Tibet, with a cross-band (Strachey). The Pico of ancient Egypt (H. Smith). Tasandunt of the Shelluhs (H. Smith). The Djaar of Arabia (H. Smith). The Lalisiones, or Wild Ass Colts (H. Smith). Lalisio (Martial). Wild Ass (Lenant; Hoskins). Egyptian Ass (H. Smith).

The common Domestic Ass is sometimes of the usual gray colour, without any appearance of the cross. They are sometimes black, and at other times white, rarely skewbald; but this is the common albinism and melanism of domestic animals, and when of these colours the cross is not apparent, or at least sometimes only to be seen when the animal is observed obliquely.

†† Ears moderately short, rounded.—The Wild Asses.

A. Onager, the Koulan, or Wild Ass. Pale reddish (in winter grayish); dorsal streak black, rather wider over the small of the back. Skull with the infraorbital foramen high up, about one-third the space between the face-line and the back edge of the teeth, far back, being directly over the front end of the cheek ridge and the back edge of the third grinder.

This species is the *Asinus sylvestris* (Plin.); *Onager* (Plin.); *E. Asinus Onager* (Schreb.); *Equus Onager* (Brisson); Wild Ass (Bell, Heber); Koulan, or Wild Ass (Penn.); *Equus Hemionus*, Wild Ass of Kutch and the Indus (Sykes); *Asinus Hemionus* (Gray); *Equus Khur*, Ane Khur (Lesson); Wild Ass, or Gour (Ker Porter); Wild Ass, or Khur, of the Persians; *Onager* (Xenophon); Hemione, or Dziggtai (Lesson); Hymar, or Hamar of Mesopotamia (H. Smith); *Asinus Hamar*, the Hamar (H. Smith); Chamor of the Hebrews.

This species inhabits the plains of Mesopotamia, Persia, Kutch; shores of the Indus, Panjab.

Mr. Layard says they are abundant in Mesopotamia, and are evidently the Wild Ass of Xenophon. The adults are very difficult to approach within rifle range. The young are sometimes caught alive.

The *Khur* inhabits the deserts of Persia in troops, frequenting the hills in summer and the plains in winter.

Pallas, in a paper entitled 'Observations sur l'Asne dans son État sauvage, ou sur le véritable Onagre des Anciens' ('Act. Acad. Sci. Imp. Petrop.,' 1777, 258. t. 11), figured a Wild Ass which was sent by sea from Derbent to Astrakhan. The figure greatly resembles the mule between the Hemione and the Ass now in the Zoological Gardens, but the ears appear a trifle longer. It is coloured in the same manner as the Hemione; that is to say, the more prominent parts of the body are dark, and the middle of the back, the front of the haunches and thigh, and the under part of the body are paler. The figure represents but a very indistinct cross-band on the shoulder.

This paper is translated into German, and a copy of the plates with a second figure of the back of the animal is given in Pallas, 'N. Nord. Beytr.,' ii. 22, t. 2; but in this figure the cross-band on the shoulders is not marked. From this description it would appear that the animal which is called the Wild Ass is not always marked with the cross-band on the shoulder which is so permanent in the domestic kind, and has hitherto been considered as its specific character.

The chief difference between Pallas's figure of the Wild Ass and the Hemione is the greater length and more acute form of the ears; of the latter the mule varies in this character.

Bishop Heber, as quoted by Colonel H. Smith, says, "No attempt has been made to break the Wild Ass (of Rajpootana) in for riding, nor did it appear that the natives ever thought of such.

"The Wild Ass of Cutch has the cross-stripe on the shoulder, and differs in colours and heavier proportion from the Wild Ass of Ker Porter."

Colonel Smith confounds the domesticated Gudha with the Wild Ass of the Deccan described by Colonel Sykes, and states on the colonel's authority that "it is not larger than a mastiff."

Eversmann says that many specimens of the Kulan, or *Equus Onager* of Pallas, have been brought to Orenburg from the high steppes between the Caspian and the Aral seas. A good specimen and a skull are in the Museum of the University of Kasan.

All these specimens are without the cross-band, and have only the longitudinal dorsal streak. Eversmann considers that the cross-band is either not the character of the species, or perhaps a sexual mark, as he observes that he is not able to discover the specific character which separates the *E. Hemionus* from the *E. Onager*. He further observes that the Mongolians have no particular name for the *E. Onager* of Pallas; the Tartars no name for *E. Hemionus*; the Mongolians called the *E. Hemionus* Dshiggetei, or more properly Tschikitei, meaning long ears, and the Tartars call the *E. Onager* Kulan.

Eversmann remarks that Pallas ('N. Nord. Beytr.,' ii. 34) states that the male M. Hablizl brought from Persia had no cross, but that the female which was shot on the Murecy had one. He proceeds to calculate the length of the ears of these animals, compared with the other measurements of them, and he finds that the ears of the male appear to be considerably (near two inches) shorter in proportion than the ears of the female. ('Bull. Soc. Imp. Nat. Mosc.,' 1840, 57.)

The Mule with *Asinus domesticus* has the short smooth fur exactly like the sire, but with a short narrow cross-band on the shoulder; the ears rather longer and black-tipped.

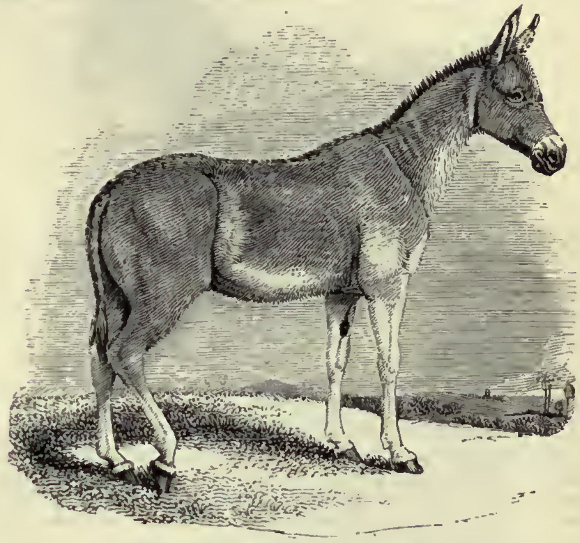
A. Hemionus, the Kiang. Fur short, smooth, bright-red bay. Legs straw-colour (in winter long, rather woolly, grayish, legs whitish), with a broad longitudinal dorsal streak, broadest over the small of the back, without any cross-band on shoulders. Skull: the infraorbital foramen low down, in the centre of the space between the face-line and the base of the teeth, and placed in a line over the back edge of the second grinder, some distance in front of the end of the cheek-ridge.

It is the *Mulus Dauricus fœcundus* (Messerschm, MSS.); *Equus Hemionus* (Pallas); *Equus Hemionus*, Kiang (Ogilby); *Equus Hemionos* (Bodd.); *Asinus Hemionus* (Gray); *Equus Onager* (Eversmann); (?) *Asinus Onager*, Onager Koulan, or Wild Ass of Tartary (H. Smith); *Asinus Equioides* (Hodgson, Blyth); Wild Ass (Moorcroft); *Equus Kiang* (Moorcroft); *Equus varius*, part. (H. Smith); *Asinus polyodon* (Hodgson); Jikta (Shaw); Dshikketee (Penn.); Dgiggetai (Cuvier); Dzigethai (Buffon); Wild Mule, Half Ass, or Fecund Mule (Penn.); Wild Ass ('English in Tibet'); Hemionos (Plin.); L'Hemione ('Ency. Méthod.'); the Ghoor, or Khur (Moorcroft, H. Smith); Wild Esol (Eversmann); the Kiang (H. Smith); Wild Horse (Gerrard).

It is found in Tibet.

This animal must not be confounded with the domestic asses which are used for burden in Tibet.

The male Kiangs are larger and deeper coloured. They live in troops of from eight to ten under the care of a solitary male, where the thermometer is below zero. They live partly on the plains and partly on the mountains; and the lower surface of the hoof varies considerably in form and concavity, perhaps from that circumstance.



Dshikketee, or Wild Ass (*Asinus Hemionus*).

The Ghoor or Khur of Ludakh, according to Moorcroft, is white about the nose and under the neck, the belly and legs; the back is light bay and the mane dun. They herd in droves, fly at a trot, stop, and look back.

Moorcroft saw the Kiangs on the highest summits of Tibet, in their shining summer coats and with their antelope form, scouring along in numbers.

Dr. Walker observes—The Kiang neighs like a horse. The Wild Ass of Cutch brays like an ass. The Kiang has no zebra stripes, neither in the adult nor in the foal. The Wild Ass of Cutch: transverse zebra stripes are seen on the shoulder in the adult, and still more in the foal; sometimes also the shoulder-cross has been seen. The habitat of the Kiang is on the high table-land of Tibet; of the Wild Ass of Cutch in the sultry plains near the mouth of the Indus.

The Kiang of Chinese Tartary greatly exceeds that of the Donkey of Cutch in size; the stallions often stand 14 hands high. Major Charlton and Major Biddulph state that they neigh like a horse. When taken young they will become so tame as to be led about like a horse, and will follow horses almost anywhere. They live in a climate where the temperature is below the freezing point in the middle of the summer; yet they throw off their pale woolly coat during that season, and become bright bay.

The Donkey of Cutch is often domesticated in India.

(??) *A. Equuleus*, the Yo-to-tze. Yellowish red-clay colour. Tip of ears, mane, long hairs of tail, well-defined line down the back to middle of tail, and cross-band on the shoulder, three or four cross streaks on knees and hocks, black.

It is the *Asinus Equuleus*, the Yo-to-tze (H. Smith); *Asinus Hippargus*, the Yo-to-tze (H. Smith).

Dr. J. E. Gray says, "The specimen described by Colonel H. Smith was alive in a livery stable near Park Lane, London; it was said to have been brought from the Chinese frontier north-east of Calcutta. It was most probably a Kiang, or perhaps a mule between it and the Domestic Ass."

** Body with a black dorsal streak and many more or less distinct transverse or curved streaks. Ears rather short and broad-tipped. —The Zebras of South Africa.

Hippotigris (H. Smith); Hippotigrine group or Zebras (H. Smith).

† Hoofs slightly concave beneath. Legs white, not or only slightly cross-streaked.

Living on the open plains.

A. Quagga, the Quagga. Brown; head, neck, and withers, or front of body, blackish streaked; lower part of body, legs, and tail, white. Hoofs flattish beneath.

It is the *Asinus Quagga* (Gray); *Equus Quoagga* (Lesson); *Equus Quagga* (Gmelin); Female Zebra (Edw.); Le Couagga (Buffon; Kwagga, or Couagga (Buff.); Opeagha, or Quagga (Masson); *Hippotigris Quacha*, the Quagga of the Cape Colonists (H. Smith); Quagga (Shaw); Quacha (Penn.).

It is a native of the Cape of Good Hope, on open plains.

E. Isabellinus, Temm. 'MSS.' (H. Smith); *Hippotigris Isabellinus*, the Isabella Quagga (H. Smith); Ane Isabelle (Le Vaillant).

Lesson places the Quagga with the true horses, because the hair extends nearer to the base of the tail, overlooking the warts and other natural characters.

Quagga (*Asinus Quagga*).

Le Vaillant, as Colonel Smith observes, only saw, and did not possess, the Ane Isabelle. The specimen in the British Museum, described and figured by Colonel H. Smith, was certainly only a young Quagga in a very imperfect condition, having lost nearly the whole of its fur before it was stuffed. It was presented by Dr. Burchell as the skin of a Quagga.

A. Burchellii, the Peetsi, or Peechi. Pale brown, under side of body whitish; head, body, and upper part of leg, black streaked; tail, inside and lower part of leg, white. Hoof rather broad, only slightly concave beneath. Skull: suborbital foramen as in *E. Hemionus*.

It is the *Equus Zebra* (Burchell); *Asinus Burchellii* (Gray); *Equus Zebroides* (Lesson); *Equus Burchellii* (Bennett); *Equus Zebra*, male (F. Cuvier); *Equus montanus*, the Dauw (F. Cuvier); *Hippotigris Burchellii*, the Dauw (H. Smith); Burchell's Zebra (Harris); Striped, or Bonte Quagga of the Cape Colonists (Harris); Peet-sey of the Matahuli and Bechianas; Dauw (F. Cuvier).

It is a native of the plains of South Africa.

It is found in herds in every district north of the Orange River. It admits of being tamed to a certain extent with considerable facility, and occasionally a half-domesticated specimen is exposed for sale in Cape Town with a rider on its back. Even in the most tractable state to which it has yet been reduced, it is regarded as wicked, treacherous, obstinate, and fickle.

M. F. Cuvier has applied the Hottentot name for the true Zebra to this species, and used for it the name *E. montanus* that Burchell gave to that animal, though it only inhabits the plains.

†† Hoofs narrow, deeply concave beneath; legs cross-banded.—Living on the Mountains.

A. Zebra, the Zebra. White; head, body, and legs to the hoofs, black-banded; nose reddish; belly and inside of thighs not banded; tail end blackish. Hoofs narrow, deeply concave beneath. Skull: suborbital foramen as in *E. Hemionus*.

Zebra (*Asinus Zebra*).

It is the *Zebra Indica* (Aldrov.); *Equus Indicus* (Jonston); *Equus Brasiliensis* (Jacob); *Hippotigris* (Dio Cass. 'Hist.' l. 77). *Equus Zebra* (Linn.); *Asinus Zebra* (Gray); Zèbre (Buffon); Zebra (Ray); Sebra (Stubb); *Hippotigris campestris* (H. Smith); *Equus montanus* (Burchell); Male Zebra (Edwards); Wild Paard, or Wild Horse, of the Dutch Colonists (Burchell); Wilder Esel (Kolbe); Daow (or True Zebra) of the Cape Colonists (Harris); Zeura or Zuora (Lobo); Wild Ass (Kolbe); Var. (?) *Hippotigris Zebra*, the Zebra (H. Smith); *Hippotigris antiquorum*, the Congo Dauw or Zebra of Pigafetta (H. Smith); *Hippotigris antiquorum*, Angola Dauw (H. Smith).

It is a native of the mountains of South Africa.

Hybrids between the species of *Equidæ* are numerous. The offspring of the male Ass (*Asinus vulgaris*) and a Mare is called a Mule, which has generally the form, in a great degree, of the dam, and the head, ears, and tail of the sire. The Spanish mules are well known for their symmetry, sureness of foot, and unwearied activity, and are the produce of a breed of asses far beyond those of this country in stature, shape, and general appearance. The Hinny, which is the offspring of the Horse and the female Ass, is altogether inferior, and is less esteemed than the Mule. Hybrids have also been produced from the Horse and the Ass breeding with the Zebra or the Quagga. Two mules that belong to the Zoological Society are the offspring of the Ass and the Zebra. The Earl of Morton bred a female hybrid from a fine male Quagga and a Mare of nearly pure (seven-eights) Arabian blood.

It may be expected that we should here notice the question as to the power of reproduction in animals so bred between different species. Mr. Bell, in his 'British Quadrupeds,' has treated this subject in his usual luminous manner. After observing that the inquiry how far the power possessed by two animals of producing young on the one hand, or fertile young on the other, bears upon the generic or specific identity of the parents, is one of the greatest interest in the investigation of zoological relations, he proceeds thus:—"It has been supposed, and with very considerable probability, that the production of male and female progeny which are fertile inter se is to be considered in itself a positive proof that the parents are of the same species, how much soever they may differ in external form and appearance. It is well known that there are many instances of animals undoubtedly distinct producing young, which become fertile in conjunction with one or other of the parent kinds. This has been proved in the case of several species both of gallinaceous and natatorial birds in a domestic state; but there is not, I believe, on record a single instance of a male and female of such hybrid progeny being mutually fertile. On the other hand the production of sterile hybrids between distinct species of the same group is a circumstance so commonly occurring as to require only an illusion; and a reference to the present animal [the Mule] is a sufficent illustration of the fact. But the power of reproduction even of such progeny is considered by some as indicative of a generic relation between the parent species, and has been urged as an argument against the separation of the Horse as a distinct genus from the Ass and its congeners. Before this observation however can be allowed to have any weight, it rests with the objectors to define the precise meaning and limits of a genus; and until this has been done, which has never yet been satisfactorily attempted, such an argument is a mere begging of the question. The Mule has been occasionally known to produce young with the Horse or the Ass: these cases are however extremely rare, and serve as illustrations of the statements which I have already made, as there is no instance on record of two Mules having bred together." Mr. Bell notices the following fact, as one which must doubtless be placed to the account of this power of reproducing in the Mule. A small mare was turned into a paddock in the Gardens of the Zoological Society of London (Regent's Park), in company with a male white Ass, and a male hybrid between the Zebra and the Ass. She had a foal which was distinctly marked with black stripes across the legs.

While upon this subject, we may as well advert to the curious point, that the characters of the male parent of the mother's first progeny show themselves in her subsequent offspring by other males, however different those males may be in form or colour. Mr. Bell observes that this truth has already been illustrated by him when treating on the Dog and on the Hog, and he adds that it receives a remarkable and interesting confirmation from the case of the mare (belonging to the Earl of Morton) quoted by him and above alluded to. In that case the mare was young, and after producing the female hybrid by the Quagga, had first a filly, and afterwards a colt, by a fine black Arabian Horse. They both resembled the Quagga in the dark line along the back, the stripes across the forehead, and the bars across the legs: in the filly the mane was short and stiff, like that of the Quagga; in the colt it was long, but so stiff as to arch upwards and hang clear of the sides of the neck: in other respects they were nearly pure Arabian. This and other such cases should not be forgotten by breeders of animals, who are anxious about the perfection of their stock, and should make them particularly careful as to the male influence which first makes its impression on the female.

Fossil Equidæ.

Remains of *Equidæ* occur abundantly in the third period of the Tertiary series (Pliocene of Lyell), in the fresh-water deposits, in what is called Diluvial Detritus, in superficial gravels, sands, and clays, in the Ossiferous Caverns, in the Osseous Breccia, in the Epplesheim Sand, &c. Bones of the Horse occurred, but not abundantly, among the remains found by Captain Cautley lying on the slopes among the ruins of fallen cliffs, and partly in situ in the Sandstone in the Sewalik Mountains at the southern foot of the Himalayas, between the Sutlej and the Ganges. Several species have been recorded, but we must not forget the opinion of Cuvier, who thought there were not sufficient data for specific distinctions. He informs us that he had carefully compared the skeletons of many varieties of horses, those of the Mule, the Ass, the Zebra, and the Quagga, and he never could find a character sufficiently fixed to enable him to pronounce on a species from an isolated bone. Size, he remarks, furnishes but incomplete means of distinction: horses and asses vary much in this particular, from their state of domestication; and he adds, that though he had not yet procured the skeleton of a Dshikketee, he doubted not its resemblance to that of the other species as much as they resembled each other in the same particular. He therefore seems to be borne out in his opinion that comparative anatomy cannot solve the question whether the horse whose remains are found in a fossil state resembled the horses of the present day. The fossil species recorded by authors are *Equus fossilis* (*E. Adamiticus* of Schlotheim); *E.* (*Caballus*) *primigenius*; *E.* (*Mulus*) *primigenius*; *E.* (*Asinus*) *primigenius.* Professor Owen, in his 'British Fossil Mammals', has described three species of *Equidæ—Equus fossilis, E. plicidens,* and *Asinus fossilis.* Their remains were all found in the Tertiary Formations of England. He thus concludes his remarks on the Fossil *Equidæ*:—

"In reviewing the general position and distribution of the fossil remains of the genus *Equus*, we find that this very remarkable and useful form of Pachyderm first made its appearance with the Rhinoceros during the Miocene periods of geology. From the peculiar and well marked specific distinction of the primogenial or slender-legged horses (*Hippotherium*), which ranged from Central Europe to the then rising chain of the Himalaya Mountains, it is most probable that they would have been as little available for the service of civilised man as is the Zebra or the Wild Ass (*Equus Hemionus*) of the present day; and we can as little infer the docility of the later or Pliocene species, *E. plicidens* and *E. fossilis*, the only ones hitherto detected in Britain, from any characters deducible from their known fossil remains. There are many specimens however that cannot be satisfactorily distinguished from the corresponding parts of the existing species, *E. caballus*, which with the Wild Ass may be the sole existing survivors of the numerous representatives of the genus *Equus* in the Europeo-Asiatic continent during the Pliocene period. The species of *Equus* which existed during that geological period in both North and South America appears to have been blotted out of the Fauna of those continents before the introduction of man. The aborigines whom the Spanish conquistadors found in possession of Peru and Mexico had no tradition or hieroglyphic indicative of such a quadruped; and the horses that the invaders had imported from Europe were viewed with astonishment and alarm.

"The researches of Mr. Darwin and Dr. Lund have however indisputably proved that the genus *Equus* was represented during the Pliocene period by a species (*E. curvidens*) which is shown to be distinct from the European fossils and the existing species. Fossil remains of the Horse have likewise been discovered in North America. The geographical range of the genus *Equus* at the Pliocene period was thus more extensive than that of the Rhinoceros, of which both the extinct and existing species are confined to the continents of the Old World of geography. The Horse, in its ancient distribution over both hemispheres of the globe, resembles the *Mastodon*, and appears to have become extinct in North America at the same time with the *M. giganteus*, and in South America with the *M. Andium* and the *Megatherium.* Well may Mr. Darwin say, 'It is a marvellous event in the history of animals that a native kind should have disappeared, to be succeeded in after ages by the countless herds introduced with the Spanish colonist.'"

EQUISETA'CEÆ, *Horsetails*, a natural order of imperfectly-formed Plants whose real affinity is uncertain, and the nature of whose parts of fructification is not yet understood. By Linnæus and almost all botanists they are referred to the Cryptogamic class. With Ferns their relation is not obvious. In the arrangement of their reproductive organs they have a striking resemblance to *Zamia*, and in their general aspect to *Ephedra* or *Casuarina.* Dr. Lindley regards them as a high form of the muscal alliance, and places them near to *Marchantiaceæ.* Only one genus is known, the stems of a species of which are employed in the shops under the name of Dutch Rushes. They are hollow-stemmed leafless plants, with a cuticle composed of pure silex. In lieu of leaves they have toothed sheaths, each of which has as many series of imperfect spiral vessels passing into fistulæ of the stem as there are toothings. Their fructification grows in terminal cones, consisting of stalked peltate scales, having on their lower side small cases wherein are lodged minute oval or round green bodies, surrounded by four elastic hygrometrical yellowish-gray granulated clavate threads. By all botanists the central green body is admitted to be a seed or spore. The nature of the clavate threads is disputed; they are usually called Elaters, and are compared to the elastic spiral threads bearing that name in *Jungermanniaceæ;* but there is no proof of such being their nature, and there is an opinion that they are rudimentary stamens.

These plants are found in ditches and rivers in most parts of the world, within and without the tropics. None of them are of any medical use; they are said to be slightly astringent and stimulating, but are not now employed. The stems of some of them are used for polishing furniture and household utensils, owing to their siliceous properties. According to the observations of John of Berlin they contain 30 per cent. of siliceous earth. The quantity of silex contained in the cuticle of *E. hyemale* is so great that Sivright succeeded in removing the vegetable matter and retaining the form. [EQUISETUM.]

Equisetum fluviatile.

1, a sterile branch; 2, a fertile branch in fructification; 3, one of the peltate scales; 4, the same viewed from below; 5, two of the cases very much magnified; 6, an ovule with the four supposed anthers.

EQUISE'TUM (from 'equus,' a horse, and 'seta,' a hair or bristle, from the character of the leaves), a genus of Plants, the type and only genus of the order *Equisetaceæ.* The species are leafless branched plants, with a striated fistular stem, articulations sheathed at the base; the sporules are surrounded by elastic clavate filaments, and inclosed in thecæ arising from the peltate scales of terminal cones; the vernation is straight, and the cuticle abounds in silex.

E. hyemale, Dutch Rush, has a simple stem, very rough, with from 14 to 20 slender furrows: the sheaths close, whitish, but the top and bottom black; the teeth slender, black, deciduous. This plant is a native of England, Scotland, and Ireland, as well as the continent of Europe. It is almost unknown in the middle and southern English counties, and is only sparingly distributed anywhere. It was recommended as a medicine by the ancients, and the earlier herbalists quoted them as authorities for its virtues; but it is not now used in medicine. It appears however to possess tannin, and to act as an astringent. It is supposed to be injurious to cows, and is said to cause their teeth to drop out, but horses eat it with impunity. This plant more than any other species is used for the purposes of polishing. Lightfoot says that in Northumberland the milk-maids scour their pails with it. It is also used for the purposes of polishing wood, bone, ivory, and various metals, particularly brass, and is brought into this country from Holland, where it grows abundantly in large quantities, and is sold in the shops of London under the name of Dutch Rush. Mr. Newman thinks however that the *Equisetum* brought from Holland is a different species from the British *E. hyemale.* The stems of this plant contain large quantities of silex, and in the ash left after burning it forms as much as 97 per cent. On subjecting a portion of the cuticle of this species to the analysis of polarised light under a high magnifying power Brewster detected a beautiful arrangement of the siliceous particles, which are distributed in two lines parallel to the axis of the stem, and extending over the whole surface. The greater number of the particles form simple straight lines, but the rest are grouped into oval forms connected together like the jewels of a necklace by a chain of particles, forming a sort of curvilinear quadrangle, these rows of oval combinations being arranged in pairs. Many of these particles which form the straight lines do not exceed the 500th of an inch in diameter. Brewster also observed the remarkable fact that each particle has a regular axis of double refraction. A very large quantity of starch is found during winter in the rhizomes, in whose cells during the month of October the particles may be seen in active motion, passing up one side and retreating by the other, much in the same way as in *Chara*. This may also be seen in *E. fluviatile*.

E. Mackaii has a simple, or very slightly branched, very rough stem, with 8-12 furrows, the sheath close, ultimately wholly black; teeth slender, persistent. This plant occurs in the north of Ireland, and is named by Mr. Newman after its discoverer, Mr. I. T. Mackay, author of the 'Flora Hibernica.' Sir Wm. Hooker has referred this plant to the *E. elongatum* of Willdenow; but Babington has adopted Newman's species.

E. variegatum has a simple stem, or very slightly branched, very rough, with 5-9 furrows, the sheaths slightly enlarged upwards, green below, black above; the teeth obtuse, each tipped with a deciduous bristle. The stem is about a foot high. It is found on sands near the sea, or in wet places in mountain valleys in Great Britain.

E. palustre has the stem with 6-8 deep furrows, branched throughout; the sheaths loose, pale, with acute wedge-shaped teeth tipped with brown, and membranous at the edges. This plant is very generally distributed over Great Britain. This species is liable to alter its characters, and three tolerably permanent varieties have been described.

E. fluviatile, Water Horse-Tail, has a sterile stem, nearly smooth, with about 30 striæ and branches; branches rough, doubly angular, simple; the fertile stem simple, with numerous crowded large deeply-toothed sheaths. This is the *E. Telmateia* of Ehrhart and Newman's 'History of British Ferns.' Its present name was erroneously given it by Smith, which has been adopted by Hooker and Babington. It is one of the most beautiful of the species, attaining a height of 3, 4, and even 5 feet. It is abundant in the neighbourhood of London, especially near Hampstead Heath. It is a native also of the more southern countries of Europe. Although it grows in water, as its name would imply, it still grows in dry situations; and the name *fluviatile* is more applicable to the original plant of Linnæus, the *E. limosum* of English botanists. Horses sometimes eat this plant; and from a passage in Haller he seems to have supposed that it was eaten by the Romans: he says, "Hoc fuerit Equisetum quod a plebe Romanâ in cibum recipitur." (Haller, 'Hist.' iii. 1.)

E. limosum has a smooth stem, with 14-16 slight furrows; the teeth of the sheaths short, rigid, and acute; the branches erect, simple, whorled, often abortive. This is undoubtedly the *E. fluviatile* of Linnæus, but we have given the name of Smith, as that which has been followed by Hooker and Babington in their Floras of Great Britain. This plant is seen very commonly in ponds and ditches, and sometimes in running streams, the roots and a portion of the stem being immersed in water. It is a common plant throughout Europe. Linnæus says that in Sweden it is used as food for cattle, in order that the cows may give more milk, and also that the rein-deer feed on it. He advises that it should be collected in summer as fodder for the winter. Cattle in this country will sometimes eat it. Mr. Knapp also records the fact that the common water-rat is very fond of it. It is probable that in some states of the system of animals it acts medicinally; but neither this nor any other of the species of *Equisetum* would be fitted for the constant food of animals.

E. sylvaticum, Wood Horse-Tail, has the sterile and fertile stems, with about 12 furrows and numerous whorls of slender compound spreading or deflexed branches; the sheaths lax, with 6-10 membranous rather blunt teeth. It is found in wet shady places and moist woods throughout Great Britain.

E. Drummondii has the sterile stem, with about twenty striæ, very scabrous, with prominent points, particularly above; the branches simple, with four simple angles, the fertile stem simple, with numerous crowded deeply-toothed sheaths. This plant has not been long known as a native of Great Britain, but Mr. Newman thinks it is probably a common plant, and says it is identical with the *E. umbrosum* of Willdenow.

E. arvense, Corn-Field Horse-Tail, has the sterile stem, with few furrows, slightly scabrous; the branches simple, rough, with four simple angles, the fertile stem simple, with few lax distant sheaths. This is the most common of all the species, and frequently a source of serious injury to the farmer and gardener. It is subject to variation according to the locality in which it grows. It is easily distinguished from *E. umbrosum*, for which it might be mistaken by its drooping and compound branches.

(Newman, *History of British Ferns and Allied Plants*; Babington, *Manual of British Botany*; Loudon, *Encyclopædia of Plants*.)

EQUUS. [EQUIDÆ.]

ERA'NTHEMUM, a genus of Acanthaceous Plants, with showy purple flowers, some of whose species are occasionally seen in hothouses in this country. It has a salver-shaped corolla with a 5-cleft nearly equal limb, a 4-parted equal calyx, and only two out of its four stamens fertile. *Eranthemum pulchellum* and *E. bicolor* are the handsomest species in cultivation, and when skilfully managed produce a very striking appearance.

ERANTHIS, a small genus of Plants cut off from *Helleborus*, in consequence of its having a deciduous calyx, stalked capsules, an involucre to the flowers, and a totally different habit. *E. hyemalis*, or Winter Aconite, is a small stemless tuberous herbaceous plant, inhabiting shady places in the midland parts of Europe, and rendering our gardens gay in the earliest spring with its cups of bright yellow. It has peltate, many-cut, pale green, smooth leaves, and a single-flowered scape only a few inches high.

Another species, *E. Sibirica*, inhabits Siberia.

ERGOT, botanically considered, is a fungus belonging to the Gymnomycetous division, and constituting one of two species of *Spermœdia* admitted by Fries. He calls it *S. clavus*, and separates it from the genus *Sclerotium*, to which it had previously been referred, on account of its growing in the inside of other plants, and having no proper fructification. He defines the genus *Spermœdia* as follows: "Variable, rounded, entophytal, rootless, of a fleshy mealy homogeneous texture, with a rind concrete, scaly, or somewhat pruinose. Proper fructification none." And then he adds "that it is only a morbid condition of the grain of corn, not propagated by seed, but generated by a particular combination of external influences (cosmica momenta)." Endlicher takes the same view of the nature of ergot, only with more consistency he does not admit it as a real fungus, but only enumerates it as a diseased state of the seed of grasses, swelling into a fungoid body, and covered externally with powder. From the researches of the late Mr. Quekett it appears that a true fungus exists in the grain of rye during its early stages of growth, which gives it the peculiar appearance called Ergot. He describes the sporidia of this fungus as elliptical, moniliform, finally separating, transparent, and seldom containing more than one, two, or three well-defined greenish granules. Mr. Quekett called the fungus *Ergotetia abortifaciens*, in reference to its action on the system. For its action, see ERGOT, in ARTS AND SC. DIV.

The ergot of rye is not confined to that kind of grass, but attacks many other species. Fries distinguishes it by the lengthened form and white interior from *Spermœdia Paspali*, a Carolina ergot, which is globose and somewhat compressed, scaly and rough externally, pale brown and yellowish inside. A third species attacks Indian corn in Columbia, and has a pear-shaped figure.

ERGYNE. [ISOPODA.]

ERI'CA, a most extensive and beautiful genus of Plants, the type of the natural order *Ericaceæ*. It is distinguished by its calyx being 4-leaved, its corolla 4-toothed, and its fruit a dry, 4- or 8-celled, many-seeded capsule, opening into valves with the dissepiments projecting from their middle.

Under this character is included a great variety of species having very narrow linear leaves arranged in whorls, and so little different in their vegetation in most cases, that when out of flower they are often not easily distinguished from each other; but exhibiting a surprising diversity in their flowers, in which their great beauty resides. The richness of colour, the elegance and variety of form, the delicacy of texture, or the minute microscopic perfection of their corolla, are such as no words can describe. Lovely as even our wild moorland heaths are, they rank among the lowest in point of beauty in this extraordinary genus, in which all the hues of red, pink, and purple vie with each other in the most brilliant manner, assuming every tint but blue, and fading into the purest and most transparent white. Some of the species have the corolla as much as two inches long, in others it is not bigger than a pepper-corn; in some it is long and slender, in others inflated like a flask, or dilated like a vase of the purest form, or as round as an air-bubble; and there are many in which it is split almost to its base, and immersed in a calyx whose texture and colours are even more brilliant than its own. Here we have a species the surface of whose corolla rivals in evenness and polish the finest porcelain; there another appears covered all over with hairs, exuding a glutinous secretion, which glitters upon its sides like solid crystals; and some again have their colours so dimmed by a loose shaggy coat, that their real tint can hardly be ascertained. There are even some in which the corolla assumes the very colour of the leaves, only clearer, brighter, and richer. This great difference in the structure of the flowers of different species is accompanied by distinctions in their anthers, which are either muticous (destitute of appendages), cristate (furnished with two little broad projecting membranes), or aristate (that is, having a couple of bristle-shaped processes proceeding from their base). It has lately been proposed to take advantage of these and similar differences for breaking up the genus *Erica*, now consisting of between 300 and 400 supposed species, into a number of new genera; and accordingly in Don's 'General System of Gardening and Botany,' we find no fewer than twenty new groups formed at the expense of *Erica*.

The genus is confined to the Old World. A few species occur in the North of Europe, and others in the countries bordering on the Mediterranean. In Great Britain, Heather (*Erica*, or *Calluna vulgaris*) [CALLUNA] covers large tracts of waste land, and is used to thatch houses, to make brooms, and even beds, in the northern parts of the island. There is a double variety of this species which is extremely beautiful. All our British heaths are improved by cultivation, and are general favourites where the climate and soil are suited to them. They will not however thrive in hot dry places and in any common soil, but require sandy peat earth, and a situation where they are moderately shaded from the sun. *Erica carnea*, one of the few plants whose flowers bid defiance to the rigour of winter, and appear as the earliest harbingers of spring, is found wild in Germany and generally on the mountains of middle Europe.

But it is at the Cape of Good Hope that the principal part of the species is found; indeed the whole of those which are cultivated in greenhouses. In their native country they are by no means so handsome as when cultivated, but form scraggy shrubby bushes, with so little beauty, that the colonist boors have not vouchsafed to give them even a name.

ERICA'CEÆ, a natural order of Exogenous Plants, deriving their name from the extensive genus that forms the subject of the last article. It is readily known from all other orders by its anthers bursting by pores at their apex, the stamens being hypogynous, the corolla monopetalous, and the ovary containing more cells than two. By this character are combined with the genus *Erica* the fragrant richly-coloured *Azalea*, the shady evergreen *Rhododendron*, and the delicate irritable *Kalmia*, together with *Arbutus*, *Andromeda*, *Gaultheria*, and many others equally beautiful; in fact it is probable that if it were necessary for a botanist to name some one natural order as pre-eminent for beauty, this would be the one selected. It is therefore not a little curious that it should also be an order of poisonous plants; for one would hardly expect danger to lurk beneath forms so fair. Nevertheless *Rhododendron ponticum*, *Azalea pontica*, and various *Kalmiæ* and *Andromedæ* are notoriously deleterious, and even the *Arbutus* berries are in no inconsiderable degree narcotic.

The order is unknown in very hot countries, except at considerable elevations; it appears generally to love exposed situations, and, with the exception of *Erica* itself, to follow mountain chains, as it advances from the cool plains of the temperate zone to equinoctial regions. Hence, although we find *Befaria*, *Gaylussaccia*, *Andromeda*, and others in Peru, Brazil, Ceylon, Java, Madagascar, and elsewhere, it is only upon the tops of lofty mountains or upon their sides.

Ericaceæ are frequently polypetalous, and give rise, along with other similar cases, to a suspicion that the usual division of Exogens into polypetalous, monopetalous, and incomplete sub-classes, is essentially bad. [EXOGENS.]

Erica longiflora.

1, stamens and pistil; 2, calyx; 3, ovary; 4, anther; 5, section of seed, showing the embryo.

The following are the British species of this genus, with their distinctive characters, as given in Babington's 'Manual of British Botany:'—

* Corolla globose or urceolate, stamens included, filaments capillary, stigma peltate.

E. Tetralix, with the leaves 4 in a whorl, downy above and on the midrib beneath; the sepals linear, downy; the ovary downy. Its flowers are rose-coloured. It grows commonly on boggy heaths, and blossoms in July and August.

E. Mackaiana, Mackay's Heath. Leaves 4, midrib beneath and upper surface glabrous; the sepals ovate-lanceolate, and with the ovary glabrous. The flowers are purplish. The only locality known for it in the British Islands is between Roundstone and Clifden in Connamara, Ireland.

E. cinerea, Fine-Leaved Heath. The leaves are 3 in a whorl, keeled beneath, with a central furrow; glabrous flowers in dense whorled racemes. Flowers reddish-purple. It is found on dry heaths.

E. ciliaris. Leaves 4 in a whorl, ovate, ciliated; flowers in terminal unilateral racemes. It is a rare plant.

** Corollas campanulate or shortly tubular, stamens exserted, filaments flattened, style capitate.

E. Mediterranea. Leaves 4 in a whorl, linear, glabrous above, convex, with a central furrow beneath; corolla cylindrical, urceolate; anthers without awns. Found in Ireland, in mountain bogs in the west of Mayo and Galway.

E. vagans, Cornish Heath. Leaves 4-5 in a whorl, corolla most campanulate. Flowers red or white; anthers purple. It is found in the western parts of Cornwall in England, and on the coast of Waterford in Ireland.

ERICHTHUS, Latreille's name for a genus of deep-sea Crustaceans, and placed by M. Milne-Edwards between the genera *Squillerichthus* and *Alima*. The last-named author makes the tribe Erichthians (Erichthiens) belong to the family of Unicuirassiated Stomapods (Stomapodes Unicuirassés), the general characters of the tribe being an undivided carapace and a styliform rostrum; no moveable rostral plate; and branchiæ in general rudimentary.

The tribe, according to M. Milne-Edwards, is composed of a certain number of small crustaceans approximating to the *Squillæ*, but which have in general only rudimentary branchiæ, and are often completely deprived of them. They are easily distinguished by their carapace, which is large, lamellar, generally transparent, without longitudinal furrows or distinct lobes, and always armed with a styliform rostrum, which advances above the ophthalmic and antennular rings. These first two rings of the head are less distinct than they are in *Squilla*, but have very nearly the same conformation, and move upon the succeeding cephalic segment. The internal antennæ are inserted below and behind the ocular peduncles; they are rather distant from each other, and their slender and cylindrical peduncles are composed of three joints, and carry at their extremity three multiarticulate filaments. The external antennæ are inserted at some distance behind the preceding, and are directed outwards; their peduncle is large, and formed of two joints, of which the first gives origin by the anterior border of its extremity to a slender and short stem (tige), composed of two peduncular joints and a multiarticulate filament, the second carrying at its extremity a large oval-shaped blade or lamina with ciliated edges. The epistome is not projecting and swollen as in *Squilla*, and the mouth resembles a pear-shaped tubercle, situated near the middle or towards the posterior third of the lower surface of the carapace. The upper lip has the form of a triangle, with a rounded base which is directed backwards. The mandibles are vertical, swollen at their base, and armed with two branches with dentilated borders, the upper of which raises itself into the interior of the pharynx; their palpiform stem (tige) is either rudimentary or null. The lower lip is large and composed of two swollen lobes. The jaws are small, and of the same conformation as those of *Squilla*, excepting that those of the second pair are narrower. The members which represent the anterior jaw-feet, the prehensile feet (pates ravisseuses), the three pairs of subcheliform feet applied against the mouth, and the three pairs of natatory feet, which terminate the series of thoracic members, are formed and disposed in the same manner as they are in *Squilla*. It is only to be remarked that often the three pairs of subcheliform feet are less approximated to the mouth than they are in the *Squillæ*, and that those of the last three pairs are sometimes rudimentary. The carapace is prolonged more or less far beyond the last rings of the thorax, or even beyond the first segments of the abdomen, but without adhering thereto. The abdomen is elongated; its last segment is very large, and entirely covers the appendages of the preceding ring, which are short, but formed like those of the *Squillæ*. Finally, the false feet suspended from the first five rings of the abdomen are more slender and more elongated than in the other division of the family, and, as has already been noticed, present in general only the vestiges of branchiæ.

The *Erichthi* have as yet occurred hardly anywhere else than in the ocean (haute mer), and have hitherto been found only in tropical regions. The following are the characters of the genus:—

Squillerichthus.—Carapace armed with spiniform prolongations and covering the base of the internal antennæ, but posteriorly it does not overpass (not comprising the spines) the last ring of the thorax. The rostrum is styliform and very long. The eyes are large, pear-shaped, and articulated, on a very slender and rather long cylindrical peduncle. The ophthalmic ring is not distinct from the antennular ring, as in the *Squillidæ* but the mode of insertion of the antennæ is the same as in those animals and in the *Erichthi*. The antennæ of the first pair are directed forwards, and present nothing remarkable. The external antennæ are directed outwards, as in the *Erichthi*, and present also a large peduncle, carrying at its extremity a large oval-shaped lamina ciliated all round, and giving insertion, by its anterior border, to a very short stemlet (tigelle), composed of two peduncular joints and a terminal filament. The mouth is little distant from the base of the antennæ, and situated towards the middle of the carapace. The upper lip is large, demicircular, and projecting. The mandibles are directed downwards as in the *Squillæ*, and there is a large denticulated tooth and a prolongation equally dentilated on its edge, which mounts towards the stomach, but the palpiform stem is null or rudimentary. Behind the mandibles are found a large inferior bilobated lip, and then two pairs of jaws, the form of which is the same as in the *Squillidæ*. The appendages that correspond to the jaw-feet of the first pair present nothing remarkable; they have the form of a long and slender stem, and, as in the other crustaceans of this family, do not seem to form a part of the buccal apparatus. The members of the following pair are very large, and constitute prehensile feet (pates ravisseuses), exactly similar to those of the *Squillæ;* their penultimate articulation is enlarged and spinous towards the base, and their terminal claw is short, and armed with spiniform teeth on the prehensile edge. The feet of the three following pairs are inserted on a transverse curved line immediately behind the prehensile feet, and are habitually applied against the mouth exactly as in the *Squillidæ;* each of these carries at its base a flattened disc-like, vesicle, and is terminated by an oval cheliferous manus. The three last thoracic rings are complete, and free below the carapace, which covers the first two. The three pairs of corresponding feet are of moderate size, and formed as they are in the *Squillidæ*, only their last joint is not setiferous. The abdomen is large, and much resembles that of the *Squillæ*, except that the last segment is much larger, and habitually covers the members of the penultimate ring. These last organs are composed, as in the *Squillæ*, of a peduncular joint, which prolongs itself inferiorly into a great lamina, and carries two appendages inserted on its edges near its base. The internal appendage consists of a great ciliated lamina, and the external one is composed of two joints, of which the last is oval, and the penultimate joint armed with spines on the external border. The false feet suspended from the first five rings of the abdomen are large, and formed of a nearly square peduncular joint, and of two great oval laminæ with ciliated edges; the internal lamina bears on its internal edge a small rudimentary appendage, and the external gives insertion, near its base, to a large ramose branchia.

M. Milne-Edwards, who founded this genus, and whose description we have above given, considers that *Squillerichthus* forms the passage between the *Squillæ* and the *Erichthi*.

It has only been found as yet in the Asiatic seas.

The species (two only are recorded) are small.

S. typus. Rostrum advancing beyond the peduncle of the internal antennæ; a great horizontal spine on the middle of the posterior border of the carapace; and, on each side, another and longer spiniform elongation, springing from the angle of the carapace; finally, a rather strong point towards the middle of the lateral border of the carapace, and another above the base of the external antennæ. Claws of the prehensile feet armed with four teeth (including the terminal point). The last thoracic ring is not covered with the carapace, and the abdomen is very large. Its last segment is much longer than it is wide, and armed with three pair of marginal teeth. Length about 15 lines. Found in the seas of Asia. (Milne-Edwards.)

The other species recorded by M. Milne-Edwards, *S. spinosus*, was taken by M. Dussumier in the Gulf of Bengal.

Erichthus.—Carapace very large, convex, and armed with spiniform elongations. It entirely covers the base of the ocular peduncles, as well as of the antennæ, and extends backwards more or less far beyond and above the abdomen, which is short and large. The eyes are large, pear-shaped, and are not carried on a slender and elongated stem, as in the *Squillerichthi* and *Alimæ*. The antennæ present nothing remarkable, except that the stemlet (tigelle) of those of the second pair is often rudimentary, and that those of the first pair are rather short. The mouth is formed in the same manner as it is in the *Squillerichthi*, only the external jaws are extremely small, and narrower. The jaw-feet of the first pair are extremely slender, and of moderate length; they are slightly enlarged towards the extremity, and have a rudimentary nail or claw at the end. The prehensile feet are but little developed; their claw is nearly straight and without dentilations, and the penultimate joint is slender, elongated, straight, and devoid of spines. The feet of the three following pairs are formed in the same manner as they are in *Squillerichthus*, but they are inserted one after the other; the flattened vesicle fixed at the base of each of these organs, as well as of the members of the two preceding pairs, is very large. The thoracic feet of the last three pairs are formed in the same manner as in *Squilla* and *Squillerichthus*, but are little developed, and sometimes want the styliform appendage; at other times they are entirely rudimentary, and are only composed of a small peduncle, terminated by two articulations nearly like the false abdominal feet, but much smaller. The abdomen is wide and short; the caudal fin which terminates it is disposed as in *Squillerichthus*, and the false feet of the first pair are large, and terminated by two great oval laminæ, on one of which is a rudimentary branchia.

M. Milne-Edwards, who gives the above characters, divides the nine species into the following sections:—

α. Species whose rostrum is very long, and passes sensibly beyond the internal antennæ.

Ex. *E. vitreus* (*Smerdis vulgaris*, Leach). Locality, the Southern Atlantic Ocean.

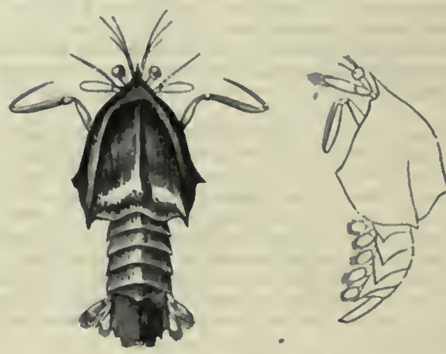
Erichthus vitreus.

β. Species whose rostrum is of moderate length, and passes beyond the peduncle of the internal antennæ without attaining to the extremity of those appendages.

Ex. *E. armatus* (*Smerdis armata*, Leach). Locality, coasts of Africa.

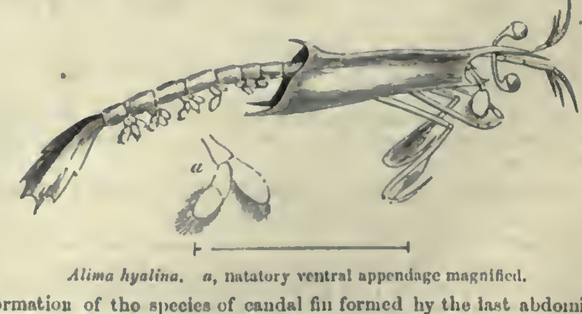
γ. Species having the rostrum extremely short (not passing beyond the peduncle of the internal antennæ).

Ex. *E. Duvaucellii.* Locality, Gulf of Bengal.



Erichthus Duvaucellii.

Alima.—Carapace narrow, straight above, if not altogether so behind, where it often presents a sudden roof-like elevation; rostrum straight and styliform. The anterior angles of the carapace constitute two acute spines directed forwards; the posterior angles are also prolonged into the form of points directed backwards on each side of the abdomen. Finally, the lateral borders of the carapace are nearly straight. The opthalmic and antennular rings are not hidden under the carapace as in *Erichthus*, but are seen uncovered under the rostrum. The eyes are carried on slender long cylindrical peduncles directed outwards. There is nothing particular about the antennæ. The mouth is situated very far from the front, towards the posterior third of the lower surface of the carapace; the upper lip, the mandibles, the lower lip, and the two pairs of jaws, have the same form as in *Erichthus* and *Squillerichthus*. The thoracic feet are formed also in the same manner as in *Erichthus*, but the three pairs of members which follow the prehensile feet are more approximated to the mouth, as in the *Squillæ*. The posterior border of the carapace is ordinarily notched, so as to leave uncovered the two last thoracic rings, and the abdomen is narrow and elongated. The false feet are large, but are in general completely devoid of branchiæ: sometimes vestiges of these organs are found upon the abdominal members of the first pair, and at other times they are represented by a small pediculated tubercle fixed to the external blade of these appendages. Finally, the con-



Alima hyalina. *a*, natatory ventral appendage magnified.

formation of the species of caudal fin formed by the last abdominal segment and the false feet of the sixth ring are entirely the same as in *Erichthus*. M. Milne-Edwards, whose description we have given, states that the *Alimæ* bear an extremely strong resemblance to the

Erichthi, but always have the body more elongated. Their manners, he adds, are not known, and he divides the five species into the following sections:—

a. Species which have the hand of the prehensile feet unarmed with spines.

Ex. *A. hyalina* (Leach). Locality, Cape Verd.

β. Species which have the hand of the prehensile feet armed with teeth or spines on the prehensile border.

Ex. *A. laticauda.* Locality, New Guinea. (Quoy and Gaimard.)

M. Milne-Edwards observes that the species figured by M. Guerin under the name of *A. triacanthura*, belongs to this division, and seems to be distinguished from the other species by the brevity of the rostrum, the shortness of the lateral blades of the caudal fin, &c.

A. longirostris of the same naturalist has not, according to M. Edwards, been described, but seems to approach very nearly to the preceding species.

ERIGERON, a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Corymbiferæ*, the tribe *Asteroideæ*, the sub-tribe *Asterineæ*, the divisiou *Astereæ*, the sub-division *Erigereæ*. It has many-flowered radiant heads; the flowers of the ray ligulate, with pistils only, and in many rows, those of the disc tubular; mostly with both stamens and pistils, the receptacle naked and foveolate; the involucre imbricated, the pappus pilose in one or many rows, the fruit compressed.

E. Philadelphicum has the stem slightly furrowed, downy, with spreading hairs; the leaves of the root cuneate-obovate, sometimes deeply sinuate, the upper becoming gradually entire, obloug-lanceolate, and amplexicaul; the florets of the ray 1-200, pale purple, slightly bifid. This plant is a native of North America, and is used as a medicine in the United States. It possesses stimulant properties, and is given as an emmenagogue; it also acts on the kidneys, and is considered a valuable diuretic. It has a powerful fetid smell.

E. acris has the stem corymbose, the branches alternate, bearing single heads; the leaves linear, lanceolate, entire, spreading; the lower leaves narrowed below; the ray erect, scarcely longer than the disc; the inner female florets filiform, numerous. It has a stem 6-18 inches high; the flowers yellow in the disc and pale blue in the ray. The ashes of this plant contain about 5 per cent. of potassa, and it is sometimes burned for procuring the alkali. It has a strong scent, and like many other species of the family is said to keep away fleas. With species of *Conyza* [CONYZA] and *Pulicaria* [PULICARIA], it has the name of Flea-Bane. It is a native of Europe, and is a common plant in Great Britain. *E. Canadensis* and *E. alpinus* are also found in England and Scotland: tho first is a rare plant, aud is found on waste grouud; the second is a native of highland mountains. The species are numerous, and some of them are ornamental plants.

(Babington, *Manual*; Burnett, *Outlines of Botany*; Lindley, *Flora Medica*.)

ERINACEUS, a genus of Animals to which the Hedgehog (Hérisson of the French) is referred. The Hedgehogs are placed by Cuvier at the head of the Insectivorous Mammifers; and M. F. Cuvier observes that in *Chrysochloris* the normal system of dentition of the *Insectivora* may be seen reduced to tho narrowest dimensions, whilst in the Hedgehogs it appears to be brought to the greatest development.

Dental Formula:—Incisors, $\frac{6}{2}$; canines, 0; molars, $\frac{7-7}{7-7}=36$.

It has the following characters:—Body covered with spines, with the power of rolling itself up into a ball by means of appropriate muscles; muzzle pointed; ears more or less apparent; tail short; each foot 5-toed, and armed with robust claws.

The species of Hedgehog have been recorded as inhabitants of Europe, Africa, and India.

E. Europæus, tho Common Hedgehog, is the Riccio of the Italians; Erizo of the Spanish; Ourizo of the Portuguese; L'Hérisson of the French; Igel of the Germans; Egel-Varken of the Dutch; Pin-Suin of the Danes; Draenog and Draen y Coed of the Welsh; Urchin of the British; *Echinus terrestris* of Gesner; *Echinus* (*Erinaceus*) *terrestris* of Ray; and *Acanthion vulgaris* of Klein. There can be little doubt that it is the *Echinus* (Ἐχῖνος) of Aristotle.

This indigeuous animal is too well known to need a lengthened description. The length is generally rather more than 9 inches.

The food of the Hedgehog, which is a nocturnal animal, consists principally of insects, worms, slugs, and snails. That it will eat vegetables is shown by White of Selborne, who relates how it eats the root of the plaintain by boring beneath it, leaving the tuft of leaves untouched. In the 'Zoological Journal' (vol. ii.) is an account by Mr. Broderip of an experiment made by Professor Buckland, proving that in captivity at least the Hedgehog will devour snakes; but there is no good reason for supposing that it will not do the same in a state of nature, for frogs, toads, and other reptiles, and mice have been recorded as its prey. From its fondness for insects it is often placed in the London kitchens to keep down the swarms of cockroaches with which they aro infested; and there are generally hedgehogs on sale in Covent Garden market for this purpose. It is hardly worth while to refute the idle story that this persecuted animal sucks the cows; but according to Sir William Jardine it is very foud of eggs, and is consequently mischievous in the game-preserve and hen-house. The Hedgehog hybernates regularly, and early in the summer brings forth from two to four young ones at a birth, which at the time of their production are blind, and have the spines white, soft, and flexible. The nest wherein they are cradled is said to be very artificially constructed, the roof being rain-proof. The mother has been known to eat her young in confinement.

The flesh of the Hedgehog wheu it has been well fed is sweet and well-flavoured, and is eaten on the continent in many places. In Britain few besides the gipsies partake of it. The prickly skin appears to have been used by the Romans for hackling hemp.

Among the foreign *Erinaceadæ*, *Erinaceus spatangus* and *Erinaceus Grayii* will be found recorded in the 'Proceedings of the Zoological Society' for 1832. Both came from the Himalaya Mouutains, and the latter was considered by Dr. Gray to be identical with *Erinaceus collaris*, figured in the 'Illustrations of Indian Zoology.' Mr. Bennett however regarded it as a new species, inasmuch as *Erinaceus Grayii* was destitute of a white collar, and differed in other particulars from the figure referred to. A species from the interior of South Africa, forming part of the collection brought from that country by Mr. A. Steedman, *Erinaceus frontalis*, is recorded iu the same volume of the 'Proceedings.'

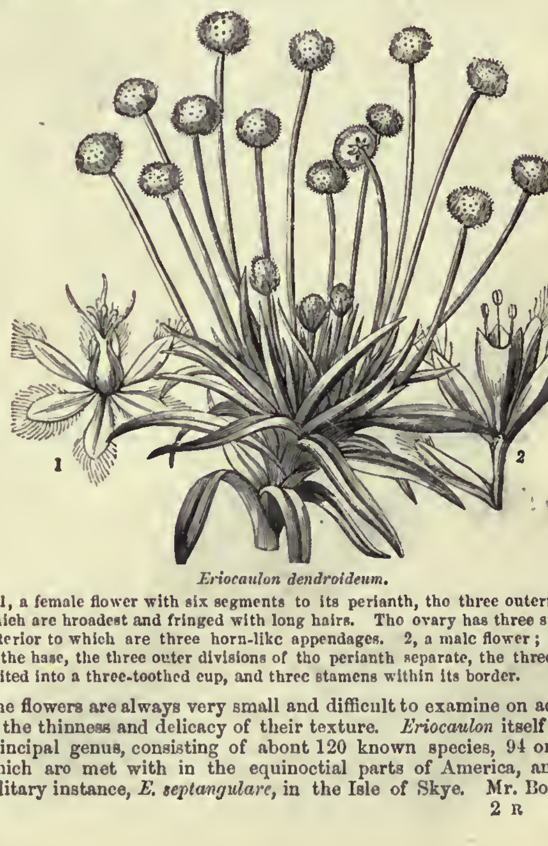
Dr. Gray places the sub-family *Erinacina* under the family *Talpidæ*.

The following species are to be found in the list of specimens of *Mammalia* in the British Museum:—*E. mentalis*, Himalaya; *E. auritus*, Siberia; *E. frontalis*, South Africa; *E. collaris*, India; *E. Grayii*, India; *E. Europæus*, England; *E. spatangus*, India.

ERINITE, a Mineral consisting of Arseniate of Copper. It occurs in conceutric and mammillated layers, between which other arseniates are found. The layers have rough surfaces and a fibrous structure. The colour is a brilliant emerald-green inclining to grass-green. Streak paler. Fracture uneven or imperfect conchoidal. Its hardness is 4·5 to 5·0. Lustre slightly resinous. Slightly translucent. The specific gravity 4·0 to 4·1. It is found near Limerick. Its analysis, by Turner, gives:—

Arsenic Acid	33·78
Oxide of Copper	59·44
Alumina	1·77
Water	5·01

ERIOCAULACEÆ, *Pipeworts*, a group of Endogenous Plants subordinate to *Restiaceæ*, for the most part inhabiting swampy or marshy places, or the bottom of lakes, and having the flowers collected into dense heads. The sexes are separated; the perianth consists of from 2 to 6 divisions immersed in soft bracts; there are from 2 to 6 stamens; the styles are 2 or 3; the cells of the ovary are the same number, and the seeds solitary, with lines of hairs upon their surface. The embryo is placed on the outside of the albumen at the apex of the seed.



Eriocaulon dendroideum.

1, a female flower with six segments to its perianth, the three outermost of which are broadest and fringed with long hairs. The ovary has three stigmas, exterior to which are three horn-like appendages. 2, a male flower; a bract at the base, the three outer divisions of the perianth separate, the three inner united into a three-toothed cup, and three stamens within its border.

The flowers are always very small and difficult to examine on account of the thinness and delicacy of their texture. *Eriocaulon* itself is tho principal genus, consisting of abont 120 known species, 94 or 95 of which aro met with in the equinoctial parts of America, and one solitary instance, *E. septangulare*, in the Isle of Skye. Mr. Bongard, who has written a monograph of the South American species, states that in that part of the world, although they prefer marshy and inundated places, yet some are found upon damp sand, others among grass, and some in dry and stony places; they are also frequently met with in alpine situations, some as high as 5590 feet above the sea on the summit of Mount Itambé. The preceding figure of *Eriocaulon dendroideum* gives a correct notion of the appearance of these plants.

ERIODENDRON, a genus of Plants belonging to the natural order *Sterculiaceæ*, known by the name of Wool-Trees. The wool-trees are large trees, with a spongy wood which is used for little besides making canoes in the districts where they grow. The leaves are palmate, and the flowers are large, red, white, or scarlet, and rising singly or in clusters from the sides or tops of the branches. The calyx is naked, irregularly 5-lobed, with the lobes usually twin; the petals are 5, joined together, and are connected with the column of the stamens at the base. The filaments of the stamens are joined together into a short tube at the base, and divided into 5 bundles at the apex; these bundles are filiform, and each bears 1, 2, or 3 linear or anfractuous anthers at the apex, which have the appearance of one anther, and are either adnate or versatile. The stigma is 5- or 6-cleft. There are 6 species of *Eriodendron*, 5 of which are natives of America, and 1 of Asia and Africa.

E. anfractuosum has versatile anfractuous anthers; leaves with 5, 7, or 8 entire cuspidate leaflets, glaucous beneath and a usually prickly trunk. This tree attains a height of 150 feet or more. There are two varieties described, the one growing in the East Indies and the other in Guinea. They differ chiefly in the colour of their flowers. The Indian species, *E. a. Indicum*, has flowers yellowish inside and white outside; whilst the Guinea species, *E. a. Africanum*, has large crimson flowers. In Guinea this tree is one of the largest and tallest of the forest-trees, and the trunk is employed for making the largest-sized canoes.

E. Samamna has versatile anfractuous anthers; leaves with 5-7 oblong, quite entire, acuminated leaflets; the petals obovately spatulate, covered with glabrous down on the outside. The flowers are cream-coloured, and are seated on the tops of the branches. The wool contained in the fruit is used in Brazil for stuffing pillows, bolsters, beds, &c. It is found in Brazil near the river Yupura.

E. Jasminodorum has anfractuous anthers; a jointed style; leaves with 3 ovate, acute, entire leaflets; the petals reflexed; the tube of the stamens thickened at the top and entire, with the filaments 1-anthered. This plant is a native of Brazil, in the province of Minas Novas. It has white flowers smelling very like to those of the jasmine.

The wool-trees may be grown in this country with heat. They may be propagated by cuttings which will root freely in sand under a hand-glass, but the plants which are produced from seeds thrive best. They do not usually produce their beautiful flowers till they are of large size in their native countries; therefore it can hardly be expected they should flower in this country.

ERIOMYS. [CHINCHILLIDÆ.]

ERIO'PHORUM, the systematic name of the sedge-like Plant which is called in this country Wild Cotton or Cotton-Grass, in consequence of the long cottony tufts which wave upon its stalks in marshy and sedgy heaths and wastes in all parts of this country. The appearance is owing to the hypogynous scales, which, in this glumaceous genus, represent the calyx, being extended into long numerous white hairs, which project far beyond the scales of the flower-head. It is not a little curious that while, in most of the species, these hairs are indefinitely numerous, they should in one, *E. alpinum*, be reduced to the regular number, six, which is the general proportion of floral envelopes belonging to Endogens. Professor Kunth enumerates twelve species, all inhabiting the colder parts of the northern hemisphere. The silky or cottony substance which clothes the fruit of the species of this genus is made into paper and the wicks of candles; it is also used for stuffing pillows, &c. The leaves of *E. comosum* are in the Himalayas extensively employed in the manufacture of ropes.

ERI'PHIA, Latreille's name for a genus of Brachyurous or Short-Tailed Crustaceans.

Carapace less wide, and more quadrilateral than in the other Cancerians; length two-thirds more than the breadth; the fronto-orbital border occupies more than one-half, and sometimes more than three-fourths of its breadth; and the latero-anterior borders, directed nearly right backwards, only describe a slight curvature, and prolong themselves but little. Orbits, as in the genus *Ruppellia;* but the space which separates their edges from the basilary joint of the external antennæ is very considerable; this joint is but little developed, and does not occupy a fourth of the space comprised between the antennary fossette and the internal canthus of the eyes; on the contrary, the moveable stem of the external antennæ is much more developed than in the *Ruppelliæ*, and is inserted at a small distance from the antennary fossette. For the rest, not differing from the other Cancerians.

M. Milne-Edwards, whose description we have given, says, that the *Eriphiæ*, which he places among the Quadrilateral Crustaceans, approach the *Ruppelliæ* nearly, but that the general form of the body of *Eriphia* tends to establish a passage towards the *Thelphusæ*. He divides the species into the following sections:—

α. Species having the hands (manus) tuberculous.

* Front armed with spines.

Ex. *E. spinifrons* (*Cancer spinifrons*, Herbst). It inhabits all seas (Milne-Edwards.)

Eriphia spinifrons.

** Front devoid of spines.

Ex. *E. gonagra* (*Cancer gonagra*, Fabricius). Found on the coasts of South America.

Eriphia gonagra.

β. Species having the hands (manus) smooth, not tuberculous.

Ex. *E. lævimana.* It inhabits the Isle of France.

Eriphia lævimana.

M. Milne-Edwards observes that the *Eriphia* figured by Savigny ('Egyp'., pl. 5, fig. 1), and referred with doubt by M. Audouin to *E. spinifrons*, appears to him (Edwards) to be a distinct species; and that *E. prismatica* of Risso has not been described with sufficient details to justify its reference to this genus with certainty. *Cancer Eurynome* (Herbst) appears to M. Edwards to be an *Eriphia*.

ERLANITE, a Mineral containing Silica, Alumina, &c. It occurs massive and amorphous. Its fracture is in some specimens foliated, in others splintery. The structure granular and compact. Colour light greenish-gray. Streak white, shining. Hardness 6·25 to 7·0. Lustre feebly shining, or dull. Opaque. The specific gravity 3·0 to 3·1. It is found near Erla in the Saxon Erzgebirge, forming a bed of 100 fathoms in thickness. Its analysis, by Gmelin, gives:—

Silica	53·16
Alumina	14·03
Lime	14·39
Magnesia	5·20
Soda	2·61
Oxide of Iron	7·14
Oxide of Manganese	0·64
Water	0·60

ERMINE. [MUSTELA.]

ERNE. [FALCONIDÆ.]

ERNTO. [CYPRÆIDÆ.]

ERO'DIUM (from ἐρώδιος, a heron), a genus of Plants belonging to the natural order *Geraniaceæ*. It has 5 sepals, 5 petals, 10 monadelphous stamens, 5 fertile and 5 sterile with glands at their base; the fruit beaked, separating into five 1-seeded capsules, each with a long ultimately spirally-twisted awn, bearded internally. The species are herbs or undershrubs, having variously-formed leaves, membranous stipules, and many-flowered peduncles. The species of this genus, like those of *Geranium* and *Pelargonium*, are numerous, upwards of fifty having been described.

E. cicutarium, Hemlock-Leaved Heron's-Bill, has a procumbent hairy stem, the peduncles many-flowered, the claws of the petals ciliated, the perfect stamens dilated, not toothed below, glabrous, the beak hairy, the leaves pinnate, the leaflets sessile, pinnatifid, cut. The flowers are purplish or white. It is a native throughout the whole of Europe, and is found in the north of Africa. It is abundant on sandy soils and waste ground in Great Britain. There are several well-marked varieties, some of which may be really species, as the *E. c. pimpinellæfolium*.

E. moschatum, Musky Heron's-Bill, has a procumbent hairy stem, many-flowered peduncles, the claws of the petals not ciliated, the perfect stamens toothed at the base, glabrous, the beak downy, the leaves pinnate, the leaflets nearly sessile, ovate, unequally cut. It is found in waste places in Great Britain, but is an unfrequent plant. It is a larger plant than the preceding, and emits, when handled, a strong musky odour. It is very generally diffused, and has been found all over Europe, at the Cape of Good Hope, and in Peru.

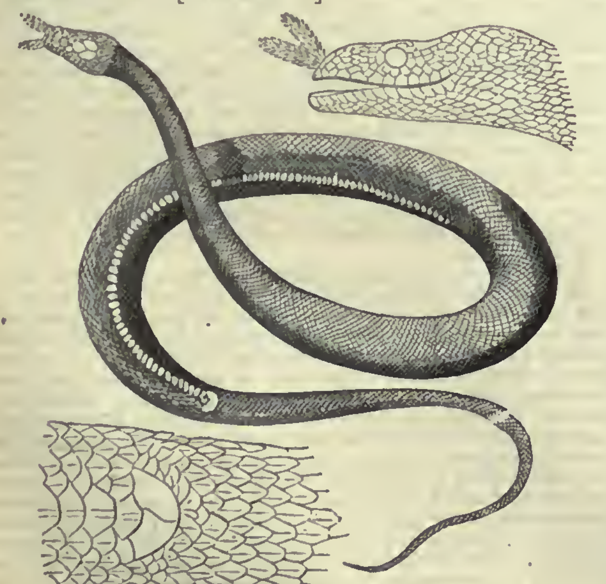
E. maritimum, Marine Heron's-Bill, has a prostrate slightly-hairy stem, the peduncles 1-2-flowered, the petals very minute, the leaves simple, ovate, cordate, stalked, lobed, and crenate. It is a rare plant, but a native of Great Britain, in sandy places near the sea.

Most of the remaining species are natives of Europe; some are found in the north of Africa, two or three in Asia, and the same number in America; but the mass of them are truly European. The perennial species are ornamental, and will thrive well in any kind of garden soil. They may be propagated by dividing the roots or by seed. Many of the annual species are handsome plants, and may be propagated by seed, which ripens in this country, and only requires to be sown in the open border to spring in any kind of soil.

EROPHILA. [DRABA.]

EROTYLUS. [TETRAMERA.]

ERPETOLOGY. [HERPETOLOGY.]



Herpeton tentaculatus.

E'RPETON, Lacépède's name for a genus of Serpents, placed by Cuvier next to *Eryx*. The name should be written *Herpeton*.

The genus is furnished with two soft prominences, covered with scales on the muzzle. The head is protected by large plates; those beneath the belly are not large, and those beneath the tail scarcely differ from the other scales. The tail however is very long and pointed. Cuvier, who speaks of the priority of Lacépède, who first described the genus under the name of *Erpeton*, remarks that Merrem has changed the name to *Rhinopirus*.

ERRATIC BLOCKS are those weather-worn and more or less rounded fragments of the harder rocks which are found very widely scattered over the surface of the earth, and at great distances from the places whence they are supposed to be derived.

In size they vary from 10,000 cubic feet and upwards to a few inches. M. Brongniart has proposed to designate the several sizes by particular names, as gigantic, metric, cephallary, pugillary, &c. But in England we generally confine the term Erratic Blocks to the larger masses, calling those of middling size Boulders, and arranging the smaller along with gravel: this is however too vague. The nature of Erratic Blocks is not less various than their size. Every species of rock seems to have contributed a portion of its substance towards the mass, though the harder, being better capable of resisting the disintegrating and corroding influence of atmospheric causes, are found in the greatest abundance, such as quartz, petrosilex, greenstone, granite, porphyry, syenite, gneiss, primitive and transition limestone, dolomite, serpentine, siliceous pudding-stones, siliceous sandstones, &c.

The distribution and situation of these blocks are also very different. Seldom isolated, they are generally found in patches or groups, as in the environs of Geneva, the plains of Westphalia, in Sweden, &c.; or in long bands or trains, as in the north of Mecklenberg Strelitz, where they run in a direction west-north-west and east-south-east; or widely spread over considerable tracts, as between Warsaw and Grodno, between St. Petersburg and Moscow, in East Prussia, &c. Sometimes they cover horizontal plains, as in the north of Germany; sometimes they rest on the sloping sides of mountains, as in the Alps and the Jura, and occasionally on the very tops of lofty eminences, as on the summits of the calcareous mountains of Rettwick, of Rædaberg, and of Osmund, about 6000 feet above the level of the sea. Sometimes they are seen in greatest abundance at the bottom of valleys where they open into the plains, and in other instances they are found collected in the largest quantity in the high and narrow parts of the valleys, as is observed at Detmold and east of Lemgo. At times they are so abundant as to be accumulated into hills of a particular form, as is the case in Smaland, in Sweden; and sometimes they form even mountains of considerable height, as may be seen near Quedlie, in Norway; and what is remarkable, the larger blocks are at the top, the others diminishing gradually towards the bottom.

Though generally superficially disposed, Erratic Blocks are however in some places found imbedded in a fine sand which has nothing in common with their nature or origin, as in the plains of Westphalia. Some blocks (and this may depend either on their own particular nature, or the greater or less friction to which they have been subjected, the length of time they have been exposed to atmospheric influence, or the nature of the climate), have their angles and edges as sharp as though they were just detached from their native mountains, as is the case in the neighbourhood of Groningen.

When the Erratic Blocks are not at any great distance from the spots whence they come, they may be easily traced up to their origin. Thus those which are in the basin of the Rhine come from the Grisons; those of the valley of the Lake of Zürich and of the Limmat have been detached from the mountains of Glaris; those of the basin of the Reuss come from the rocks at the source of this river; and those of the Aar and the Jura from the lofty mountains in the canton of Berne. Even those which cover the widely extended tract from Holland on the west, to St. Petersburg and Tver on the east, are supposed by Von Buch, Hausmann, Brugmans, Alex. Brongniart, &c. to be traceable to Scandinavia. It is however remarkable that, contrary to what is generally observed of transported debris, the blocks are frequently largest as they are farthest removed from the place whence they came, diminishing gradually in size as they approach the parent rock; thus the blocks found in Mecklenberg and Seeland, which are ascertained to be derived from the Scandinavian peninsula, are larger than the blocks of the same rocks in Scania and East Gothland, and they disappear altogether close to the primordial mountains whence they were derived.

In certain places the blocks are almost exclusively of a particular kind, while in others they vary greatly in their mineral character, proving, together with the ascertained situation of the same rocks in situ, that they must have been assembled from various quarters. This is the case with the Erratic Blocks of Yorkshire, and with those of Lithuania, for though the greater part, perhaps, of those in the latter locality may be similar to the rocks in Sweden and Norway, there are many evidently derived from other places.

As for the direction in which the bands of Erratic Blocks seem to lie, and the quarter whence they seem to have come, they are very various. We have just seen that in the north of Mecklenberg the trains are in a line west-north-west and east-south-east. Count Rasoumovski observes that, when many blocks are accumulated they form parallel lines with a direction from north-east to south-west. Brongniart says they have a general direction north and south. Sir James Hall speaks of those in the neighbourhood of Edinburgh as coming from the west. We have said that those on the north of the Alps come from the south.

If anything further were necessary to complicate the problem of Erratic Blocks, it is the immense distance at which they are sometimes found from the nearest rocks of similar composition; thus blocks of granite are found on the mountains of Potosi, while the nearest granite rocks are in Tucuman, about 400 leagues off. Nor is distance all; the detached blocks are found separated from their parent rocks by intervening hills, broad and deep valleys, as that of the Aar, and even by straits and seas: thus in the north of Cumberland there are boulders which have been transported across the Solway Frith from Dumfries, and the blocks on the low plains of Germany are separated from their parent rocks by the Baltic.

England, as well as the continent of Europe, has many spots covered with Erratic Blocks, some of which seem to be derived from Norway, while others are evidently the debris of our own mountains. For details we refer the reader to the observations and works of Sedgwick, Conybeare, Lyell, Buckland, Phillips, Hibbert, &c.

Erratic Blocks are also common in America and other parts of the world.

From what has been already said, and from the circumstance of Erratic Blocks lying on some of the most modern formations, it will be easily conceived that they present one of the most inexplicable of geological phenomena. The blocks on the Jura, and from the Alps generally, having first attracted notice, have given rise to a great variety of hypotheses, the most remarkable of which are the following:—1. De Luc was of opinion that these blocks had been projected into the air by the same force which upheaved the Alps, and that they had fallen at greater or lesser distances, according to the strength and direction of that force. 2. Von Buch, Escher, &c., attribute their existence to an immense débacle which swept down the blocks from the Alps to the foot of the Jura, up the slope of which they were forced by the impulse they had received, in the same way as a ball rolled along with force rises up a hillock. 3. Others, as Daubuisson, have thought that these blocks, which are almost wholly of transition rocks, were the remains of a mantle of these rocks, of later formation than the limestone of the Jura, and consequently much more recent than is generally admitted, and which, having been destroyed, left nothing but these testimonials of their former existence. 4. Dolomieu supposed that the summits of the Alps were formerly connected with those of the Jura by an inclined plane, which has been destroyed by the same revolution that precipitated the blocks from the summit of the Alps to the plateau, and into the valleys of the Jura. 5. Venturi has attempted to explain the passage of the blocks from the Alps into the basin of the Po, by floating them down on rafts of ice. 6. Others have upheaved the Jura, which they suppose to have been formerly on a level with the base of the Alps, and with it the blocks which had rolled down upon this calcareous plain. 7. Finally, Von Buch, extending his general theory to the particular phenomenon, thinks that the dispersion of the blocks is the result of an upraising of the Alps posterior to the formation of the tertiary rocks.

M. Brongniart very justly observes that these hypotheses leave many difficulties unexplained: he conceives that as the phenomenon of Erratic Blocks is a very general one, it is presumable that the cause also is general. Certain it is that even if it were possible satisfactorily to assign a cause for the Erratic Blocks found upon the Jura, the same reasoning would hardly be applicable to other cases; and in the utter impossibility of discovering any single cause competent to the production of such different effects, we must have recourse to the more probable conjecture of M. Larivière, that the dispersion and disposition of Erratic Blocks have been effected in different ways. The more powerful cause however he conceives to be the transporting power of icemeers and icebergs, in which opinion he is followed by Mr. Lyell and others.

Erratic Blocks, like other phenomena, are attended with their peculiar advantages: thus on hot and dry soils, and when not in too great abundance, they keep the soil cool and moist, sheltering it from the direct rays of the sun in the day, and thus diminishing the evaporation of its moisture. On cold soils they tend to maintain an equable warmth by diminishing radiation at night. In some countries they are the only building-stones, as in East Friesland and the neighbourhood of Groningen. In others they supply the necessary lime, as at Königsberg, Revel, &c. Those of a convenient size are used in Russia and Poland for paving the towns: when broken they are exceedingly well adapted for the repairs of roads.

ERRINA. [MILLEPORIDÆ.]

ERU'CA, a genus of Plants belonging to the natural order *Cruciferæ*, and to the tribe *Brassiceæ*. It has an erect calyx, obovate petals, distinct, not toothed stamens; an oval, oblong, two-celled, two-valved, silique; smooth concave valves, with an ensiform seedless beak, scarcely shorter than the valves; the seeds globose. The species are annual branched herbs, with erect terminal racemes of flowers, which are white and yellow, and remarkable for their beautiful reticulation of brown veins.

E. sativa, Garden-Rocket, has lyrate pinnatifid leaves, with toothed acute lobes, a hairy stem, the pedicels shorter than the deciduous calyx. It is a native of cultivated fields and waysides in the north of Africa, in Spain, Portugal, France, Italy, Switzerland, and Greece. It is very subject to varieties, and many have been described by various botanists. Although mostly hairy, sometimes its stem is smooth. In height it varies from three inches to two feet, and the flowers are very variable in the depth and arrangement of their colours. When full grown it has an acrid and unpleasant taste, and a strong, peculiar, almost fetid smell; but when young and tender it is frequently eaten as a salad, especially on the Continent. It is the Roquette Cultivée and La Rocket des Jardins of the French, Raukette of the Germans, and Ruccola of the Italians. The whole plant has been used in medicine as a sialagogue. The ripened seeds are a good substitute for the seeds of the mustard, but not so pungent. When cultivated as a salad, the seeds should be sown in a warm border early in February, and again in March and April for successive crops. The plants should be thinned, after they have produced the first rough leaves, to about three or four inches apart, and they should be kept clear of weeds. If a supply is required throughout the year, the seeds may be sown every month. The plants sown in February should be allowed to produce seed, which ripen in August, and may be used for all the sowings. *E. hispida* and *E. vesicaria* are European plants, and when cultivated as ornament need only to be sown in the open border and treated as other hardy annuals.

(Lindley, *Flora Medica*; Don, *Dichlamydeous Plants*.)

ERUCASTRUM, a genus of Plants belonging to the natural order *Cruciferæ*, and to the tribe *Brassiceæ*. It has a square pod, the valves convex, with one straight nerve, the seeds oval or oblong in a single row. This genus has been formed by Schimper and Spenner for some of the species of the old genus *Sinapis*. *E. incanum*, the *Sinapis incanus* of Linnæus, has been found in sandy places in Jersey and Alderney, and has consequently a place in the British Flora. It has adpressed pods, which are turgid, with a short one-seeded beak. The stem reaches from one to three feet high. This plant is also a native of the South of Europe, especially Spain: and is the *Cakile Hispanica* of L'Heritier; the *Hirschfeldia adpressa* of Moench. Koch, in the 'Synopsis Floræ Germanicæ et Helveticæ,' gives three species of this genus as natives of Switzerland and the upper district of the Rhine. (Babington, *Manual of British Botany*; Don, *Dichlamydeous Plants*.)

ERUCIVORA. [LANIADÆ.]

ERVUM, a genus of Plants belonging to the natural order *Leguminosæ* and the tribe *Vicieæ*. It is known by a 5-cleft calyx, with linear acute segments, about equal in length to the corolla; glabrous stigma; an oblong 2-4-seeded legume. Most of the species of this genus are weeds, two of which, the *E. hirsutum* and *E. tetraspermum*, are found in Great Britain. The former is called Tine-Tare, and is a great pest in corn-fields.

E. Lens is the plant which produces the Lentil. It has branched stems; oblong nearly glabrous leaflets, usually eight in number; the stipules lanceolate and ciliated; the peduncles 2-3-flowered, about equal in length to the leaves; the legumes short, broad, finely reticulated; seeds two, compressed. It is a native of corn-fields on the continent of Europe. Lentils are not much eaten in this country, but they are consumed in considerable quantities in France, Germany, and Italy. The Lentil is one of the oldest leguminous plants used as food of which we have any record. Ever since the time of Esau they have been eaten in the East. In Egypt and Syria they are parched in a frying-pan and sold in the shops, and are considered by the natives as the best food for those who are on long journeys. The Lentil is still cultivated in this country. There are three varieties known in France and Germany: the small brown, which is the lightest-flavoured and the best for soups; the yellowish, which is a little larger and the next best; and the Lentil of Provence, which is almost as large as a pea, with luxuriant straw, and it might be cultivated as food for cattle.

In its cultivation the Lentil requires a dry warm soil; it should be sown later than the pea, at the rate of a bushel or a bushel and a half to the acre. It ripens earlier than the pea, and requires the same treatment and harvesting. The produce of the Lentil in grain is about a fourth less than that of the tare, and the straw is not more than a third as much. The straw is however considered very nourishing, and is used for feeding calves and lambs. Lentils, like all other leguminous fruits, contain a large quantity of nitrogenised matters. Einhoff found that 3840 parts of lentils contained 1260 parts of starch and 1433 parts of a matter analogous to animal matter. In a late analysis made by Dr. Playfair for the Royal Agricultural Society he found that 100 parts of lentils contained 33 parts of albumen or gluten and 48 parts of starch, &c.; whilst the same quantity of peas contained 29 parts of albumen, and of beans 31 parts. If the theory of nutrition propounded by Professor Liebig in his late work on 'Animal Chemistry' be correct, then lentils constitute one of the most highly nutritious foods in nature.

ERYCINA. [VENERIDÆ.]

ERY'NGIUM, a genus of Plants belonging to the natural order *Umbelliferæ*, and the tribe *Saniculæ*. It has a calyx of five leafy teeth, the petals erect, oblong, with a long inflexed point; the fruit obovate, covered with chaffy scales without ridges or vittæ. The species are usually perennial spiny herbs, with the flowers congregated into oblong or roundish dense heads.

E. maritimum, Sea-Holly, has the radical leaves roundish, plaited, spurious stalked, the upper leaves embracing the stem, palmately lobed; the leaves of the involucre 3-lobed, spurious, longer than the heads; the scales of the receptacle 3-lobed. The stem is more than a foot in height, and is branched and leafy. It is a native of Europe on the sands of the sea-shore, and is found on the European and African shores of the Mediterranean Sea. It is abundant on the eastern shores of England, and is found in Scotland and Ireland. The plant is called in England Sea-Eryngo, Sea-Hulver, and Sea-Holme. According to Linnæus the flowering shoots are very good when boiled and eaten like asparagus. The leaves are sweetish, with a warm aromatic flavour. The root also is sweet to the taste, and has an aromatic smell. It has been used in medicine as a tonic, and Boerhaave regarded it as a valuable aperient and diuretic. The root is also supposed to possess aphrodisiac virtues. It is candied, and sold in the shops of London as a sweetmeat. There is still an establishment at Colchester, in Essex, where the roots are candied, in which town this preparation was first made, more than two centuries since, by Robert Buxton, an apothecary. It is not now much used by medical men, but at one time it had a reputation in many diseases.

E. campestre has the radical leaves two or three times pinnatifid, spinous, stalked; the stem-leaves embracing the stem, bi-pinnatifid; the leaves of the involucre lanceolate, spinous, longer than the heads; the scales of the receptacle undivided. It is a more bushy and slender plant than the last. It grows on waste ground and in dry sandy fields, and is a very common plant in the south of Europe. It is found in England and Scotland, but is a rare plant. There is a plant found on the banks of the Tyne called *E. campestre*, but Mr. Babington thinks this may be a different species. The plant which Ray describes as growing on the shore, called Friar's Goose, below Melling, in Yorkshire, Mr. Babington thinks requires further examination, before determining the claim of this plant to be considered a true native of Great Britain.

E. fœtidum has the radical leaves lanceolate, bluntish, narrowed at the base, spinous; the floral leaves palmate, sessile; the leaves of the involucre lanceolate, much longer than the heads; the palea among the flowers entire. It is a native of Jamaica, Guyana, Demerara, Florida, and Brazil, in fields and woods. The negroes and poorer whites in Jamaica regard this plant as a valuable remedy in hysterical fits; hence it is called in the West Indies Fit-Weed. It is admistered in the form of a decoction or infusion of the whole plant.

E. aquaticum, Rattle-Snake-Weed, has the leaves broadly linear, with parallel nerves; the lower leaves ensiform; the floral leaves lanceolate, toothed; the leaves of the involucre shorter than the heads of flowers; the stems dichotomous. It is a native of North America, from Pennsylvania to Virginia. It is also found in the Society Islands, California, and Buenos Ayres. It inhabits marshes, inundated pastures, and the banks of rivers. This plant is employed in North America as an application to the bite of the rattle-snake; hence its common name.

Nearly 100 species of this genus have been described. They are found in greatest numbers in America, but many are inhabitants of Asia, Africa, and Europe. They are most of them handsome and ornamental plants, and worthy of cultivation. They will grow freely in any common garden soil, but the lighter or more sandy the soil the better they will grow. Some of the species require the greenhouse or frame, and they should be grown in pots. They may be propagated by dividing the roots, or by sowing the seed.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Lindley, *Flora Medica*.)

E'RYON, Desmarest's name for a Macrourous Crustacean only known in a fossil state.

External antennæ short (one-eighth of the total length of the body including the tail), setaceous, provided at their base with a rather large scale, which is ovoid and strongly notched on the internal side; intermediate antennæ setaceous, bifid, much shorter than the external ones, and having their filaments equal. Feet of the first pair nearly as long as the body, slender, linear, not spinous, terminated by very long and narrow chelæ, with fingers little bent, but slightly inflected inwards; carpus short; feet of the other pairs also slender, and those of the second and third pairs terminated with pincers, like the feet of the crawfishes (écrevisses). Carapace very much depressed, wide, nearly square, but little advanced anteriorly, profoundly notched on its latero-anterior borders. Abdomen rather short, formed of six articulations, of which the four intermediate ones have their lateral borders prolonged in angles, well detached, as in the crawfishes. Caudal fin formed of five pieces, of which the two lateral are entire, rather large, a little rounded on the internal side, and the three middle ones triangular and elongated, especially the intermediate one.

It is found in the lithographic limestone of Pappenheim and Aichtedt in the margraviate of Anspach. (Desmarest.)

M. Desmarest observes that this genus is entirely anomalous, and ought in a natural classification to form a section by itself. According to the method of Dr. Leach it would belong: 1st, to the order *Macroura*; 2nd, to the second section, which includes those *Macroura* which are provided with a caudal flabelliform fin; 3rd, to the subsection *B*, which have the peduncles of the internal antennæ moderately elongated; 4th, to the fifth division, which have the natatory blades of the extremity of the tail formed of a single piece, the second articulation of the abdomen not dilated, and rounded anteriorly and posteriorly on each side: and, finally, feet to the number of ten.

M. Desmarest goes on to say that it is to the *Callianassæ*, the *Thalassinæ*, the *Gebiæ*, and the *Axii*, that *Eryon* bears relation. Nevertheless it has not, he observes, the habit of any of them. Its short depressed carapace, and its little elongated abdomen, approximate it to *Scyllarus*, but its internal antennæ with short peduncles, its external setaceous antennæ, and its greater anterior didactylous feet, widely separate it from that genus. It cannot be confounded with *Palinurus*, which has the external antennæ and the peduncles of the internal ones so long, and whose feet are all monodactylous; and, finally, it cannot be referred to the crawfishes or lobsters (*Astacus*), whose shell is differently formed, and which have the external natatory blades of the tail composed of two pieces; but Desmarest thinks that it is to the last-named genus that *Eryon* most approximates, taking into consideration its general character. He regrets that he has not been able to satisfy himself whether the four antennæ are inserted on the same horizontal line or not, a fact which would have assisted him in his comparison with other genera.

E. Cuvieri. Carapace finely granulated above, marked by two deep and narrow notches on the two latero-anterior borders, and finely crenulated on the latero-posterior borders. Length 4 to 5 inches, French.

Eryon Cuvieri.

The fossil was noticed by Richter, Knorr, and others, before M. Desmarest, as indeed he states.

ERY'SIMUM (from ἐρύω, to draw), a genus of Plants belonging to the natural order *Cruciferæ*, and to the tribe *Sisymbreæ*. It has a tetragonal pod, the valves prominently keeled with one longitudinal nerve, the stigma obtuse, entire or slightly emarginate, the seeds in a single row, the funiculus filiform. The species are annual, biennial or perennial herbs, with variable leaves, and elongated, termina many-flowered racemes.

E. Alliaria of Linnæus, Smith, Schkuhr, and others, is generally now admitted as the type of a new genus, *Alliaria* of Adanson. It differs from *Erysimum* in not having its valves keeled with a single nerve, but having 3 longitudinal nerves, and in the seeds being striated, and the funiculus flattened and winged. *E. Alliaria* is the *A. officinalis* of Andrzeijowski, who is followed by De Candolle in his 'Prodromus,' and Babington in his 'Manual.' Koch however follows Scopoli, and places it in *Sisymbrium* as *S. Alliaria*; from which genus it differs only in its flattened winged funiculus. It has heart-shaped leaves, the lower ones being reniform and coarse, repando-crenate; the pods are erect and patent, much longer than their stalks, and the seeds are oblong and cylindrical. The stem is erect, one to two feet high, and slightly branched. The flowers are white. It is a native all over Europe, under hedges and in ditches. It has a strong smell, and a taste not unlike garlic, for which it is frequently used as a substitute, whence it has obtained its Latin name *Alliaria*, from 'allium,' garlic. It is very generally used by the poor people of the countries in which it grows as a condiment, with bread and butter, salted meats, or in salads. In England it is known by the name of Sauce Alone, and Jack by the Hedge. In German it has several names, as Das Knoblauchkraut, Der Knoblauchhederich, Lauchel

Waldknoblauch, Ramfen, Ramschelwurzel, Gernsel, Salsekraut, Saskraut. In French it has the names L'Alliare, L'Herbe aux Aillets, &c. Although not often found on the tables of the middle or upper classes, Mr. Neill says, that "when gathered as it approaches the flowering state, boiled separately, and then eaten to boiled mutton, it certainly forms a most desirable pot-herb, and to any kind of salted meat an excellent green." Linnæus says that sheep and cows and poultry eat it, but that horses and goats refuse it. When eaten by cows it gives a disagreeable flavour to the milk. Poultry also which eat it have a bad flavour when cooked. The seeds when powdered produce sneezing, and have been employed as a sternutatory. The leaves were formerly used as a diaphoretic, and a poultice of them was recommended as an antiseptic in gangrenous and cancerous ulcerations.

A second species of *Alliaria* has been described as *A. brachycarpa*, a native of Iberia.

E. cheiranthoides, Worm-Seed, Treacle-Mustard, has oblong-lanceolate leaves, sligbtly toothed, with stellate three-parted hairs, all narrowed into a sligbt footstalk, tho pedicles longer than the calyx, two or three times shorter than the pods; the pods patent, ascending; the seeds small, numerous. It is a native of Europe, also of North America. It is found not uncommonly in Great Britain; it inhabits cultivated ground, waste places, and osier holts. It varies greatly in size according to situation. The flowers are very numerous, small, and yellow. It has obtained its name Worm-Seed from the fact of its seeds being sometimes used as a remedy for intestinal worms. It was also formerly employed as an ingredient in the famous Venice Treacle, and hence the whole genus have been called Treacle-Mustard. Babington marks this and all other species of *Erysimum* as plants that have been possibly introduced into Great Britain, though now looking very like true natives.

E. virgatum has linear lanceolate leaves, entire, with stellate two- or three-parted hairs, the lower ones narrowed into a footstalk, the upper leaves mostly sessile, tho pediclos as long as the calyx, many times shorter than the pod, the pod erect, the seeds large. It is found in Great Britain plentifully near Bath. It is also a native of the Alps and of Holland.

E. orientale has elliptical heart-shaped obtuse leaves clasping the stem, the radical leaves obovate, all smooth, glaucous, undivided, entire. This is the *Coringia orientalis* of Andrzeijowski, and *E. alpinum* of Baumgartner, and *Brassica alpina* of Linnæus. It is a native of the south of Europe, and is found in England and Ireland, in fields and cliffs near the sea. It has white or cream-coloured flowers. There are about fifty species of *Erysimum*, most of them natives of Europe, and a few in the temperate districts of Asia, Africa, and America. Some of them are ornamental and worthy of cultivation. The perennial herbaceous species are well adapted for the flower-border, and may be grown in any common garden soil. The smaller species may be employed for ornamenting rock-work, and many of them may be grown in pots with other alpine plants. The perennial species may be propagated by cuttings, by dividing the roots, or by seeds. The annual and biennial species may be sown in the open ground.

(Babington, *Manual of British Botany;* Don, *Dichlamydeous Plants;* Sowerby, *English Botany.*)

ERYSIPHE. [FUNGI.]

ERYTHACA, a genus of Birds belonging to the family *Sylviadæ*, the order *Insessores*, having the following characters:—Beak rather broad and depressed at the base, becoming narrower towards the point, and slightly compressed; upper mandible deflected and notched. Nostrils basal, lateral, oval, pierced in a membrane partly hid by feathers and hairs projecting from the base of the beak. Wings rounded; the three exterior quills graduated; the first only half as long as the second, which is shorter than the third; the fourth, fifth, and sixth longer than the third; the fifth the longest in the wing. The tarsus longer than the middle toe; the lateral toes nearly equal to each other in length; the outer toe united at its base to the middle toe; the claw of the hind toe longer and stronger than the others.

E. rubecula, *Sylvia rubecula*, *Motacilla rubecula*, the Robin Red-Breast, Robin-Redstart, Robinet, Ruddock, is so generally distributed over the British Islands, and so universal a favourite, that all are sufficiently interested in the bird to make themselves acquainted with its habits. These may be observed in any garden, field, or wood, for there is scarcely a hedge without its Robin inhabitant, and if Robins appear to be more numerous in winter than in summer, it is partly owing to the state of vegetation at the former season, which leaves them more exposed to observation, and partly because they resort to the habitations of men for food, when other means of supply fail. The song of the Robin is sweet and plaintive, but not very powerful. Mr. White of Selborne, says, "The robin sings all through the year. The reason that he is called an autumn songster is, because in the spring and summer his voice is lost in the general chorus, while in the autumn it becomes distinguishable."

The Robin is one of the latest birds to retire to rest, and the earliest to be seen moving in the morning, requiring apparently but little sleep.

This bird is very easily tamed, soon becomes familiar with those who feed it, and constantly builds its nest in places frequented by man.

Mr. Blackwall relates that a pair of Robins built their nest in a small saw-pit. Soon after the hen had begun to sit the sawing of timber was commenced at this pit, and though this noisy occupation was carried on every day close to the nest during the hatching of the eggs and rearing of the young birds, the old birds exhibited no signs of alarm or interruption. These birds exhibit great attachment to each other, and many instances have been related to prove that they pair for life. With all his interesting qualities the Robin is one of the most pugnacious of birds, and not only maintains his right against all intruders, but is said to kill those of his own family when they become troublesome to him. Robins breed early in the spring. The nest is composed of moss, dead leaves, and dried grass, lined with hair, and sometimes a few feathers; it is frequently placed on a bank sheltered by brushwood, or a short distance above the ground in a thick bush or lane hedge, sometimes in a hole of a wall partly covered with ivy. The eggs are from five to seven in number, white, spotted with pale reddish-brown; the length nine lines and a half, by seven lines and a half in breadth. The bird is found all over England, Ireland, and Wales, it is also an inhabitant of the most northern counties of Scotland. It also visits Denmark and Sweden in the breeding season; and so well does it bear cold weather, that among the summer visiters to the latter country, the Robin is one of the first to come and the last to go.

It is a constant resident throughout the year in all the temperate and warmer parts of Europe, abundant in Spain and Italy, Sicily, and Malta.

In the adult bird the beak and irides are black; upper part of the head, neck, back, upper tail-coverts, and tail-feathers, a yellowish olive-brown; quill-feathers rather darker, the outer edges olive-brown; greater wing-coverts tipped with buff, over the base of the beak, round the eye, the chin, the throat, and the upper part of the breast, reddish-orange, encircling this red is a narrow band of bluish-gray, which is broadest near the shoulders; lower part of the breast and belly white; sides, flanks, and under tail-coverts, pale brown; under surface of wing and tail-feathers dusky gray; legs, toes, and claws, purple brown. The whole length of the bird is 5¾ inches. The female is not quite so large as the male, and her colours are less bright. The young birds, after their first autumn moult, resemble adult females; but the red of the breast is tinged with orange, and the legs are dark brown. The Red-Breast is subject to variation in the colouring of the plumage. White and partly white varieties are not uncommon.

(Yarrell, *British Birds;* MacGillivray, *Manual of British Birds.*)

ERYTHRÆA, a pretty genus of annual Plants belonging to the natural order *Gentianaceæ*, and inhabiting dry sandy places in Great Britain and other parts of Europe, especially near the sea.

E. pulchella has an erect, much branched, acutely quadrangular stem; the leaves ovate, the uppermost oblong-lanceolate; flowers, all stalked, axillary, and terminal, the calyx rather shorter than the tube of the opening corolla, the lobes of the corolla elliptic oblong, obtuse. The inflorescence is forked, the lateral flowers distant from the floral leaves. It is found in sandy ground in England.

E. Centaurium, Common, or Lesser Centaury, has an erect branched stem, elliptic oblong leaves, the upper ones acute; flowers nearly sessile, corymbosely panicled; the calyx not half as long as the tube of the opening corolla; the lobes of the corolla oval. It is found in dry pastures in Great Britain. It flowers in August, at which time it is to be collected. The whole plant is taken up. It has a square stem, with opposite entire 3-nerved leaves. It is devoid of odour; the taste is strongly bitter, but not unpleasant: 100 parts of the fresh herb dry into 47; 10 lbs. of the dry herb yield by a single decoction 3 lbs. of extract. It contains a principle called Centaurin, which at present is known only as a dark brown extract-like mass; but which, united with hydrochloric acid, furnishes an excellent febrifuge medicine. As a bitter, it suits irritable systems better than any article of that class of medicines, and is therefore to be preferred. In other respects it has the general properties of bitter tonics.

E. latifolia and *E. littoralis* are both British species of this genus, found near the sea-shore. All the species are extremely bitter, and are collected by the country people under the name of Centaury as a substitute for Gentian in domestic medicine.

ERYTHRI'NA, a genus of Tropical Trees and Tuberous Herbs belonging to the natural order *Leguminosæ*. The species have ternate leaves and clusters of very large long flowers, which are usually of the brightest-red; whence the species have gained the name of Coral-Trees. Frequently their stem is defended by stiff prickles. They occur in the warmer parts of the Old and New World. An Indian species, *E. monosperma*, is said to yield gum-lac. De Candolle mentions 32 species; of which *E. Crista Galli* is commonly cultivated in green-houses for the sake of its splendid blossoms.

ERYTHRINUS, a genus of Tropical Fishes belonging to the family *Clupeidæ*.

ERYTHRO'NIUM, a genus of Plants belonging to the natural order *Liliaceæ*. *E. Dens Canis*, a pretty little bulbous plant (whose name, Englished Dog's-Tooth Violet, is derived from the form of its long slender white bulbs), is a native of woody subalpine places among bushes and stones, in Croatia, Idria, and about Laybach; it also occurs in Switzerland, but more seldom, and is also met with in the north of Italy. It is not mentioned in the Floras of the south of Europe. Two or three varieties are known in gardens as gay hardy flowers appearing early in the spring; one with purple, a second with white flowers, and a third, elevated by some into a species, with a somewhat stronger habit of growth.

E. Americanum is said to be emetic.

ERYTHROPHYS. [Cuculidæ.]

ERYTHROXY'LEÆ, a group of Exogenous Plants, considered by some as a distinct natural order; by others as a subordinate division of *Malpighiaceæ*. They have alternate stipulate leaves and small pallid flowers. The calyx is 5-lobed; the petals are 5, with a remarkable appendage at their base, which afford one of the marks of distinction between *Erythroxyleæ* and *Malpighiaceæ;* the stamens are 10, slightly monadelphous. The ovary is superior, 3-celled, with 3 styles, and solitary pendulous ovules. The fruit is drupaceous. Some of the species of *Erythroxylon*, the only genus, have a bright-red wood, occasionally used for dyeing; but the most extraordinary species is the *Erythroxylon Coca*, an account of the inebriating effects of which is given under Coca.

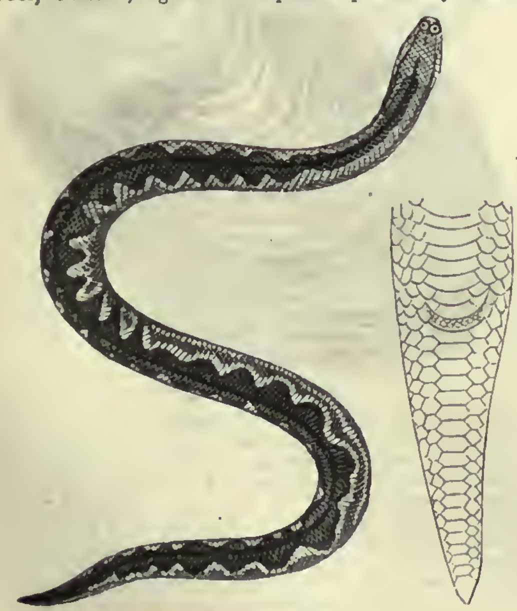
1 4 5 2 3

Erythroxylon laurifolium.

1, a calyx with the monadelphous stamens; 2, a petal with its appendage; 3, the ovary, with the three styles; 4, a half-ripe fruit; 5, a transverse section of the same, showing that one only of the seeds comes to perfection, the two others being abortive.

ERYTHROXYLON. [Coca.]

ERYX, or ERIX, a genus of Serpents separated by Daudin from *Boa*, and differing from it in having a very short obtuse tail, and the ventral plates narrower. The head of *Eryx* is short, and the characters geuerally would approximate the form to *Tortrix*, did not the conformatiou of the jaws place it at a distauce from the last-named genus. The head besides is covered with small scales only. *Eryx* has no hooks at the vent.



Eryx Bengalensis.

ESCALLONIA'CEÆ, *Escalloniads*, a small natural order of Exogenous Plants, related to the genus *Ribes*, in the opinion of some, but to that of *Saxifraga*, according to other botanists. It consists of shrubs with evergreen leaves, which ofteu emit a powerful odour like that of melilot; their flowers are red or white, and often are quasi-monopetalous, in consequence of the approximation of their petals. They have au inferior many-sceded ovary, with two large placentæ in the axis, a definite number of epigynous stamens, a single style, and minute chaffy seeds with a very small embryo lying in oily albumen. All the species inhabit South America, on the mountains, especially in alpine regions. *Escallonia rubra*, *E. Montevidensis*, *E. illinita*, and others, have now become common in warm sheltered gardens in this country.

2 1

Escallonia serrata.

1, a flower magnified, without the petals; 2, a transverse section of the ovary.

ESCHARA. [Polyzoa.]

ESCHSCHO'LTZIA, a genus of beautiful yellow-flowered Plants belonging to the natural order *Papaveraceæ*, inhabiting California and the north-western coast of North America, and now become extremely common in the gardens of Great Britain. They are known by the base of their calyx remaining at the base of the siliquose fruit in the form of a firm fleshy rim, by their calyx being thrown off like a calyptra when the petals unfold, and by the stamens being inserted iuto the edge of the permanent rim of the calyx. Otherwise they are very near our sea-shore *Glaucium*. Two certain species only, *E. Californica* and *E. crocea*, have yet becu introduced; a third, *E. compacta*, is figured in the 'Botanical Register,' but it is probably a mule between the first two. It has been recently proposed to alter this name, which has a barbarous sound and appearance, for the more harmonious one of *Chryseis*, and it is hardly to be doubted that the latter will be adopted. (*Botanical Register*, t. 1948.)

ESOX, a genus of Fishes established by Linnæus for the reception of the Pike and some allied forms. It is now subdivided, and the resulting genera, with the Flying-Fish (*Exocetus*), constitute the family *Esocidæ*. The genus *Esox*, as at present received, has for its type the *Esox Lucius* of Linnæus, tho Common Pike. The generic character is founded on the form and armature of the organs of mastication. The jaws, palatine bones, and vomer are furnished with teeth of various sizes. The head is oblong, obtuse, depressed, and large in proportion to the body. The dorsal fin is placed far back and over the anal. Both these fins are entire, which is also the caso in the genus *Belone*, of which the Gar-Fish is the type (*Esox Belone* of Liunæus); but in that fish the head and jaws are greatly produced, the latter being linear and pointed. *Scomberesox* (the Saury) is a third genus of this family, haviug a head resembling that of *Belone;* but the anal and dorsal fins are divided posteriorly into finlets resembling those of a mackerel. *Hemiramphus* is a curious genus of Sea-Pikes, in which the upper jaw is extremely short, while the lower one resembles that of the gar-fish. *Exocetus*, the Flying-Fish, was distinguished from *Esox* by Linnæus. [Exocetus.] It has tho head comparatively short, the dorsal and anal fins placed much farther forward, and the pectoral fins so large as to serve the purpose of wings, or rather of parachutes, which sustain the fish in the air for some time after it has sprung out of the water.

E. Lucius, the True, or Fresh-Water Pike, Pickerell, True Jack, or Gedd, is a well-known fish, esteemed for its food, and remarkable for its voracious and destructive habits. It is the longest-lived and largest of fresh-water fishes, and many wonderful stories are narrated of it. Gesner gives an accouut of one, the skeleton of which was preserved at Mannheim, which weighed 350 lbs., and was probably between 200 and 300 years old. Pennant informs us of one 90 years old; and pikes from 50 to 70 lbs. weight have been taken in Scotland and Ireland. It grows with great rapidity, attaining a length of from 8 to 10 inches in its first year. The Mannheim pike was said to have been 19 feet in length, and in our own country they have been taken 9 feet long. The Pike eats up everything eatable which comes in its way. Being strong, swift, and courageous, it masters all other fishes in its locality. It will also attack birds and small quadrupeds, if within reach, and has been known to quarrel with the otter for its prey, and to assault man himself. Pikes are found in Europe, Asia, and North America. In the United States there are several species of *Esox*.

The habits of the Sea-Pike, or Gar-Fish (*Belone vulgaris*), and the Saury (*Scomberesox*) are not so well known. They are gregarious, and swim near the surface of the water, leaping out of it with great agility, and playing round bodies which float on the surface of the sea. The peculiar formation of the heads of these fishes renders the nature of the food a subject of curiosity among naturalists; but the question is not yet settled. On the southern coasts of England and Ireland they are common. The bones of the *Belone* are green: the flesh is firm and white, and has much the flavour of that of the mackerel. [BELONE; SCOMBERESOX.]

ESSONITE. [GARNET.]

ESTRILDA, a genus of Birds belonging to the *Passerinæ*. The species are known by the name of Waxbills. They inhabit the Indian Archipelago and Australia.

ETÆ'RIO is a kind of fruit consisting of achenia, or small closed-up seed-like seed-vessels, placed upon a succulent receptacle. The strawberry and the raspberry are of this nature, and are very incorrectly called Berries, in the botanical sense of the word berry. [FRUIT.]

ETHE'RIA, Lamarck's name for a genus of Conchiferous *Mollusca*, placed by many authors among the *Chamidæ*, but separated by Deshayes and others. [CHAMACEA.]

Animal closely approximating to that of *Unio*. Lobes of the mantle disunited throughout their length, and consequently without either tubes or syphons. Below the foot the branchiæ of the right side unite themselves to those of the left side in the medial line, and leave below them a rather large canal, in which the vent terminates. The branchial leaflets are unequal, strongly striated and festooned on their free border. The mouth is rather large, and furnished on each side with a pair of palps like those of the *Uniones*. Finally (and, as Deshayes observes, it is a great singularity in an animal that lives attached to foreign substances), it is provided with a very large foot, which may be compared in regard of its form and position with that of *Unio*.

Shell adherent, thick, nacreous, very irregular, inequivalve, inequilateral; umbones short, thick, indistinct; hinge toothles, irregular, undulated, callous; ligament longitudinal, tortuous, external, penetrating pointedly into the interior of the shell; muscular impressions oval, irregular, one superior and posterior, the other inferior and anterior; pallial impression narrow and small.

M. Deshayes observes that on examining the shells of this genus, in which the ligament is not ruptured, it appears that the ligament is not entirely internal or subinternal, like that of the oysters, but that it has completely the structure of external ligaments. It is when the shells are young that the structure of the ligament is most easily recognised. There are two muscular impressions, always very distinct in old individuals; but in the young ones it sometimes happens that one only can be distinguished, and it was upon an individual in this state of growth that M. de Férussac established his genus *Mulleria*, which, in the opinion of M. Deshayes, cannot be retained. With regard to the crenulations on the hinge adverted to by M. de Férussac, M. Deshayes states that he had seen on the very individual which M. de Férussac had in his hands some small fractures resulting, as it appeared to M. Deshayes, from this cause, namely, that the shell having been taken with the animal, the valves had been separated by attacking the ligament with a sharp instrument.

Lamarck considered the genus *Etheria* to be marine, and accounted for its having escaped the notice of zoologists because it was attached to rocks at great depths in the sea. Mr. G. B. Sowerby, after noticing the locality attributed to the genus by Lamarck, remarks that two circumstances observable in the *Etheriæ* (*E. semilunata*), figured in his plate, would have induced him to suspect that this was a fresh-water shell, or at least an inhabitant of æstuaries at the mouths of rivers; 1st, its having an epidermis, which remains only in those parts least exposed to the action of the water, the greater part especially of the upper valve being eroded in a very irregular manner; and 2ndly, its being partly covered with the remains of those ovate vesicular bodies, supposed to be the eggs of some molluscous animals so frequently seen on fresh-water shells. M. Cailliaud was the first to make known the fact that the genus is an inhabitant of the fresh-waters, and M. de Férussac ('Mémoires de la Société d'Histoire Naturelle', vol. i.) published a paper on the subject from M. Cailliaud's materials, in which the former also made a revision of the species. M. Deshayes, in his treatise on the genus ('Encyclopédie Méthodique'), states that individuals of the same species adhere by the one or the other valve indifferently, which, he remarks, is not the case with the Oysters or the *Chamæ*. That *Etheria* may be attached indifferently by either valve there is no reason to doubt after the assertion of M. Deshayes; but Mr. Broderip ('Zool. Trans.,' vol. i.) observes that the same species of *Chama* is sometimes attached by the right, sometimes by the left valve. [CHAMACEA.] M. Rang, during a voyage to Senegal, made some interesting observations on *Etheriæ* which live two hundred leagues from the mouth of the river in the Senegal, and, together with M. Cailliaud, who received the animal from the Nile, published a memoir ('Mémoires du Muséum d'Histoire Naturelle') full of interest, in which the animal was described for the first time. The rivers of Africa and Madagascar appear to have afforded the specimens (which are still rather scarce in cabinets) hitherto collected. M. de Férussac, in his memoirs, gives the following information from M. Cailliaud.—"We first meet with *Etheriæ*," says that zealous traveller, "after passing the first cataract; and they do not appear to exist below; they become very abundant in the province of Rebata, beyond the peninsula of Meröe. The inhabitants collect them on the banks of the river to ornament their tombs with them, and they say that they come from the more elevated parts of the Nile, from Saïda, where they are eaten." M. Cailliaud found them as far as Fazoql, the most distant country into which he penetrated from the Blue River. In Sennaar the inhabitants informed M. Cailliaud, that during the summer season, when the river was low, they took them with the animal; but notwithstanding all his endeavours M. Cailliaud could not obtain any living specimens, the river being then always too high. They are said to be very common in the Jaboussi, a river which runs into the Blue Nile, and in all appearance the numerous confluent streams of this great arm of the Nile produce them also. The number found upon the tombs throughout Ethiopia is so great, that it is astonishing that Bruce and Burckhardt should not have mentioned them. ('Zool. Journ.,' vol. i.)

Etheria semilunata.

Lamarck recorded four species of *Etheria*, which he divided into two sections, each containing two species. The first of these consists of species which have an oblong callosity in the base of the shell; the second, of those which have no encrusted callosity at the base of the shell. These four species M. de Férussac (with justice, in the opinion of M. Deshayes) reduces to two; so that the sections, as left by Lamarck, would each, in that case, consist but of one species, namely, the first of *E. elliptica*, and the second of *E. semilunata*. M. Deshayes remarks that Lamarck saw but a very small number of individuals, and not being aware of their extreme variation, established species from the form of the shell; and it is certain, he adds, that if we were to follow the same indication at the present day, we might establish a species for each individual. He notices M. Rang's judicious observation, that in the same species there are individuals armed with spines, and others devoid of those appendages, and that the shades of this character are so gradual that it is impossible to regard it as of the smallest importance. In following out this principle, M. Rang considers *E. tubifera* of Sowerby and *E. Cailliaudi* of Férussac as identical, and *E. Corteroni* of Michelin to be the same as *E. plumbea* of Férussac. It is to the last-named species that M. Deshayes thinks that the genus *Mulleria* should be referred.

Etheria, or, as some write it, *Ætheria*, has not yet been discovered in a fossil state. It should be remembered that Rafinesque uses the term for a genus of Macrourous Crustaceans belonging to the *Palæmonidæ*.

ETHU'SA, a genus of Brachyurous Crustaceans (tribe Dorippians), established by M. Roux at the expense of the genus *Dorippe* of Fabricius and other naturalists.

M. Milne-Edwards observes that this genus is easily distinguished from *Dorippe* by the conformation of the apertures leading to the respiratory cavity, which here present the normal disposition.

Carapace nearly quadrilateral, but rather longer than it is wide, and very much flattened; front large, orbits directed forwards, very incomplete; eyes carried on a rather long and very projecting peduncle; they pass beyond the external angle of the carapace, and are not retractile. The internal antennæ are bent back (se reploient) forwards, in fossettes placed under the front; the external antennæ are rather long; their first joint is cylindrical, and separates the antennary fossette from the orbit; the third is longer than the second. The buccal frame (cadre buccal) is triangular, and reaches to the border of the antennary fossettes; the jaw-feet are much shorter, and leave naked the anterior portion of the jaw-feet of the first pair, which complete forwards the canal of the respiratory cavity; the third joint of the external jaw-feet is shorter than the second, nearly oval, sharply truncated forwards, and articulated with the following joint by the middle of its anterior border. The Pterygostomian regions are nearly quadrilateral, and are not prolonged between the base of the external jaw-foot and of the first thoracic foot, as in the Dorippes. The sternal plastron is oval. The anterior feet are short and slender in both sexes; in bending they form a double elbow, as in *Homola*. The succeeding feet are long, especially those of the third pair; those of the fourth pair are, on the contrary, extremely short, and inserted below the preceding; finally, the posterior feet, longer than the fourth pair, are inserted above and in front of them, and, like them, are terminated by a very short, hooked, and subcheliform tarsus. The abdomen in the male has seven distinct joints; in the female it has only five: the first two rings are directed backwards and on the same plane with the carapace.

Ex. *E. Mascarone* (Roux), *Cancer Mascarone* (Herbst).

Ethusa Mascarone.

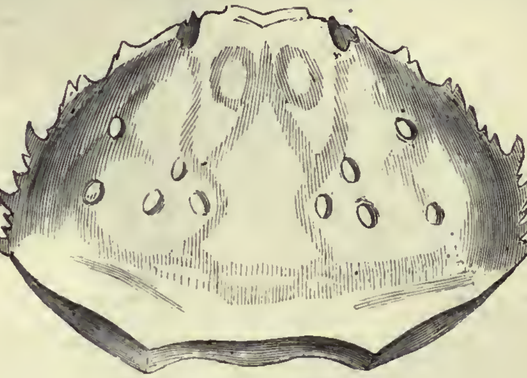
ETI'SUS, a genus of Brachyurous Crustaceans (Cancerians of M. Milne-Edwards).

Carapace less oval and wide than in most of the Arched Cancerians (Cancériens Arqués). The front is large, lamellar, and divided on the mesial line by a fissure, as in the *Xanthi*; but the two large and truncated lobes which form the principal part are separated by a deep notch of the anterior and superior angle of the orbit, which is rounded and projecting; the latero-anterior borders of the carapace are strongly toothed. The internal antennæ are bent back nearly longitudinally, and the basilary joint of the external antennæ, which is very large, unites with the front, and presents on the external side a prolongation which fills the hiatus of the internal orbital angle; finally, the moveable stem of these antennæ, which is very short, is inserted completely out of this hiatus, below the front and nearer to the antennary fossette than to the orbit. The external jaw-feet present nothing remarkable; the feet of the first pair are rather large, and the chelæ, which are much enlarged and rounded at the end, are deeply hollowed into a spoon-shape.

M. Milne-Edwards, who gives the above description, divides this small group, which he considers as forming the passage between the *Xanthi* and *Platycarcini*, into the two following sections:—

α. Carapace scarcely knobbed above.

Ex. *E. dentatus.* Length three or four inches; colour reddish. Locality, the Indian Archipelago.



Etisus dentatus.

β. Carapace covered with knobs, separated by deep furrows.

Ex. *E. anaglyptus.* Length about an inch and a half; colour whitish (?). Locality, Australia.

EUASTRUM. [DESMIDEÆ.]

EUCALY'PTUS, a genus of Australian Plants, consisting of lofty trees, with a volatile aromatic oily secretion in their leaves, and a large quantity of astringent resinous matter in their bark. They belong to the alternate-leaved division of *Myrtaceæ*, and are generically known among these plants by their corolla being absent, and the limb of their calyx consolidated into a hemispherical or conical cap, which is thrown off when the stamens expand.

This genus occurs in the Malayan Archipelago, but is chiefly Australian, and, together with the leafless Acacias, gives a most remarkable character to the scenery. The species exist in great profusion, and form the largest trees in the forests of that part of the world. A modern writer upon the plants of Van Diemen's Land says that *Eucalyptus* seems as if it had taken undisturbed possession of those Australian regions, clothing as it does with a stupendous mantle the surface both of Van Diemen's Land and Australia; while the intermixture of other plants which this lordly tribe permits is, compared with its own great extent, but small and partial. Wherever you go, one species or other is constantly before you.

No trees in the world so constantly or rapidly arrive at gigantic dimensions: they often become hollow, and are then used by the traveller as roomy places of shelter at night. Frazer found a hollow *Eucalyptus* at Moreton Bay, used by the natives as a cemetery. Even at Swan River, where, according to the report of Frazer, the species are stunted, they also attain a huge size. *E. calophylla* attains a height of 150 feet, and a girth of from 25 to 50 feet is not an uncommon dimension of these trees. Their timber is represented as highly useful for domestic and other purposes; being so soft at first as to render the felling, splitting, and sawing up of the tree, when green, a very easy process, and when thoroughly dry becoming as hard as oak.

E. resinifera has leaves with very minute and numerous little dots, ovate-lanceolate, with long tapering points narrowed to the base, with a vein next the margin. The flowers are umbellate, on a compressed peduncle rather longer than the petiole. The lid is conical, taper, leathery, twice as long as the capsule. The bark is so extremely astringent as to yield a gum not inferior to Kino, and sold as such. The bark of this and other species is so hard as to cause them to be called Iron-Bark Trees by the colonists. The Blue Gum-Tree and some others have the singular property of throwing it off in white or gray longitudinal strips or ribands, which, hanging down from the branches, have a singular effect in the woods.

In many species the leaves are so variable in their form and other characters at different ages of the tree, or in different situations, that it is a matter of difficulty to know how they are to be botanically distinguished from each other; and in fact the subject of the distinction of species has hardly yet been taken up, no botanist feeling competent to undertake the task without some personal acquaintance with the plants in a native state. The leaves, instead of presenting one of their surfaces to the sky and the other to the earth, as is the case with the trees of Europe, are often arranged with their faces vertical, so that each side is equally exposed to the light.

E. robusta contains large cavities in its stem between the annual concentric circles of wood, filled with a most beautiful red or rich vermilion-coloured gum, which flows out as soon as the saw affords an opening.

E. mannifera exudes a saccharine mucous substance resembling manna in its action and appearance, but less nauseous. It is not produced by insects, and only appears in the dry season. Other species yield a similar secretion at Moreton Bay and in Van Diemen's Land. Mr. Backhouse says it coagulates, and drops from the leaves in particles often as large as an almond.

E. Gunnii, when wounded, furnishes the inhabitants of Van Diemen's Land with a copious supply of a cool, refreshing, slightly aperient liquid, which ferments and acquires the properties of beer.

Upon the whole this genus must be considered the most important that Australia produces. As it occurs so far to the south as Van Diemen's Land it is almost certain that it might be naturalised in Devonshire, Cornwall, and in the west of Ireland. Even in the neighbourhood of London certain kinds bear moderate winters without shelter, especially *E. pulverulenta*.

It is very much to be regretted that some settled nomenclature is not introduced, for the colonists apply the same names to different species in different parts of the country; this renders it difficult to tell of what they are speaking. As far as we can collect the evidence, it appears that the following are, or should be the botanical species to which the colonial names belong:—

Blue Gum of Port Jackson	*E. piperita.*
Blue Gum of Hobart Town	*E. globulus.*
Stringy Bark	*E. robusta.*
Iron-Bark	*E. resinifera.*
Kino-Gum	*E. resinifera.*
Peppermint-Tree	*E. piperita.*
Weeping Gum of Van Diemen's Land	Uncertain.
Mountain Blue Gum of Van Diemen's Land	Uncertain.
Black Gum of Van Diemen's Land	Uncertain.
Black-Budded Gum of Van Diemen's Land	Uncertain.
Cider-Tree of Van Diemen's Land	Uncertain.
Manna-Gum	Uncertain.
Manna of Moreton Bay	*E. manna*, Cunn.
Blood-Wood of Port Jackson	*E. corymbosa.*
White Gum of Van Diemen's Land	*E. resinifera.*
White Gum of Moreton Bay	*E. subulata*, Cunn.
White Gum of the S.W. Interior	*E. Leucadendron*, Cunn.

EUCHARIS. [Acalephæ.]

EUCHROITE, a Mineral consisting of Arseniate of Copper. It occurs crystallised. Its primary form is a right rhombic prism. Cleavage indistinct. Colour bright emerald-green. Streak pale apple-green. The fracture is uneven. Hardness 3·5 to 4·0. Lustre vitreous. Refraction double. It is transparent, translucent. Specific gravity 3·38 to 3·41. Found at Libethen in Hungary. The analysis, by Turner, gives—

Arsenic Acid	33·02
Oxide of Copper	47·85
Water	18·80
	99·67

EUCHYSIDERITE (*Achmite*), a Mineral which occurs crystallised. Primary form an oblique rhombic prism, of same cleavage and measurements as Pyroxene. Colour brownish-black. Lustre vitreous. Nearly opaque. Specific gravity 3·34. Hardness 6·0 to 6·5. Streak yellowish-gray. Fracture imperfect, conchoidal. It occurs in Norway. Before the blow-pipe alone readily fuses into a brilliant black globule; with borax forms a coloured glass.

According to Berzelius it consists of—

Silica	55·25
Oxide of Iron	31·25
Soda	10·40
Lime	0·72
Oxide of Manganese	1·08
	98·70

EUCLASE, a crystallised Mineral, the primary form of which is an oblique rhombic prism. It is either colourless and nearly transparent, blue, or pale bluish-green. It refracts doubly. Lustre vitreous. Hardness 7·5. Specific gravity 3·098. Cleavage very distinct, parallel to the oblique diagonal, but indistinct parallel to the terminal plane and horizontal diagonal. The fracture is uneven, and the streak white. It was first found in Peru, but has since been met with in detached crystals in alluvial ground in Brazil.

According to Berzelius it consists of—

Glucina	21·78
Silica	43·32
Alumina	30·56
Oxide of Iron	2·22
Oxide of Tin	0·70
	98·58

EUCNEMIS. [Elateridæ.]

EUCŒLIUM. [Synoicum.]

EUDEA. [Spongiadæ.]

EUDENDRIUM, a genus of Zoophytes belonging to the family *Tubularidæ*. There are two British species, *E. rameum* and *E. ramosum*. [Tubularidæ.]

EUDIALYTE, a Mineral which occurs both crystallised and massive. The crystals are generally small. The primary form is a rhomboid; the colour is red or brownish-red, and the crystals are faintly translucent or opaque. Lustre vitreous, sometimes dull. Specific gravity 2·9. Hardness 5·0 to 5·5. Streak white. Fracture uneven. The massive varieties are imbedded and amorphous. It occurs at Kandarluarsuk, in West Greenland. Before the blow-pipe it fuses into a leek-green scoria.

According to Stromeyer it consists of—

Silica	52·47
Zirconia	10·89
Lime	10·14
Soda	13·92
Oxide of Iron	6·85
Oxide of Manganese	2·57
Muriatic Acid	1·03
Water	1·80
	99·67

EUDORA. [Acalephæ.]

EUDYNAMIS. [Cuculidæ.]

EUDYTES. [Colymbidæ.]

EUGENESITE. [Palladium.]

EUGE'NIA, a genus of Dicotyledonous Polypetalous Plants of the natural order *Myrtaceæ*, so named in honour of Prince Eugene of Savoy, who was a patron of botany and horticulture. The genus, as at present constituted, contains nearly 200 species, though numbers have been removed to the genera *Nelitris*, *Jossinia*, *Myrcia*, *Sizygium*, *Caryophyllus*, and *Jambosa*, in which are now contained the Clove-Tree, the Rose-Apple, and Jamoon of India, formerly included in *Eugenia*. This genus is confined to the hot and tropical parts of the world, as Brazil, the West India Islands, and Sierra Leone, and extends from the Moluccas and Ceylon to Silhet and the foot of the Himalayas in Asia.

Eugenia is characterised by having the tube of the calyx of a roundish form, and the limb divided into four parts; the petals equal in number, and inserted on the calyx. The stamens are numerous. The ovary 2-3-celled, with several ovules in each. Seeds 1 or 2, roundish, and large, with the cotyledons and radicle united into one mass. In habit and inflorescence the species resemble many myrtles. Like the family to which they belong, some of the species of *Eugenia* secrete a warm volatile oil in their herbaceous parts; abound in tannin; yield good wood; and a few have fruit which is edible, though not very agreeable, from being impregnated with the aroma of the oil.

Eugenia Pimenta, the Allspice Pimento, or Bayberry-Tree, is a native of South America and the West India Islands, especially Jamaica, and from being cultivated there is often called Jamaica Pepper. The tree is very handsome, often 30 feet high, and much resembles the Clove-Tree in the form and appearance of its leaves, as well as in habit. The trunk is smooth, and much branched towards the top. The older branches are round, the younger compressed, and the twigs as well as the flower-stalks pubescent; the leaves are petiolate, oblong or oval, smooth, and marked with pellucid dots, forming a dense evergreen foliage; the flower-stalks are both axillary and terminal, and are divided into 3-forked panicles; the flowers are small, without show, and conformable in structure to the character of the genus. The berry is spherical and crowned with the persistent calyx; when ripe, smooth, shining, and of a dark purple colour; usually 1-celled, occasionally 2-celled, containing large roundish seeds.

The *Pimenta* is cultivated with great care in Jamaica, and abounds especially on the hills on the north side of the island. The trees are formed into regular walks, and begin to bear when three years old, but are not in perfection until they have been planted seven years. They thrive best in rocky lands, or a rich soil having a gravelly bottom. Mr. Bryan Edwards says that a single tree has been known to yield 150 lbs. of the raw fruit, or 100 lbs. of the dried spice; but the crop is uncertain, and plenteous perhaps only once in five years. The tree has been introduced into and flourishes in the southern parts of India.

The berries, being the valuable part of the tree, require care in gathering as well as drying; the processes for which are described by Browne in his 'History of Jamaica,' p. 248. They must be picked when they have arrived at full growth, but before they begin to ripen; they are dried in the sun, on raised boarded floors, and frequently turned during the first and second day; they are then put into sheets, often winnowed, and exposed to the sun until sufficiently dried, which is known by the colour and the rattling of the seeds in the berries. Browne says, "Such of the berries as come to full maturity do, like many other seeds, lose that aromatic warmth for which they are esteemed, and acquire a taste perfectly like that of Juniper Berries, which renders them a very agreeable food for the birds, the most industrious planters of these trees."

The leaves and bark participate in the warm aromatic properties for which the berries are celebrated, and which have received their name of Allspice from their fragrant odour being thought to resemble that of a mixture of cinnamon, cloves, and nutmeg. Their taste being warm and aromatic makes them useful as a spice in cookery, and a stimulant in medicine.

Eugenia Michelii is a Brazilian species, cultivated in Martinique, whence it is called Cerisier de Cayenne, as it yields a small edible fruit.

E. acris, Wild Clove, is a native of the West India Islands. It is arborescent and glabrous; the young branches acutely 4-angled, the leaves elliptic oval, obtuse, more or less convex coriaceous, very glabrous, the upper side reticulated with elevated veins, finely pellucid, dotted; the peduncles are compressed, axillary, and terminal, trichotomous, corymbose, rather longer than the leaves. The calyx-limb 5-partite; segments roundish, the style filiform, acute, the berry globose, 1-4 seeded. This species is sometimes confounded with the former species, in whose qualities it participates. *E. cauliflora*, the Jabuticaba or Jaboticaburas, is one of the most agreeable fruits in Brazil, and the taste will be improved by future culture. Very good wine, syrup, &c., are made of it. *E. dysenteria*, *E. Michellii*, and *E. Brasiliensis*, called respectively Aracea, Pitanga, Grumixameira, Cambuy, Uvaltra, Pitangueira, &c., are all spoken of by Martius as excellent dessert fruits. The Rose-Apples of the East are produced by species of this genus.

EUGENIACRINITES (Goldfuss), a genus of Fossil *Crinoidea*. [ENCRINITES.]

EU'GNATHUS, a genus of Fossil Pacoid Fishes, from the Lias, of which there are thirteen British species. (Agassiz.)

EUKAIRITE, a Mineral consisting of seleniuret of silver and copper, discovered by Berzelius. It occurs in thin films of a shining lead colour; opaque; its texture is granular. It yields readily to the knife, and acquires a silvery lustre. It occurs in a copper mine in Sweden. Before the blow-pipe it exhales a strong smell of selenium; and with charcoal fuses into a brittle metallic globule. It consists of—

Selenium	26
Silver	38·93
Copper	23·05
Earthy Matter	8·90
Carbonic Acid and loss	3·12
	100

EULABES. [CORACIAS.]

EULA'LIA, a genus established by Savigny, and placed by Cuvier among his Dorsibranchiate Annelides.

EU'LIMA, a genus of marine Gasteropodous *Mollusca*, established by M. Risso.

Shell turreted, acuminated, polished, with many whorls; aperture ovate, acuminated posteriorly; external lip thickened, generally forming numerous obsolete varices. Operculum horny, thin, its nucleus anterior.

Mr. G. B. Sowerby, who gives this generic character, says ('Zool. Proc.,' 1834) that this genus of marine shells appears to be most nearly related to *Pyramidella* and *Rissoa*. A species, he adds, which has been long known has had the appellation of *Turbo politus* among British Linnean writers; and a fossil species has been placed by Lamarck among the *Bulini*, under the specific name of *B. terebellatus*. Mr. Sowerby separates the genus into the two divisions below stated, which are characterised by the two species above mentioned; one has a solid columella, and the other is deeply umbilicated. All the species, he observes, are remarkable for a brilliant polish externally, and the shells are frequently slightly and somewhat irregularly twisted, apparently in consequence of the very obsolete varices following each other in an irregular line, principally on one side, from the apex towards the aperture. He describes sixteen species, chiefly from Mr. Cuming's collection.

The geographical distribution of this genus is wide; they have been principally found, as yet, in warm seas (South and Central America and Pacific Ocean, Australia). Messrs. Forbes and Hanley record four British species *E. polita*, *E. distorta*, *E. subulata*, and *E. trilineata*.

The species found by Mr. Cuming were dredged or otherwise collected in sandy mud, coarse sand, and coral sand, on mother-of-pearl shells, or on the reefs; at depths (not including the reefs) ranging from six to thirteen fathoms.

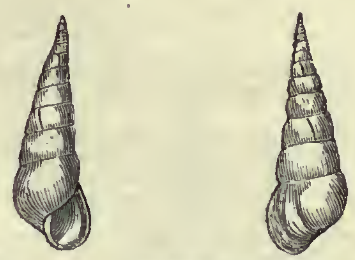
α. Perforated *Eulimæ*.

E. splendidula. Shell acuminate-pyramidal, brownish, articulated with white and chestnut near the sutures; umbilicus large; aperture angulated anteriorly. Length 1·45, breadth 0·6 inches. Locality, St. Elena, South America. Mr. Cuming dredged a single specimen in sandy mud at from six to eight fathoms depth.

Eulima splendidula.

β. Imperforated *Eulimæ*.

E. major. Shell acuminate-pyramidal, opaque, milk-white; external lip subarcuated. Length 1·6 inches, breadth 0·4. Locality, the Island of Tahiti. The largest specimen was found in coral sand on the reefs.



Eulima major.

Fossil species are found in the Calcaire Grossier near Paris.

EULIMELLA, a genus of *Mollusca* belonging to the family *Pyramellida*, founded by E. Forbes, to receive forms that had been previously referred to *Eulima* and *Odostomia*. The shell is elongated, and consists of many whorls, solid, smooth, and polished; the apex of the spine has a persistent embryonic sinistral shell; the aperture subquadrate; peristome imcomplete; columella not plicated, straight or nearly so; operculum corneous, pyrifom. There are four British species. *E. scillæ* (*Eulima crassula*, Jeffreys), *E. acicula* (*Melania acicula*, Philippi), *E. affinis* (*Eulima affinis*, Philippi), *E. clavula* (*Turbinella clavula*, Loven).

EULO'PHIA (from εὖ, and λόφος, a crest), a genus of Plants belonging to the natural order *Orchidaceæ*. It has an open spreading perianth; the sepals and petals ascending, nearly equal, either quite distinct, or united with the more or less lengthened base of the column; the lip horned or shortly spurred, sessile, with the veins crested, bearded, or quite smooth, usually 3-lobed, sometimes undivided; the column half-terete, edged; the anther terminal, opercular; the pollen masses 2, waxy, 2-lobed, or hollowed out at the back, with a short linear caudicula, and a transverse gland. The species are terrestrial plants, with pseudo-bulbous rhizomata, long membranous plaited leaves, and radical many-flowered scapes. Most of the rhizomata and roots of the species of the family *Orchidaceæ* yield starch in a peculiar form. The roots of the species of *Orchis* are used in Europe under the name of Salep as an article of diet, and the same use is made of the rhizomata of a species of *Eulophia* in the East Indies. Although specimens of the plant were brought from Cashmere by Dr. Royle, they were not in a state of preservation to be identified. (Lindley, *Flora Medica*.)

EULYMENE. [ACALEPHÆ.]

EUME'DONUS, a genus of Brachyurous Crustaceans, the first of the Parthenopians of M. Milne-Edwards, and which in his opinion establish in some sort the passage between the *Stenorhynchi*, *Achæus*, on the one side, and *Eurynome*, *Lambrus*, and *Parthenope* on the other. The form of the carapace is nearly pentagonal as in the latter, but it is at the same time thrown forwards, as it were, and scarcely overpasses the line of the feet of the hind pair of limbs—a disposition which recalls the construction of the former. The body is depressed; the rostrum, which is very large and projecting, is only divided towards its extremity; the eyes are very short, and their peduncle entirely fills the orbits, which are circular—a character which again approximates these crustaceans to the *Stenorhynchi*; the internal antennæ are folded back very obliquely outwards, and the external antennæ are but little developed. The epistome is shorter than in the majority of the *Oxyrhynchi*. The external jaw-feet present nothing remarkable. In the male the thoracic feet of the first pair are large, and much longer than the rest; all these are a little compressed, and their third joint is surmounted by a crest, which is not distinctly perceptible on the other joints; the feet of the second pair are rather shorter than those of the third and fifth pair, which are nearly as long as the fourth. The abdomen of the male is composed of seven articulations.

E. niger. This small species, the only one known, is of a bronzed black colour, and inhabits the coasts of China.

EUMORPHUS, a genus of Coleopterous Insects belonging to the section *Trimeri* of Latreille, and being the typical genus of the family *Fungicolæ*. These insects are characterised by having the antennæ longer than the head and thorax, the body oval, and the thorax irregularly square; the maxillary palpi filiform, or slightly thickened at the end, but not terminated by a large process as in some genera: the last joint of the tarsus is always deeply divided into two lobes.

Latreille ('Règne Animal') divides the genus *Eumorphus* into several sub-genera. Some of the species have the third joint of the antennæ much longer than any of the other joints; these form the genus *Eumorphus* (proper), in which the antennæ are club-shaped. All the species are natives of America or the East Indies. Ex. *Eumorphus immarginatus*. (Latr., 'Gener. Crust. et Insect.,' tab. xi. fig. 12.)

Second Sub-Genus, *Dapsus* (Ziég.). Some of the species have the antennæ club-shaped as in *Eumorphus* proper, but straighter and more elongated, and with the joints bent laterally: among these *Eumorphus Kirbyanus* (Latr.) is now placed. In other species of *Dapsus* the third joint of the antennæ is not longer than any of the others. Many of the species of *Dapsus* are indigenous in Europe, living in different *Fungi*, whence the name of the family (*Fungicolæ*). Some of these insects are also found under the bark of the birch and other trees.

Third Sub-Genus, *Endomychus* (Fab.), has the three last joints of the antennæ bent laterally, larger than the others, and forming a triangular club-shaped mass.

Fourth Sub-Genus, *Lycoperdina* (Latr.), has the maxillary palpi filiform, and the last joints of the labia are enlarged. [TRIMERI.]

EUNICE, a genus of Dorsibranchiate *Annelida*. It is furnished with tuft-like gills; the trunk is armed with three pairs of horny jaws; each of the feet has two cirri and a bundle of bristles; two tentacles upon the head above the mouth, and two on the neck.

E. gigantea is the largest Annelide known. It attains a length of from one to four feet, and inhabits the sea around the Antilles.

EUO'MPHALUS, a genus of fossil *Gasteropoda*, from the Palæozoic Strata. (Sowerby.) [TROCHIDÆ.]

EUO'NYMUS (*εὐώνυμος*, literally 'having a good name,' and hence various derived senses), a genus of Plants belonging to the natural order *Celastraceæ*. It has a flat 4-5-lobed calyx with a peltate disc at the base; 4-5 petals, inserted in the margin of the disc; 4-5 stamens, inserted in the disc; a single style; the capsule 3-5-celled, 3-5-angled, the dehiscence loculicidal; the seed solitary, with a fleshy arillus, not truncate at the hilum. The species are shrubs with tetragonal or terete branches, and ovate usually opposite leaves, yielding a fetid odour when bruised, and considered poisonous.

E. Europæus, Spindle-Tree, has the petals oblong; the flowers mostly 4-cleft and tetrandrous; the branches tetragonal, smooth, and even; the leaves elliptic-lanceolate, minutely serrate; the capsule obtusely angular, not winged. It is a native of Europe in hedges and thickets, and is found abundantly in Great Britain. The flowers are small, of a greenish-white colour, and give out a fetid odour. Its wood is tough and white, and is used for making skewers. It has from this got the name of Prick-Wood; Gerard calls it Prick-Timber. Its French name is Fusain, in allusion to its use in making spindles. It is called also in French Bonnet de Prêtre and Bois à Lardoire; the former in allusion to the capsules, which when open bear some resemblance to a priest's cap, the latter from the use made of the wood in making skewers and larding-pins. It has, in common with the *Cornus sanguinea*, the names of Dog-Wood and Gatteridge-Tree; the first name is in allusion to the use of the wood of these trees for making an infusion with which mangy dogs were washed. It is also known in English by the name of Louse-Berry, a name which it has got from its berries being used when powdered as an application to the head for the destruction of lice. The wood of this tree is also used by musical instrument makers. When used for skewers, toothpicks, &c., the branches are cut when the shrub is in blossom, as that is the period when the wood is toughest. Linnæus says that cows, goats, and sheep eat the leaves, but that horses refuse them. The berries are poisonous, and produce when eaten vomiting and purging. Whilst growing wild in hedges and coppices this plant does not attain any great size; but when planted and allowed to grow alone it becomes a tree, and reaches a height of twenty or thirty feet. Although almost entirely neglected in the planting of pleasure-gardens, it forms a singularly beautiful object in the autumn, when its clusters of red berries are ripe. The seeds are covered with an arillus, which is of a beautiful orange colour.

E. verrucosus has the branches warted with proximate lenticular glands; the leaves ovate and slightly serrate; the flowers 3 on a peduncle; the petals ovate; the capsule bluntly 4-cornered. This is a deciduous shrub or low tree, a native of Austria, Hungary, and Carniola. It has a singular appearance, and is worthy of cultivation on that account amongst collections.

E. latifolius has smooth branches; broad ovate leaves; trichotomous many-flowered peduncles; oval obtuse petals; the lobes of the capsule acutely angular and wing-formed. It is a deciduous shrub or low tree, attaining a height of 10-20 feet, and is a native of the south of Europe. Its fruit is large, and of a deep red colour; the decaying leaves are also reddish. This is the handsomest species of the genus. It has broad shining leaves, and its large red pendulous fruits, with their orange-coloured seeds, which are suspended in the air when the capsules open, contribute much to the beautiful appearance of this tree.

E. Americanus, American Spindle-Tree, has smooth branches; the leaves almost sessile, elliptic-lanceolate, serrated; the flowers 1 to 3 on a peduncle; the petal sub orbiculate; the capsules warty. This is a sub-evergreen recumbent shrub, and is a native of North America from Canada to Florida. The capsules are of a deep crimson, the seeds white, and the arillus scarlet. They add much to the beauty of this plant, and have given rise in America to its common name, the Burning Bush. It is of easy culture in a moist soil. Several varieties have been described by botanists. *E. atropurpureus* is found in English gardens, and is a native of America. *E. Hamiltonianus* is a Nepaul species, introduced about twenty years ago. *E. nanus* is a dwarf species.

About thirty species have been described. All the hardy kinds are easily cultivated in any common soil in the open air. They may be propagated by seeds which ripen in this country. Cuttings planted in the autumn will readily take root.

(Loudon, *Encyclopædia of Trees and Shrubs*; Don, *Dichlamydeous Plants*.)

EUPATORIA'CEÆ, one of the tribes of composite plants admitted by De Candolle, who defines it thus:—"Style of the hermaphrodite flowers cylindrical; the arms long, somewhat clavate, covered externally with downy papillæ at the upper end. The stigmatic series but little prominent, and usually disappearing before they reach the middle of the arms of the style." Under this character are arranged 38 genera, the most extensive of which is the genus *Eupatorium*, including no fewer than 294 species.

EUPATO'RIUM, a genus of Plants belonging to the natural order *Compositæ*, the tribe *Eupatoriaceæ*, the sub-tribe *Eupatorieæ*, and the division *Adenostyleæ*. It has 3-100-flowered heads, a flat naked receptacle, the scales of the involucre in one or two or more rows, equal or unequal, loosely or closely imbricated, the throat of the corolla hardly dilated, the anthers inclosed, the arms of the style exserted, cylindrical, obtuse; the pappus in one row, hairy, rough.

E. cannabinum, Hemp-Agrimony, has the leaves in 3 or 5 deep lanceolate serrated segments, the middle one longest. It is a native of Europe, and is mostly found on the banks of streams. It is a common plant in the British Isles. The stem is about three feet high, and has a slightly aromatic smell. The whole plant is bitter, and was formerly employed in medicine as a tonic and febrifuge. An infusion of this plant is said to be the common medicine of the turf-diggers in Holland against the ulcerations and diseases of the feet and legs to which they are subject. The expressed juice, when taken in large quantities, produces both vomiting and purging.

E. perfoliatum, Thorough-Wort, Thorough-Wax, Cross-Wort, or Bone-Set, has subsessile opposite linear-lanceolate acuminate leaves, decreasing gradually in breadth from the stem, where they are widest, to the extremities; serrated, wrinkled, pale underneath, and hairy, especially the veins. This plant is a native of North America, in meadows and boggy soils. It has erect round hairy stems, branched only at the top, with a cylindrical imbricated involucre, inclosing from 12 to 15 flowers, the florets of which are tubular. All parts of this plant are intensely bitter, and a decoction of the leaves has been recommended by American physicians as a valuable tonic and stimulant, and used as a substitute for Peruvian bark in the cure of intermittent fever. In large doses the infusion or decoction of the whole plant is emetic, sudorific, and aperient. It is used with advantage instead of the infusion of chamomile flowers in working off emetics.

E. Ayapana has subsessile, opposite, lanceolate, triple-nerved, acuminate, nearly entire, smooth leaves. It is originally a native of South America, on the right bank of the river Amazonas, whence it has been introduced into the East Indies. It has a stem shrubby at the base, branched, and smooth; the heads are pedicellate, and contain about 20 florets. An infusion of this plant is used in Brazil as a diuretic and diaphoretic. It has also been employed as an antidote against the bites of venomous serpents and insects. A quantity of the bruised leaves is laid upon the scarified wound, and the fresh juice is administered from time to time to the patient. The reputation of this plant for the bites of poisonous serpents, like that of many others, is probably undeserved. Other species of *Eupatorium* possess medicinal properties: *E. aromaticum* and *E. odoratum* have very fragrant roots; *E. perfoliatum* and *E. rotundifolium* have been employed in renal diseases and consumption. The *E. Guaco* of older botanists is now referred to the genus *Mikania*. [MIKANIA.]

(Burnett, *Outlines of Botany*; Lindley, *Flora Medica*; Lewis, *History of Materia Medica*.)

EUPHEUS. [ISOPODA.]

EUPHO'RBIA, a genus of Exogenous Plants, giving its name to an extensive and important natural order. It has very small monandrous naked male flowers, crowded round an equally naked female one, in the inside of an involucre looking like a calyx, and formerly mistaken for that organ. The species have either a common leafy appearance, with the involucres proceeding from among large foliaceous bracts, or they are nearly leafless, with their stem excessively succulent, so as to resemble *Cacti*. Those with the former character are natives of most parts of the world, and are the only kinds found in Europe; the succulent species chiefly appear in the hottest and driest countries. Barren uncultivated places in the plains of Hindustan, and the arid regions of Asia and the north of Africa are their favourite stations; in the Canaries, on volcanic soil, *E. Canariensis* and *E. laphylla* form great bushes with arms like candelabras. From *Cacti*, which some of these plants much resemble, they are readily known by their spines, when they have any, not growing in clusters, and by their emitting, when punctured, an abundant discharge of milky juice. This, in a concrete state, forms what is called the gum-resin, or rather resin, called *Euphorbium*, an acrid, corrosive most dangerous drug, principally furnished by

E. officinarum, *E. antiquorum*, and *E. Canariensis*. The same properties exist in the herbaceous leafy species, diffused in some, concentrated in others.

Euphorbia officinarum.

E. Lathyris, a common weed in cottage gardens, where it is called Caper, yields from its seeds an oil of the most violent purgative nature. If it were less dangerous it might be substituted for Tiglium oil. Fée states that with as much of this oil as could be sold for a franc ninety adults might be purged.

E. Tirucalli has erect naked round branches, which are succulent, polished, and abounding in milky juice. The leaves are small, linear, fleshy, sessile, and at the ends of the twigs. The flowers are crowded, sub-sessile, terminal, and axillary; the lobes of the involucre are five in number, roundish, smooth, and peltate; the tube woolly on the inside. The capsule is villous. The milk when introduced into the eye produces severe inflammation and even blindness. It is used medicinally in India.

E. tribuloides has a stem about two inches high and one inch broad, ovate, fleshy, quadrangular, having two opposite, stalked, ovate spathulate leaves growing from its base. The prickles are in pairs, white, clustered on the margin of the angles. It is said to be a sudorific.

E. antiquorum is common on barren and uncultivated lands all over India and Arabia Felix. It has a shrubby leafless succulent stem. The branches are spreading, triangular or quadrangular, the angles sinuated, and armed with double spines at the protuberances. The peduncles are solitary or in pairs, 3-flowered. There are only 5 stamens. The bark of the root when bruised in water is taken as a purgative. Some writers consider that this plant yields the drug *Euphorbium*, a resinous substance possessing acrid irritant properties. In all probability however this substance is chiefly obtained from *E. officinarum*. The Arabs make up violent diuretic pills by rubbing over the juice of *E. antiquorum* with flour, yet their camels will eat the branches when cooked. The juice of *E. heptagona*, *E. virosa*, and *E. cereiformis*, African species, furnishes the Ethiopians, and *E. cotinifolia*, the wild Brazilian, with a mortal poison for their arrows. The juice of the leaves of *E. nereifolia* is prescribed by the native practitioners of India internally as a purge and deobstruent, and externally, mixed with Margosa oil, in such cases of contracted limb as are induced by rheumatic affections. The leaves have no doubt a diuretic quality. Of the leafy Euphorbias great numbers are found to possess a milk with purgative or emetic qualities. The roots of some of the species are emetic.

According to Deslongchamps the powdered root of *E. Gerardiana* is emetic in doses of 18 or 20 grains. The root of *E. Ipecacuanha* is said by Barton to be equal to the true Ipecacuanha—in some respects superior. *E. Pithyusa* is esteemed in the Mediterranean. *E. thymifolia* is somewhat aromatic and astringent, and is prescribed in India in the diarrhœa of children, and as a vermifuge. In the same way is employed *E. hypericifolia*, a plant of tropical America, which is astringent and somewhat narcotic. Nevertheless, *E. balsamifera* has no such qualities, and is eaten when cooked. *E. Mauritanica* is also employed as a condiment; but its acridity is unpleasant. It is said to be used in adulterating scammony. The sap of *E. phosphorea* shines with a phosphorescent light in a warm night in the ancient forests of Brazil. (Lindley, *Vegetable Kingdom.*)

EUPHORBIACEÆ, *Spurgeworts*, a natural order of Exogenous Plants with definite suspended anatropal ovules, scattered flowers, and tricoccous fruit. The genera consist of trees, shrubs, or herbaceous plants, often abounding in acrid milk. The leaves are mostly opposite or alternate, simple, rarely compound, often with stipules. The flowers are axillary or terminal, arranged in various ways, sometimes inclosed within an involucre resembling a calyx; flowers monœcious and diœcious. The calyx inferior, with various glandular or scaly internal appendages (sometimes wanting). Corolla either consisting of petals or scales, equal in number to the sepals, or absent, or sometimes more numerous than the sepals; sometimes monopetalous. The stamens definite or indefinite, distinct, or monadelphous; anthers 2-celled, sometimes opening by pores. Ovary free, sessile, or stalked, 1-2-3- or more celled; ovules solitary or twin, suspended from the inner angle of the cell; styles equal in number to the cells, sometimes distinct, sometimes combined. Fruit generally tricoccous, consisting of three carpels splitting and separating with elasticity from their common axis, occasionally fleshy and indehiscent.

Andrachne telephioides.

1, a male flower; 2, a female flower; 3, an ovary nearly ripe; 4, a section of a ripe fruit.

This extensive order, which probably does not contain fewer than 2800 species, described or undescribed, exists in the greatest abundance in equinoctial America, where about three-eighths of the whole number have been found, sometimes as large trees, frequently as deformed bushes, still more usually as diminutive weeds, and occasionally as leafless succulent plants resembling Indian figs in aspect, but not in any other particular. In the Western World they gradually diminish as they recede from the equator, so that not above 50 species are known in North America, of which a very small number reaches as far as Canada. In the Old World the known tropical proportion is much smaller, arising probably from the species of India and equinoctial Africa not having been described with the same care as those of America, not above an eighth having been found in tropical Africa, including the islands; a sixth is about the proportion in India. A good many species inhabit the Cape, where, and in the north of Africa, they often assume a succulent habit; and there are about 120 species from Europe, including the basin of the Mediterranean, of which 16 are found in Great Britain, and 7 in Sweden. A large number of these plants are poisonous. The poisonous principle resides chiefly in their milky secretion. The hairs of some are stinging. The bark of many is aromatic; and the flowers of some tonic. Many are used in medicine, such as *Croton*, *Cascarilla*, and *Euphorbia*. The stimulating poisonous principle however appears to be volatile, since the action of heat is sufficient to dispel it. Thus the starchy root of the Manihot, or Cassava, which when raw is a violent poison, becomes a wholesome nutritious food when roasted. Some yield a fixed oil from their seeds, as the species of *Elæococca*. For further particulars respecting the important and various properties of the species of this order, see PEDILANTHUS, CROTON, BUXUS, CASCARILLA, JATROPHA, RICINUS, and EUPHORBIA. The order contains 191 genera, and 2800 species.

EUPHOTIDE, a Compound Rock, consisting of Diallage and Felspar. It is sometimes called Diallage Rock.

EUPHRA'SIA (from εὐφρασία, delight), a genus of Plants belonging to the natural order *Scrophulariaceæ* or *Scrophularineæ*. It has a campanulate 4-cleft calyx; the upper lip of the corolla galeate, emarginate, the lower larger, spreading, with the middle lobe emarginate; 4 stamens, fertile, the lower cells of the upper anthers with a long spur; the capsules oblong-ovate, compressed, emarginate, with entire valves; the seeds few.

E. officinalis, Euphrasy, Eyebright, has ovate or cordate-ovate nearly sessile serrate leaves, the corolla glabrous, the lobes of the lower lip emarginate, of the upper lip patent sinuate-dentate, the anthers unequally mucronate, hairy. It is from one to four inches high, and is a native of the heaths and pastures of Europe, the Himalaya Mountains, Cashmere, and all the north of Asia. It is common in Great Britain. This species is peculiarly subject to variation. The leaves are ovate, or cordate-ovate, or cordate-triangular, with the teeth acute or obtuse, ascending or spreading. The capsule also varies much in shape. There is scarcely a character permanent except the pubescence of the corolla. This elegant little plant has a slightly bitter and aromatic flavour, and has been employed much in medicine, particularly in diseases of the eye. Its use in these complaints seems to have originated in its bright appearance, and when the doctrine of signs and seals prevailed this was supposed to indicate its value in brightening the eyes. Although it has lately fallen into disuse its astringent effect is undoubtedly of value in certain diseases of the eye, and will explain the fact that Professor Kranichfeld has related of its being useful in catarrhal affections of the eye. The expressed juice and distilled water of this plant have been the forms in which it has been employed.

E. Odontites has the leaves narrowed from the base, opposite, linear-lanceolate, remotely serrate; the floral leaves longer than the flowers; the corolla pubescent; the lobes of the lower lip oblong, obtuse; the anthers with two equal points, hairy. It is a native of Europe, and is abundant in Great Britain in meadows, corn-fields, and waste places. This plant is the *Bartsia Odontites* of Hudson, and the *Odontites rubra* of Persoon.

There are several other species of *Euphrasia*. Although pretty plants none of them will grow well in cultivation.

(Babington, *Manual of British Botany*; Lindley, *Flora Medica*.)

EUPHROSINE, a genus of Dorsibranchiate *Annelida*. It has but one tentacle on its head.

EU'PODA (from εὖ, and πούς, ποδός, a foot), Latreille's fifth family of Tetramerous *Coleoptera*. The great size of the posterior thighs in many insects of this family gives rise to the appellation. The genus *Sagra*, many species of which, remarkable for brilliant red, purple, and green colours, are brought from the East, and the genus *Crisceris*, are types of sub-divisions of the family.

EUPYCHROITE, a fibrous mammillary variety of *Apatite*, from Point Crown, Essex county, New York, United States. [APATITE.]

EURIBIA. [THECOSOMATA.]

EU'RYALE (after one of the Gorgons, in allusion to the threatening armed appearance of the plant), a genus of Plants belonging to the natural order *Nymphæaceæ*. It has a calyx of 4 sepals inserted in the torus, and adhering to it; 16-28 petals; numerous stamens; 16-20 carpels; the fruit half-inferior, arising from the sepals; petals and stamens adhering half-way up. There is but one species of this genus, *E. ferox*, which is an elegant aquatic, covered all over with prickles, with large peltate orbicular leaves, and bluish-purple or violet flowers, about the size of those of the yellow water-lily. It is a native of the East Indies in the lakes Gumtoe and Gogra, also in the province of Kianaug in China. This plant presents a very singular appearance. Its petioles and calyces are hispid with stiff prickles. The leaves are about a foot in diameter. The root or rootstock contains starch, which may be separated as food, or the root may be eaten, as is done by the inhabitants of the districts where it grows.

In cultivation, this plant must be kept in water in a hotbed or stove. It will produce seeds if the pollen of the anthers, when it is in full bloom, be shaken on the stigmas. It can only be propagated by means of its seeds.

(Don, *Dichlamydeous Plants*.)

EURY'ALE. [ACALEPHÆ.]

EURYBIA. [ACALEPHÆ.]

EURYDICE. [ISOPODA.]

EURYLAIMUS. [MUSCICAPIDÆ.]

EURY'NOME, a genus of Brachyurous Crustaceans established by Dr. Leach, and forming the second genus of the Parthenopians of M. Milne-Edwards, who remarks that it establishes the passage between *Parthenope* and *Lambrus* and the other *Oxyrhynchi*. The general form of the body and aspect approximates these crustaceans to *Parthenope*, whilst the disposition of their external antennæ is similar to the conformation in *Maia*. The carapace is nearly in the form of a triangle with a rounded base, and is strongly tuberculated

Eurynome aspera.

and covered with asperities. The rostrum is horizontal, and divided into two triangular horns. The eyes are small; the orbits deep, their upper border very much projecting, and separated from the external angle by a slit. The internal antennæ are bent back longitudinally, and the first joint of the external antennæ terminates at the internal angle of the orbit. The epistome is nearly squared, and the third joint of the external jaw-feet strongly dilated externally. The sternal plastron is nearly oval, and its median suture occupies the two last thoracic rings. The feet of the first pair are scarcely longer than the succeeding ones; in the male they are rather long, whilst in the female they are very short, but less than those of the second pair; the succeeding feet diminish progressively in length. Abdomen consisting of seven articulations in both sexes.

E. aspera. Length about half an inch; colour lively red with bluish tints. Locality, the coasts of Noirmoutier and the Channel (La Manche), at rather considerable depths. (Leach; Milne-Edwards.) [PARTHENOPE.]

EURYNO'TUS, a genus of Fossil Ganoid Fishes, from the Limestone of Burdie House and the shales of Newhaven. (Agassiz.)

EURYO'CRINUS, a genus of Fossil *Crinoidea*, from the Mountain Limestone. (Phillips.)

EURYPODIUS. [MACROPODIDÆ.]

EURY'PTERUS (Harlan), a singular genus of Fossil *Crustacea*, from North America and Scotland. *E. Scouleri* occurs in Carboniferous Limestone at Kirkton, near Glasgow.

EURYSTOMIDÆ. [CORACIAS.]

EUSTACHIAN TUBE. [EAR.]

EUXENITE, a Mineral, containing Yttrium, occurs massive without any trace of cleavage. Its colour is brownish-black. In thin splinters it has a reddish-brown translucence, lighter than the streak. The streak is reddish-brown. Fracture subconchoidal. Hardness, scratches Thorite. Lustre metallic, greasy. Specific gravity 4·60. It is found at Jölster, in Norway. Its analysis, by Scheerer, gives—

Columbic Acid, with some Titanic Acid	49·66
Titanic Acid	7·94
Yttria	25·09
Protoxide of Uranium	6·34
Protoxide of Cerium	2·18
Oxide of Lanthanium	0·96
Lime	2·47
Magnesia	0·29
Water	3.97
	98·90

EVAGORA. [ACALEPHÆ.]

EVANIA. [PUPIVORA.]

EVENING PRIMROSE. [ŒNOTHERA.]

EVERGREENS are plants which shed their old leaves in the spring or summer after the new foliage has been formed, and which consequently are verdant through all the winter season; of this nature are the Holly, the Laurel, the Ilex, and many others. They form a considerable part of the shrubs commonly cultivated in gardens, and are beautiful at all seasons of the year.

The principal circumstances in which Evergreens physiologically differ from other plants are the hardness of their cuticle, the thickness of the parenchyma of their leaves, and the small number of breathing pores, or stomates, formed on the surface of those organs. These peculiarities, taken together, enable them to withstand heat and drought with more success than other plants, but are often not sufficient to protect them against such influences in excess. Hence we find them comparatively uncommon in those parts of the continent of Europe where the summers are hot and dry, and most flourishing in a moist insular climate like our own. This is rendered more intelligible by a comparison of the proportions borne by their stomates, and those of deciduous plants. As far as this subject has been investigated, it appears that their leaves are usually altogether destitute of such organs on the upper side, and that those of the lower are mostly fewer in number and much less active than in deciduous plants.

The greater part of Evergreens are raised from seed; some are propagated by cuttings or layers, and the variegated varieties by budding and grafting. The soil in which they succeed best differs with the kinds; American Evergreens, such as Rhododendrons, Kalmias, &c., grow best in equal quantities of peat-earth, sand, and vegetable mould; European sorts grow in their greatest vigour in a fresh hazelly loam, but will thrive in almost any kind of soil.

The operation of transplanting Evergreens may be performed with success at almost all seasons of the year. Midsummer planting has even been recommended; it however is a work of necessity rather than propriety, because its success depends entirely upon the nature of the weather after the operation; if it be cloudy and wet for some time they may succeed; but if, on the contrary, it be hot and dry, they are sure to suffer: for this reason, if the practice may be adopted, it is not to be recommended. The Common Holly however has been often known to succeed when planted at this season, either for hedges or as single plants. The hollies in one very remarkable case were carefully dug up in the cool of the evening, and removed to large trenches, which had been prepared for their reception; a quantity of water was then poured upon the roots, and the soil thrown upon the top of it, which of course was carried down and deposited in all the crevices in the trench, rendering the plants perfectly firm. In the instance alluded to the weather was very favourable for a considerable period after the operation was performed.

Autumn and spring are much better seasons for work of this kind; the plants are not so liable to suffer from the intense heat of the sun, and are more likely to be benefited by dews and frequent rains.

But, according to the most experienced cultivators, the winter months (that is, from October to February) are decidedly the best time for transplanting Evergreens. Mr. McNab, who is one of the greatest authorities upon this subject, says—"I have planted Evergreens at all seasons of the year with nearly equal success, except from the middle of June to the middle of August, and even during this period I have planted some; but unless the weather is very dull and moist, it is difficult to prevent the plants suffering considerably, and in many cases it is years before they recover. Although, however, I have planted Evergreens ten months out of the twelve with little difference of success, yet one season has a preference over the others with me, and when there is the power of choice I would recommend late in autumn, winter, or early in spring; that is, any time from the middle of October till the middle of February; and in general the beginning of this period is the best; that is, from the middle of October till the middle of December; always providing that the weather and the ground are favourable; that is, supposing there is no frost, no drying wind, nor much sunshine, and that the ground is not too much saturated with wet, either from continued rain or from the nature of the soil. One of the principal things to be attended to in planting Evergreens is to fix on a dull day for winter planting, and a moist day for spring and autumn planting."

It is of great importance to keep a number of the more tender sorts of Evergreens in pots, in order to send them to a distance if required; and if they are to be transplanted at home their roots are not so liable to be injured as when they are dug from the ground. The more tender species of the following genera should be treated in this way:—*Arbutus, Cupressus, Daphne, Erica, Juniperus, Laurus, Magnolia, Phyllirea, Pinus, Quercus, Rhamnus, Thuja*, &c.

In lifting Evergreens particular care should be taken of the young rootlets, as upon their preservation the success of the operation in a great measure depends; especially if the specimens have arrived at any unusual size. Small Evergreens are planted like other things; but the following precautions should be observed in all cases where individuals of any great size are the subject of the operation.

When the plant has been lowered into the hole dug for its reception, the soil must be thrown in loosely around it (not trod in), and a basin made to hold a quantity of water, which must be filled several times until the whole is completely saturated; this will convey the particles of soil down to the roots of the plant, and render it much more firm than any other method. By this treatment we have seen plantations of Evergreens formed without a single failure, which, when finished, appeared to have been growing for many years.

It matters little what size the plants have attained, if they can only be lifted without injuring the small fibres of the roots; they have been moved from 10 to 20 feet high, and otherwise large in proportion, with complete success. Should however the roots be unavoidably injured in transplanting, the branches must be closely pruned and shortened in proportion; so that when they begin to draw upon the roots for support they may not require more nourishment than the latter can supply.

Considering the great importance of Evergreens in a climate like that of Great Britain, where they flourish in such unrivalled beauty, and form so much natural protection to bleak exposed situations, they cannot be too extensively planted. The following lists will furnish information as to the principal kinds found in the nurseries and gardens of Great Britain:—

I. Evergreens whose beauty depends exclusively upon their foliage.

TREES.

Abies.—All the species, where the soil is light enough to suit them, particularly *A. Douglasii*, *A. excelsa*, the Norway Spruce, *A. Deodara*, the Cedar of India, *A. Cedrus*, the Cedar of Lebanon, and *A. Larix*, the common Larch, together with *A. balsamea*, the Balm of Gilead, *A. picea*, the Silver-Fir, and *A. Webbiana*, the Silver-Fir of the Himalaya Mountains. [ABIES.] The Cedar of Lebanon will grow well in a swamp.

Araucaria imbricata, the glory of the mountains south of Chili; it will hardly succeed north of the midland counties. [ARAUCARIA.]

Cunninghamia lanceolata, the Chinese Fir; very handsome, but only suited to the south of England. [CUNNINGHAMIA.]

Cupressus sempervirens, the Common Cypress, and *C. horizontalis*, the Spreading Cypress, are quite hardy: and the latter, if to be procured, forms a tree much more ornamental than the other with its formal shape. But the nurserymen almost always sell a slight variety of *C. sempervirens* for it. [CUPRESSUS.]

Cupressus Lusitanica, the Cedar of Goa, is a beautiful tree, but only suits the climate of southern counties.

Ilex aquifolium, Common Holly. The nurseries contain endless varieties of it, both green and variegated. The latter are not to be compared with the others for beautiful effect. [ILEX.]

Juniperus.—The *J. excelsa* forms a fine tree; *J. Virginiana*, the Common Virginian Cedar, is less handsome; but both are quite hardy. [JUNIPERUS.]

Pinus.—All the species, where the soil is light and sterile enough, with that proportion of decayed unfermented vegetable matter which this genus delights in. The finest, as ornamental plants, are *P. pinaster*, *P. Taurica*, *P. Pinea*, the Stone Pine, *P. nigricans*, *P. halepensis*, and *P. Pallasiana*, which will grow in any soil that is not stiff and swampy in winter. *P. sylvestris*, and *P. nigricans* are the hardiest. [PINUS.]

Quercus.—The *Q. Ilex*, or Evergreen Oak, of which there are many varieties; *Q. Austriaca*, of which the Lucombe and the Fulham oaks are possibly domesticated forms; *Q. Turneri*, *Q. Suber*, the Cork-Tree, and *Q. gramuntia*, the *Q. Ballota*, or Spanish Oak, with sweet acorns, are all fine species equally handsome when young as bushes, and when old as trees. [QUERCUS.]

Taxus baccata, the Common Yew, and *T. fastigiata*, the Irish Yew. [TAXUS.]

Thuja occidentalis, the American Arbor Vitæ, and *T. orientalis*, the Chinese Arbor Vitæ. [THUJA.]

SHRUBS OR BUSHES.

Aristotelia Maqui, a Chilian broad-leaved shrub, quite hardy.

Abies Clanbrasiliana, a curious dwarf fir, only suited to plant singly upon grass.

Cunninghamia lanceolata, the Chinese Fir, rarely grows beyond the size of a bush.

Arbutus Andrachne, the Oriental Strawberry-Tree, and *A. hybrida*. [ARBUTUS.]

Aucuba Japonica, a Japanese spotted-leaf bush. [AUCUBA.]

Buxus sempervirens, the Box-Tree, will succeed in light soil, especially if sandy and sterile; it prefers chalky downs, and will not thrive in stiff wet soil. [BUXUS.]

Juniperus communis, the Common Juniper; *J. Suecica*, the Swedish Juniper, much less handsome; *J. Sabina*, the Savin Bush, excellent for undergrowth, and ornamental as a single bush upon lawns.

Laurus nobilis, the Sweet Bay; quite hardy, though a native of the warm south; its aromatic leaves employed in confectionary, pickles, &c. [LAURUS.]

Ligustrum vulgare, the Common Privet; excellent for hedges and for undergrowth, especially the evergreen variety. [LIGUSTRUM.]

Phyllirea.—Every variety of this valuable genus should be cultivated: *P. obliqua* and *P. latifolia* as large species, *P. media* as a middle-sized one, and *P. angustifolia* as a graceful bush.

Pinus pumilio or *Mughus*, the Alpine Pine-Tree.

Rhamnus alaternus, of which there are several varieties, and *R. Clusii*; hardy bushes, which bear pruning or cutting down to the ground remarkably well. [RHAMNUS.]

TWINERS.

Hedera, many varieties of the common Ivy; *H. Canariensa*, the Irish Ivy; and *H. chrysocarpa*, the Golden-Berried Ivy. [HEDERA.]

II. Evergreens whose flowers have a conspicuous appearance.

TREES.

Andromeda arborea requires peat; grows 40 feet high in North America.

Arbutus Unedo, the Common Strawberry-Tree; of this there is a beautiful variety with deep red flowers, and another with double flowers, much less handsome than either.

Acacia affinis grows without protection near Edinburgh; *A. dealbata*, *A. lophanta*, and several other Australian species will flourish without protection in the southern counties. [ACACIA.]

Eucalyptus perfoliata, *E. pulverulenta*, exist in the open air near Edinburgh; they and other species will thrive in the south and west of England. [EUCALYPTUS.]

Ligustrum lucidum, the Wax-Tree, a Japanese plant.

Magnolia grandiflora, with many varieties; they are scarcely hardy enough to live in this country away from the shelter of a wall, except quite in the south; unprotected specimens exist however near Edinburgh. [MAGNOLIA.]

SHRUBS OR BUSHES.

Andromeda.—The handsomest species are *A. Catesbæi*, *A. angustifolia*, *A. Mariana*, which is rather tender, *A. pulverulenta*, *A. speciosa*, and *A. floribunda*. They require peat soil.

Arctostaphylos Uva-Ursi, a trailing plant. [ARCTOSTAPHYLOS.]

Ammyrsine Lyoni, a beautiful little American bush, requiring peat.

Berberis aquifolium, *B. fascicularis*, *B. repens*, *B. Asiatica*, *B. aristata*. [BERBERIS.]

Bupleurum fruticosum stands the sea breeze well upon chalky cliffs. [BUPLEURUM.]

Cistus, all the species. They are quite hardy if planted where wet cannot lodge in winter, and exposed to the full sun in summer. [CISTUS.]

Colletia spinosa.

Cotoneaster microphylla and *C. rotundifolia*, small bushes. [COTONEASTER.]

Cytisus scoparius, Common Broom; there is a double variety; *C. albus*, the Portugal White Broom. [CYTISUS.]

Daphne.—All handsome, the following the most so: *D. Laureola*, the Spurge-Laurel, grows well beneath trees; *D. pontica*, with pale green fragrant flowers; and *D. Cneorum*, or Garland-Flower, one of the most lovely and sweetly-perfumed plants in the world, but not to be cultivated except in a dry peaty soil and a well ventilated situation; late spring frosts injure it so much that it is not worth cultivating in valleys. [DAPHNE.]

Durana dependens, and some others.

Erica Australis, E. carnea, E. stricta, E. Mediterranea, E. codonodes. [ERICA.]

Escallonia rubra, E. illinita, E. Montevidensis, handsome South American shrubs. Bees take great delight in the blossoms of the last; the second species smells very strongly of melilot.

Garrya elliptica, with long pendulous catkins of a yellowish-green colour. [GARRYA.]

Genista tinctoria, the Dyers' Broom, with a few others. [GENISTA.]

Helianthemum, of all kinds, to cover rockwork, or ground where the wet does not lodge in winter.

Kalmia latifolia, K. angustifolia, especially the first; require peat. [KALMIA.]

Lavandula spica and *L. latifolia*, Common Lavender. [LAVANDULA.]

Ledum latifolium, Labrador-Tea, and *L. palustre;* low bushes requiring peat. [LEDUM.]

Menziesia polifolia, Irish Heath; there is a white variety. [MENZIESIA.]

Myrtus communis, and its varieties; lives out of doors south of London. [MYRTUS.]

Prunus Laurocerasus, the Common Laurel; *P. Lusitanica*, the Portugal Laurel. [PRUNUS.]

Pittosporum Tobira, quite hardy south of London; sweet-scented. [PITTOSPORUM.]

Rosmarinus officinalis, Common Rosemary. [ROSMARINUS.]

Rhododendron.—Numerous varieties are to be procured; those of *R. ponticum, R. maximum*, and *R. catawbiense* are the must robust; *R. hybridum* obtained between the Indian and American species is less hardy; *R. ferrugineum* and *R. hirsutum*, dwarf alpine species; *R. campanulatum*, a North Indian species. [RHODODENDRON.]

Spartium Junceum, Spanish Broom; and *S. acutifolium*, a Turkish Broom. [SPARTIUM.]

Viburnum.—Of the Laurustinus, one of the prettiest of all Evergreens, there are three species: *V. Tinus*, the Common Laurustinus, the hardiest: *V. lucidum*, with shining leaves, rather larger and more delicate; *V. strictum*, with upright shoots, more hairy, and the least hardy of the three. [VIBURNUM.]

Ulex Europæus, the Common Furze; a double variety, which is particularly handsome; and *U. strictus*, the Irish Furze, a smaller species, which does not flower abundantly. [ULEX.]

Yucca.—Several species quite hardy. They only require to be grown in places where water does not stagnate in winter; *Y. gloriosa, Y. filamentosa, Y. Draconis, Y. flaccida*, and *Y. superba*, are the handsomest species. [YUCCA.]

TWINERS OR CLIMBERS.

Bignonia capreolata, with dull brownish-red trumpet-shaped flowers; rather tender. [BIGNONIA.]

Caprifolium flexuosum, C. gratum, C. Japonicum, C. sempervirens; all handsome Honeysuckles. [CAPRIFOLIACEÆ.]

Jasminum revolutum and *officinale*, the Common White Jasmine. [JASMINUM.]

Vinca major and *minor*, the Larger and Smaller Periwinkle; they are trailing plants. [VINCA.]

EVERLASTING FLOWERS. This name is popularly given to certain plants whose flowers have the property of retaining their brightness and colour for many months after being gathered. They owe this quality to a hardness of their tissue, which has exceedingly little moisture to part with, and which, consequently, does not collapse or decay in the progress of acquiring perfect dryness. It is generally in the scales of the involucre of composite plants or in the bracts of others that this property resides. Those who wish to possess such plants will easily find the following in the gardens of this country.

Hardy Annuals.—*Helichrysum bracteatum* (yellow), *Xeranthemum annuum* (purple or white).

Hardy Perennials.—*Antennaria dioica* (pink), *A. triplinervis* and *A. margaritacea* (white). *Ammobium alatum* (white). *Gnaphalium stœchas* and *G. arenarium* (yellow).

Tender Annuals.—*Rhodanthe Manglesii* (red), *Morna nitida* (yellow), *Gomphrena globosa* (purple).

Greenhouse Shrubs or Herbaceous Plants.—*Astelma eximium* (crimson), *Helichrysum argenteum* (white), *H. ericoides* (pink), *H. sesamoides, H. proliferum*, and others (purple).

EVERNIA. [LICHENS.]

EVO'DIA (from εὐωδία, a sweet smell), a genus of Plants belonging to the natural order *Rutaceæ*. It has the calyx 4-5-parted; 4-5-equal petals; 4-5-stamens, smooth; the filaments subulate; the anthers heart-shaped, moveable; the disc cup-shaped, sinuated; the ovary single, deeply 5-lobed, with two collateral ovules in each cell; the style single, very short; the stigma terminal, obtuse; the cocci 2-valved, 1-seeded, with a separable 2-valved endocarp. The species are shrubs and trees, with a grateful smell.

E. febrifuga is a tree, and has trifoliate leaves, the leaflets lanceolate elliptical, somewhat acuminate; the panicle terminal, downy; the ovary simple, warted. It is a native of the forests of the province of Minas Geraes in Brazil. The bark and young wood are bitter and astringent, and are employed by the medical practitioners of Brazil as a tonic and febrifuge.

E. hortensis has simple or trifoliate leaves, which are pubescent as well as the branches. It is a native of the Friendly Islands and the New Hebrides.

E. drupacea has smooth leaflets, and a 4-seeded drupaceous fruit. It is a native of New Caledonia. The last two are shrubs. All the species are worth cultivation on account of their agreeable scent. They may be grown in a mixture of loam, peat, and sand, and propagated by means of cuttings, which should be allowed to strike root under a hand-glass in heat.

(Lindley, *Flora Medica;* Don, *Dichlamydeous Plants.*)

EXCÆCA'RIA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has monœcious or diœcious amentaceous flowers; the sterile flowers nothing but staminiferous bracts; the stamens 7-9, united into about three parcels, all connected at the base; the fertile flowers with the calyx 3-fid or absent; the style 3-parted; the capsule 3-coccous.

E. Agallocha is a small crooked stunted tree, with alternate leaves about the extremities of the branches, stalked, ovate, or cordate, but usually acute at the base, smooth on both sides, remotely and slightly serrate, pointed with two glands at the base, and about two inches long; the petioles about an inch long, smooth, channelled; the stipules small, fine-pointed. The trunk of this plant abounds in a virulently acrid milk, which acts as a powerful poison. Roxburgh says that wood-cutters who accidentally injure this tree have inflammations and ulcerations on those parts of the body where the milk touches. Rumphius calls this tree 'Arbor excæcans,' and says that the Dutch sailors who were sent ashore at Amboyna to cut down timber became furiously mad from the pain produced by the juice of this tree getting into their eyes, and that some of them lost their sight altogether. This tree is common on various parts of the continent of India, and in the Indian Islands, especially near the coast. Its specific name appears to have been given it on the supposition that it was one of the plants that yielded the *Agallochum*, or Aloes-Wood, but this is not the case, and this wood is yielded by a different family of plants. [AQUILARIACEÆ.]

(Lindley, *Flora Medica*).

EXCENTROSTOMATA. [ECHINIDÆ.]

EXCRETION in Plants. [ROOT.]

EXIDIA. [TREMELLINI.]

EXILARIA. [DIATOMACEÆ.]

EXOCA'RPEÆ, a small division of Thymelaceous Plants. [THYMELACEÆ.]

EXOCETUS, a genus of Fishes belonging to the Abdominal *Malacopterygii*, forming part of the family *Esocidæ*. The distinguishing characters are—pectoral fins nearly equal to the body in length; head flattened above and on the sides; the lower part of the body furnished with a longitudinal series of carinated scales on each side; dorsal fin placed above the anal; eyes large; jaws furnished with small pointed teeth.

The species of this genus are called Flying Fishes. The species of the genus *Dactylopterus* [DACTYLOPTERUS] are also known by this name.

The species of *Exocetus* when in their own element are constantly harassed by various fishes of prey; and it is supposed that their flights are performed for the purpose of escaping from these enemies: when in the air however they are subject to the attack of various species of gulls.

Whether these fishes possess the power of flying, in the true sense of the term—that is, by beating the air with their members, or whether their large fins merely serve as parachutes to sustain them in the air for a short time, after a leap from the water, is not yet fully ascertained; observers having given different accounts. The latter is perhaps the prevailing opinion of naturalists, and is that of the more recent observers. "I have never," observes Mr. George Bennett, the author of 'Wanderings in New South Wales,' "been able to see any percussion of the pectoral fins during flight; and the greatest length of time that I have seen this volatile fish on the fin has been thirty seconds by the watch, and their longest flight mentioned by Captain Hall has been 200 yards, but he thinks that subsequent observation has extended the space. The most usual height of flight, as seen above the surface of the water, is from two to three feet, but I have known them come on board at a height of 14 feet and upwards; and they have been well ascertained to come into the channels of a line-of-battle ship, which is considered as high as 20 feet and upwards. But it must not be supposed they have the power of elevating themselves in the air after having left their native element; for, on watching them, I have often seen them fall much below the elevation at which they first rose from the water, but never in any one instance could I observe them rise from the height at which they first sprang; for I regard the elevation they take to depend on the power of the first spring or leap they make on leaving their native element."

Judging from the foregoing quotation, and several other accounts which we have perused, it would appear that something beyond the mere leap of the fish would be required to account for the great heights (of 14 or 20 feet) at which these fishes have been seen. If they cannot fly (which one would judge to be the case upon examining the structure and position of the fins), it seems probable that they take advantage of the wind at times, and so adjust their fins that they are carried upward by it.

Several instances are on record of the appearance of Flying Fishes off the British coast, but the species is doubtful. It is probable that both the *Exocetus exiliens* and the *E. volitans* may have made their appearance in our seas; these two species being very abundant, the former in the Mediterranean Sea (where many fishes similar to those of our own coast occur), and the latter in the Atlantic Ocean.

The *E. exiliens* has the ventral fins placed behind the middle of the body, and the *E. volitans* has the ventrals (which are much smaller than in *E. exiliens*) placed anterior to the middle part of the body: these two species therefore are easily distinguished; of the latter there is a figure in Yarrell's 'British Fishes.'

The American seas afford us examples of other species of this genus.

E'XOGENS, the largest primary class in the vegetable kingdom, are so named in consequence of their woody matter being augmented by additions to the outside of that which is first formed near the centre. As long as they continue to grow they add new wood to the outside of that formed in the previous year, in which respect they differ essentially from Endogens, whose wood is constructed by successive augmentations from the inside. [ENDOGENS.] All the trees of cold climates, and the principal part of those in hot latitudes, are exogenous. In many cases they are easily recognised by the wood of each different year forming a distinct zone, so that a section of their wood exhibits a number of concentric circles; but there are so many exceptions to this rule as to render it necessary to consider this character as by no means essential to them.

The nature of the exogenous mode of growth will be best compared with that of an Endogen, if we pursue the same mode of illustration as in the article which treats of the latter form. We will therefore proceed from an explanation of the typical mode of growth in a common Exogen to such remarks as we may have to offer upon deviations from it.

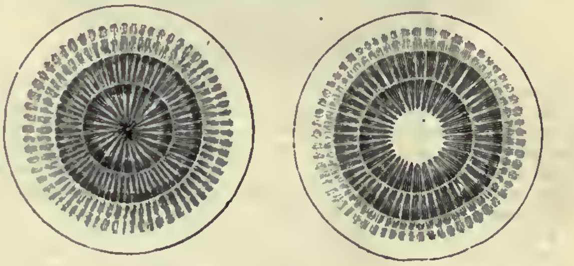
In an Exogen of ordinary structure the embryo consists of a cellular basis, in which there is usually no trace of woody or vascular tissue; but as soon as germination commences fine ligneous cords are seen proceeding from the cotyledons towards the radicles from the opposite sides of the young stem, meeting in the centre of the embryo, and forming a thread-like axis for the root. As the parts grow the ligneous cords are increased in thickness and number, and having been introduced among the cellular basis of the embryo, are separated from each other by a portion of the cellular substance, which continues to augment both in length and breadth as the woody cords lengthen. By degrees the plumule or rudimentary stem becomes organised, and having lengthened a little, forms upon its surface one, two, or more true leaves, which gradually expand into thin plates of cellular substance traversed by ligneous cords or veins converging at the point of origin of the leaves. If at that time the interior of the young plant is again examined, it will be found that more ligneous cords have been added from the base of the new leaves down to the cotyledons, where they have formed a junction with the first wood, and have served to thicken the woody matter developed upon the first growth. Those ligneous cords which proceed from the base of the leaves do not unite in the centre of the new stem, there forming a solid axis, but pass down parallel with the outside, and leave a small space of cellular tissue in the middle; they themselves being collected into a hollow cylinder, and not uniting in the middle until they reach that point where the woody cords of the cotyledons meet to form the solid centre of the root. Subsequently the stem goes on lengthening and forming new leaves: from each leaf there may be again traced a formation of woody matter disposed cylindrically as before, and uniting with that previously formed, a cylinder of cellular substance being left in the middle; and the solid woody centre of the root proceeds in its growth in a corresponding ratio, lengthening as the stem lengthens, and increasing in diameter as the leaves unfold and new woody matter is produced: the result of which is, that when the young Exogen has arrived at the end of its first year's growth it has a root with a solid woody axis, and a stem with a hollow woody axis surrounding cellular tissue, the whole being covered in by a cellular integument. But as the woody cords are merely plunged into a cellular basis, the latter passes between them in a radiating manner, connecting the centre with the circumference by straight passages, often imperceptible to the naked eye, but always present. The following diagram illustrates this.

Here we have the origin of pith in the central cellular tissue of the stem, of wood in the woody axis, of bark in the cellular integument, and of medullary processes in the radiating passages of cellular tissue connecting the centre with the circumference.

The woody axis is not however quite homogeneous at this time. That part which is next the centre contains great numbers of vessels of different kinds, particularly dotted vessels (vasiform tissue); the part next the circumference is altogether destitute of vessels, and consists of woody tissue exclusively: of these two parts that with the vessels belongs to the wood, properly so called, and serves as a mould on which future wood is added; the other belongs to the bark, separates under the form of liber, and in like manner serves as a mould upon which future liber is disposed.

Root. Stem.

At the commencement of a second year's growth the liber separates spontaneously from the true wood, a viscid substance called Cambium is secreted between them, and the stem again lengthens, forming new leaves over its surface. The ligneous cords in the leaves are prolonged into the stem, passing down among the cambium, and adhering in part to the wood and in part to the liber of the previous year, the former again having vessels intermingled with them, the latter having none. The cellular tissue that connected the wood and liber is softened by the cambium, and grows between them horizontally while they grow perpendicularly, extending to make room for them, and consequently interposed between the woody cords of which they each consist, forming in fact a new set of medullary processes terminating on the one hand in those of the first year's wood, and on the other in those of the first year's liber. This addition of new matter takes place equally in the stem and in the root, the latter extending and dividing at its points, and receiving the ends of the woody cords as they diverge from the main body. The following diagram illustrates this, and shows, when compared with the last, what difference there is in the appearance of the stem of an Exogen one and two years old.



Root. Stem.

And thus, year after year, the Exogen goes on, forming zone upon zone of wood, which is permanent, and zone within zone of liber, which perishes as the stem increases in diameter. [BARK.]

If this account is compared with that given of Endogens, it must be obvious that the stem of these two great classes is formed from the very beginning in an essentially different manner. Endogens have no cylindrical column of pith; their woody arcs are never collected into a cylinder, through the sides of which the cellular tissue passes in the form of medullary processes; and the woody matter of their bark, so to call their cortical integument, is not parallel with that of the wood and spontaneously separable from it: not to speak of important anatomical differences, or of the concentric arrangement eventually assumed by the wood of Exogens. In both Exogens and Endogens a cellular substance is the basis of the whole structure, and extends horizontally wherever it is necessary to do so; and in certain Exogens woody arcs, stated to be like those of Endogens, are found in the pith. These cases properly belong to anomalous forms, but nevertheless may be noticed here, in consequence of their direct connection with this branch of the subject. One case is that of *Zamia*; but as that genus now belongs to the new class of Gymnosperms and not to Exogens proper, it need not be considered here. The other cases are *Piper*, Nyctaginaceous plants, and some others. Professor Schultz states ('Natürliches System des Pflanzenreichs,' p. 320, &c.) that in *Piper*, *Mirabilis*, and *Boerhaavia*, the central part of the stem consists of cellular tissue, amongst which cords of spiral vessels and woody tissues are placed either without order, or (in *Boerhaavia*) in a cruciate manner, as in Tree-Ferns, and that on the outside of this the woody bundles are arranged circularly into a cylinder. A similar statement had long previously been made by Mirbel, who ascribes to *Mirabilis* and some Umbelliferous plants longitudinal vessels in the pith ('Elém. de Physiol. Veget.,' i. 112), and by Professor Meyer, who finds the pith of *Mirabilis longiflora*, *M. dichotoma*, *Boerhaavia scandens*, and *Oxybaphus Cervantesii* abounding in many large bundles of spiral vessels within the woody radiated zone. ('De Houttuynia atque Saururcis,' p. 40.) This, if correctly described, only shows that in certain Exogens a portion of the central tissue is placed at first in a confused manner, and that the wood does not assume a definite circular disposition till afterwards; that it does assume it eventually is admitted. We find in *Piper nigrum* and *P. Lonchitis* that from the beginning the woody bundles are placed circularly, but they are separated by a good deal of cellular tissue, and do not assume in the first zone the wedge-like or triangular form which is most common in Exogens, and which they themselves at last take on. In *Boerhaaria repanda*, a specimen of which is now before us, we find the wood regularly disposed in two zones, and instead of spiral vessels a very singular structure in the pith, which is filled with fistular passages of lax soft spheroidal cellular tissue, surrounded by smaller, harder, and more cubical cellular tissue which passes off into the medullary processes. It is in such plants as *Piper incanum* that the organisation of Exogens most nearly approaches that of Endogens; but in the first place the whole race of Pipers forms a sort of transition from Exogens to Araceous Endogens; and secondly, it is probable that when they are most endogenous in appearance they are not really so in regard to the final development of their woody tissue.

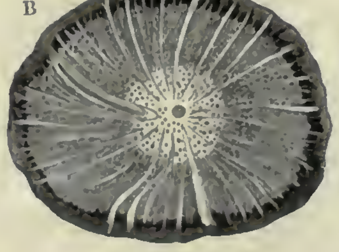
Let it however be admitted that in certain cases Exogens are in the centre of their stem organised less regularly than usual; this will offer no argument in favour of their analogy with Endogens. In all such cases it will be found that they eventually assume their typical conformation. We are acquainted with some striking proofs of this. Among twining plants of tropical countries we occasionally find instances like the following:—

A

Beneath a most irregularly-compressed and lobed bark there lies a mass of wood, apparently so confused and irregular in its arrangement in the centre, that nothing symmetrical can be made out by the most acute observer; but it will be seen that towards the circumference it distinctly assumes the radiated appearance of an Exogen. In other cases, where the structure is sufficiently regular, this circumstance is still more distinctly illustrated.

It is however more commonly at the centre that we look for typical structure, and at the circumference that we find irregularity; as if Exogens usually commenced their growth according to the plan to

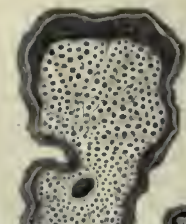
B



C

which nature has subjected them, and only deviated from it under the influence of unknown causes coming into operation and controlling their development after they have advanced to a certain stage in their growth. Thus, in the singular instances shown in cuts D, E, F, and G, the principal part of the stem is so confused and irregular as to look more like an Endogen than an Exogen, and a fragment might easily be mistaken for the former; nevertheless in a young and tolerably regular shoot (D) the radiated appearance is sufficiently well-marked; and in two others, irregular and distorted as they are (E and G), the central pith is visible, although far out of the centre; and in the fourth (F) the centre has not only pith, but a radiated structure that is quite regular.

D



E

F

G

By far the most singular case of this sort is in an unknown twining plant in the possession of Dr. Lindley, from the Malayan Archipelago, of which the cuts H and I are representations. In old stems of this plant a section exhibits a most irregular combination of wood, looking like palm wood, broken up into lobed cords lying amongst still more irregular cellular tissue, and inclosed in a common bark; so that we doubt whether it would be possible to tell to which class it really belongs, if it were not for its young shoots and the pith of the old ones. The latter may be seen lying quite out of the centre towards one side (near the bottom of our figure, a little to the right); and in the former (H) the pith is found with wood radiating around it, although still with sufficient irregularity.

H

I

The cases already given are evidences of exogenous wood being sometimes extremely different from the condition in which we see it in Europe, and attest the necessity of forming our ideas of its nature from a more extended examination than that which is commonly given to it. Several curious cases have been also published by Dr. Lindley in his 'Introduction to Botany' (ed. 2, p. 77, &c.), and others have been noticed by Schleiden and other writers.

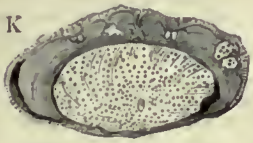
Irregularity in the structure of exogenous wood is usually owing either to a confused disposition of the tissue at some particular period of the growth, or to some derangement of the medullary processes, or to the absence of concentric circles, or to the formation of a deep zone of cellular tissue alternately with each zone of wood, or, finally, to the production of wood within the bark instead of beneath it. The first cause has been already sufficiently illustrated.

The sinuosity and partial obliteration of the medullary processes is a principal cause of the anomalous appearances at *figs.* D, E, F, G, where they are reduced to fine lines, only visible beneath a microscope, and not radiating from the centre, but disposed in no certain manner, sometimes even transversely, owing to the excessive disturbance of the wood itself. In *fig.* I, the singularity of structure is owing in part to the excessive irregularity with which the wood has been developed, and in part to the looseness and irregular shape of the medullary rays, which seem huddled as it were round the woody cords; the latter are moreover extremely variable in size, some of them being as much as half an inch in diameter, and others so small as to consist of no more than a single vessel with its usual coating of woody tissue.

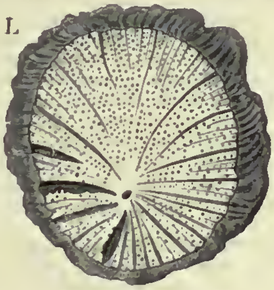
The absence of concentric circles is an extremely frequent occurrence in the wood of tropical countries, and it is almost certain that many families of Exogens never form them visibly under any circumstances. We say visibly, because in fact they must be annually formed in all cases, although we do not see them. The reason why Exogens have their wood marked by concentric circles is, that the ligneous tissue formed at the end of a season is more compact than that formed at the beginning, and hence, as the two are in juxtaposition, the difference in their density distinctly separates the one from the other. But if, from any cause,—whether proper to plants as species, or owing to the external influence of an equable climate—the tissue of wood formed at all seasons is exactly alike, no zone will be visible, although in fact the formation of the wood is exogenous in the most regular manner. Such cases are seen at *figs.* K, L, S, and elsewhere in the illustrations of the present article.

It is not a little remarkable however that while the wood in some cases has no trace of zones, the bark should show them most distinctly, as in the instance of *fig.* K.

K



L



O

P

N

M

Q

When a deep zone of cellular substance is formed between each zone of wood, a curious banded appearance is produced, as in the singular Indian climber marked N M O P Q, where extremely excentrical growth is combined with this peculiarity. At N we have the stem two years old, the second zone passing pretty regularly round the first aud cut off from it by a broad deep band. At M the specimen is of the same age, but the second zone is formed on one side only. At O the specimeu is two years old, with the first zoue perfect, but the second broken up into a number of unequal irregular pieces, and it would seem as if a third growth had commeuced ou one side (to the left of the cut). At P the growth is of three zones, both the second and third being much lobed, and the third only extending three quarters round the second. Finally, at Q, where the irregularity is the greatest, there is a growth of four zones, the first symmetrical, the second very much deeper on one side thau the other, the third but half surrounding the second, aud the fourth formed only along two ridges on the third.

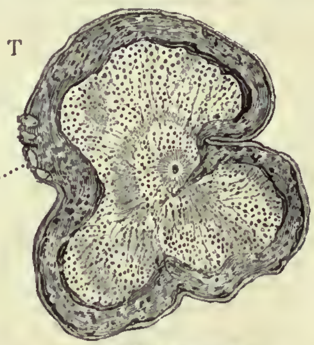
If it happens that, in addition to the presence of a thick cellular layer between each zone, the medullary processess are also very thick, an appearance still different from the last is produced, as at *fig.* R.

R

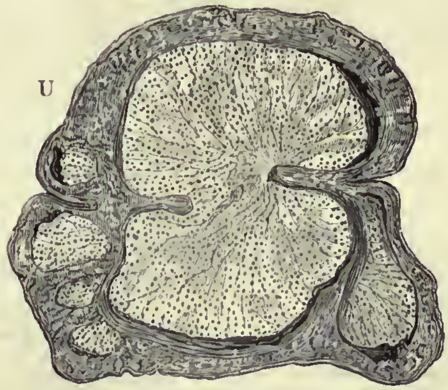
S

That wood is sometimes formed in the bark itself has been long since shown by Mirbel, in the case of *Calycanthus floridus*, where four additional woody columns appear equi-distant iu the bark, without any separate pith, but radiating from their first line of origin. We are now acquainted with mauy such cases. In *fig.* T are the commencement of four such columns at *a* on one side; but in that specimen no further indication of such a structure is visible; but at *fig.* U, which

T



U



is the same plant in a more advanced state of growth, four such columns on one side and one on the other have acquired considerable size, and each radiates towards the circumference of the stem. As in the *Calycanthus*, so in these and all the other instances of the same kind, which these cuts represent (see F, K, and S), the woody columns of the bark are destitute of pith.

Perhaps what we have called the separation of zones of wood at N, M, O, P, Q, R, by thick layers of cellular tissue, are rather to be considered as other instances of wood formed in bark, but in a regular and uniform manner. We are however uncertain how this may be, and prefer allowing the statement to stand in its present form until some one shall have examined such plants in their native forests at Singapore.

In addition to such anomalous kinds of structure as those now described, Exogens, like Endogens, contain species, the organisation of whose stem is so imperfect as to be reducible within no certain rules. Not to speak of *Callitriche*, *Ceratophyllum*, or *Myriophyllum*, wherein vessels are scarcely developed, and the woody matter merely forms a simple central axis of growth, we have in this class an exact parallel with *Lemna* among Endogens; some Podostemaceous plants have their leaves and stem completely fused together so as to resemble a *Marchantia* or an *Alga*. Such plants are to be regarded rather as instances of imperfect organisation than as deviations from a typical form; and it is by no means a violent supposition to conclude that if their organisation were more complete it would then become such as is characteristic of the class to which they belong.

Schleiden, in his 'Principles of Scientific Botany,' has treated the structure of the stems of Exogens in his usual lucid manner, and we subjoin an analysis of his views upon the subject. He divides the Dicotyledonous axial organs into two groups, the stalks and stems. Of the stalks he says they frequently exhibit no essential differences from those appertaining to Monocotyledonous plants, since the distinction of the unlimited or indefinite vascular bundles is often imperceptible in the growth of one year. But the vascular bundles generally close in the first year into a simple circle, and the external parts in several circles to form a ring, so that the parenchymatous masses separating the individual bundles are compressed together into medullary rays. In most cases the vascular bundles run from below upward in straight parallel lines. They form a loop where the leaf begins, the edges of which furnish vascular bundles for the leaf and the axillary bud, and the pith of the bud is thus brought in connection with that of the stem by means of their opening, as in the case of *Tropæolum*. The vascular bundles supplying the leaves and buds generally separate from this loop exactly at the point where they enter the leaf. Sometimes however they first pass through a longer portion of the parenchyma of the pith or the bark (as in the *Amaranthaceæ* and *Chenopodaceæ*). In perfect nodes loops of vascular bundles are seldom found passing across the stem; in general the parenchyma merely appears to be tougher and closer at these points. We are here, on the whole, very destitute of accurate investigations, more especially with regard to the first year's stalk with undeveloped internodes.

Stems differ in structure according as the internodes are developed or undeveloped. Those with developed internodes are divided into several sections:—

A. With a Simple Ring of Vascular Bundles.—Here the vascular bundles very seldom run parallel, but generally in serpentine lines, alternately approximating and retreating from each other; the meshes thus formed are filled by the medullary rays. Where liber-bundles lie in front of the vascular bundles they follow the same course. Large and small medullary rays and annual rings are formed in the manner indicated. Wherever there is a leaf, one large or several smaller loops are formed, from whose circumference the vascular bundles are given off for the leaf and axillary bud, while the openings furnish parenchyma for the formation of the bud. The vascular bundles of every newly developed internode stand in immediate connection with, and are immediate prolongations of, that portion of the vascular bundle of the preceding internode still capable of development, and thus the cambium of the vascular bundles forms a continuous net through the stem and branches of the whole plant. During the developments of the vascular bundles of the stem, and those connected with them, and belonging to an axillary bud that grows into a branch, the base of this branch becomes more and more covered with newly formed wood. We thus see the same condition established as in the Monocotyledons: an under lateral branch crosses all the layers of wood passing to the upper parts. The difference is merely, that in the Dicotyledons they are portions of the continuous mass of the progressively developing vascular bundles; while in the case of Monocotyledons they are discrete parts, new vascular bundles.

B. With Several Concentric Rings of Vascular Bundles.—This condition appears to be only met with in *Piper* (?) and *Pisonia*; and, perhaps, in a few of the *Crassulaceæ*, as in the *Crassula*. The separate vascular bundles continue to grow, and finally close into a firm woody mass; each however retains its own cambium, and likewise a small portion of parenchyma, not perfectly dislodged: such, at any rate, is certainly the case in *Pisonia*.

C. Stems of Climbing Plants.—The stems of many tropical climbers (Lianes, Llanos) exhibit a peculiar structure, which has long been misunderstood. Even in our own indigenous plants we meet with some indications of it. In the first year, most of them exhibit nothing striking, if we do not regard the generally square stalk as such; and we find that they have a simple ring of vascular bundles, which closes towards the end of the first period of vegetation into an ordinary wood cylinder. In the following years however the peculiarities are more and more strikingly manifested, consisting in the wood not being uniformly developed towards the exterior throughout its whole circumference, but ceasing to grow at definite parts, often regularly, and as frequently in a fantastically irregular manner, allowing the substance of the bark to replace it. In this manner stems are produced, which, in a transverse section, exhibit the most varied distribution of the wood. We meet with the first indications of this peculiarity in our indigenous species of *Clematis* forming stems; in the strikingly broad and regularly arranged large medullary rays; and in the six narrower portions of wood which are not nearly so fully developed towards the exterior as the six broader ones. To these we may add the *Bignoniaceæ*. After the wood has continued for some time to be regularly developed, it ceases growing in four different places, so that the bark is no longer pushed outward; and on the further development of the wood in the remaining places, the bark forms, in the transverse section, four septa of variable thickness between the four portions of wood.

In some species these cortical masses become a definite degree broader in each succeeding annual ring, so that a sharply marked step is formed on each side; in another species all that is formed are four very thin flat plates, wholly separated (in consequence of drying) from the wood. Still more striking is the cross-section of many climbers of the family of *Sapindaceæ*. A hasty glance would lead us to imagine that we had here a cylinder of wood surrounded with bark in which other stems or branches with their bark had become blended in their growth. A minute observation however refutes this view at once from the absence of pith in the exterior woody masses.

Finally, the most astounding phenomena are seen in the families of the *Aristolochiaceæ*, *Asclepiadaceæ*, *Malpighiaceæ*, *Bauhiniæ*, in which, in the transverse section, the woody mass appears divided in the strangest ways by cortical substance, separated into various portions, and often elegantly lobed.

The great diameter of the porous tubes may apparently be regarded as a general peculiarity in the ligneous structure of all climbing plants. These have also strikingly large pores which (as I have never yet seen in vessels) form even ramified canals, as is seen particularly well in *Bauhinia*.

Of Stems with Undeveloped Internodes, Schleiden says they have scarcely been investigated at all in the Dicotyledons. Most of them remain very short, since they die below as they increase upward. They belong principally to the subterraneous stems and rhizomes. The leafless *Euphorbiaceæ*, *Carica*, *Theophrasta*, *Nymphæa*, and *Nuphar*, as well as many *Cactaceæ*, afford excellent material. The most important researches in reference to this point are those of Schleiden, into the stems of *Cactaceæ*, especially *Mammillaria*, *Echinocactus*, *Melocactus*. The vascular bundles at first make an arc of considerable curvature; by the gradual development of the pith the curvature becomes almost effaced, and it only remains in the upper part, where the vascular bundles pass off to the leaves. The first succeeding layer developed in the vascular bundle is applied over and up beyond this, dividing at the point where the primary vascular bundle goes off to the base of the leaf, and uniting again above to pass up to the base of a leaf situated higher up. The next layer of structure forms in the same way, by splitting and reuniting, two meshes, one for the primary vascular bundle, and one for the portion of the first layer of increase, running to the upper leaf, then above this it runs up to the base of another leaf. This structure is continued up throughout the whole stem, which thus possesses a form of wood exhibiting perfectly regular meshes, or areolæ, which appear to be formed by an alternating superposition of vascular bundles, and each gives passage to a bundle coming from the innermost part of the wood. Of course there is here a perfect crossing of the vascular bundles going to the lower leaves by all the subsequently formed portions of vascular structure, and by a little care we may make preparations not very unlike the structure of a Monocotyledonous stem with undeveloped internodes. The whole structure bears great similarity to that of the arborescent Ferns, allowing for the different nature of the vascular bundles and the difference of dimension.

Many interesting varieties in the structure of the wood occur here also; and the wood of the *Mammillariæ* and *Melocacti*, composed entirely of peculiar spiral-fibrous cells, is particular worthy of notice.

The stems of the *Rhizanthaceæ* (Blume) appear to be altogether aberrant and irregular in their structure. As a general rule, we may say that in the Monocotyledons the vascular bundles are simplest in their lower part, often, for instance in the Palms, composed at that part solely of elongated parenchyma (liber); in the middle becoming more complicated from within outward, exhibiting almost all the forms corresponding to the varied expansion of the cell; above they become simpler again, particularly where they pass off into a leaf or branch, and consist frequently merely of such elements as correspond to a considerable expansion in the longitudinal direction after the appearance of layers of thickening. In the Dicotyledons the vascular bundles appear to have a tolerably uniform structure below and in the middle, but toward the upper end the onward developing portion of each older bundle passes into the form of a primary bundle, or, in other words, every primary vascular bundle of a new internode appears as the immediate prolongation, not of the primary bundle of the preceding internode (which rather runs to a leaf), but of the layer of increase of this, the elementary portions of which do not correspond to any expansion in the longitudinal direction.

On the literature of this subject Schleiden says—"Almost all that has been said by isolated authors is wholly useless, either because they have had no regard to the history of development, or, if they have noticed this, have spoken so indiscriminately of growth, increase, and enlargement, without distinguishing whether new cells have originated, cells already existing expanded, or merely become transformed into different tissues by the alteration of the form and configuration of their walls.

"Two notions there are especially which have long sadly confused our science, from which a correct method would have completely saved us, since both were, at least at the time, and in the species on which they were built up, wholly unfounded fables, having no connection with any guiding principles, and consequently never should have assumed scientific perspicuity, much less, as did happen, have served as a temporary basis for theories pervading the whole science of botany.

"The first is the idea of Desfontaines of the distinction between Monocotyledons and Dicotyledons, that the former develop new structure in the centre of the axis, and grow in the inside (*Plantæ Endogenæ*), while the latter produce ligneous substance close under the bark, and deposit it on the inner side, and thus grow on the outside (*Plantæ Exogenæ*). All this had no greater foundation than the fact that in the Monocotyledonous axis the vascular bundles are farther apart in the centre; consequently, in the preponderance of parenchyma, the substance is more lax. It was not ever attempted to make even a superficial observation of the process of growth; if it had been merely observed that the vascular bundles going to the lower leaves, consequently the older, crossed those going to the upper leaves, which must be the younger, a child might have been made to understand at once that a growth of new vascular bundles in the interior was an absolute impossibility. Nevertheless, upon this empty fancy, which a child might have refuted, De Candolle built a grand system of vegetables, which it never did require the distinguished and comprehensive researches of Mohl to overthrow.

"The second notion is that of Du Petit Thouars, which was not less ill-grounded, which, as expressed by him, would be upset by every even the most superficial observation, and even in its more refined subsequent statement is by no means established, but has important and apparently irresistible objections against it. Du Petit Thouars thought that all increase of thickness of the axis resulted from the descent of roots from the buds. Such a crude notion scarcely required refutation. On the other hand, it was afterwards stated that the formless but organisable substance (the cambium) was gradually organised from the buds downwards. The only possible foundation for this view, namely, evidence obtained by thorough investigation of the history of development, is still due from all its assertors, the latest, Gaudichand, &c., included. Therefore it is already to be set aside as devoid of foundation. But the contrary can be made good, that, in the first place, no cambium ever exists as a formless fluid in the plant, unless we would so call the cytoblastema inclosed in the cells; secondly, that, so far as observation at present reaches, cells are always formed in cells, that this cell-formation, according to the observations I have made in the *Cacteæ*, &c., progresses from below upward; thirdly, that the axillary bud is already formed in the terminal bud before the axis begins to increase in thickness, and that certainly the cells of the bud are organised into vascular bundles from the vascular bundles of the stem upward into the bud, and not in the reverse direction. By these remarks the whole notion seems to me to be for the present set aside, and it would require quite other support than that which Gaudichand's imperfect attempts in anatomy and physiology could give it.

"Lastly, I must notice the most recent views of Martius on the structure of the stems of palms, &c. Martius asserts that here the vascular bundles, the primary structure of which is sketched out in the conical terminal bud, on the whole, as I have already explained it (Wiegmann's 'Archiv.,' 1839, 219), do not merely grow upwards into the leaves, but also downward, by their lower end, in the stem. These facts I must entirely oppose from my own observations. Hitherto I have never had an opportunity of investigating living Palms, or more than small fragments of dead ones. But from what I saw I believe I may venture to conclude that the stem of Palms does not essentially deviate in such a way from those of other Monocotyledons, that one may not transfer to the Palms, in the main points, the laws of structure found there. Now, so far as I know, such a process of growth does not occur in any Monocotyledonous plant. According to my observations the newly-produced vascular bundles merely grow continuously upward. In advancing the distinction of limited and unlimited bundles Martius follows me, but in my opinion he has not conceived nearly clearly enough the distinction between developed and undeveloped internodes; and in particular he has not formed a clear conception of the peculiarities of the stem with undeveloped internodes, and the conditions of structure resulting therefrom. Moreover he has left the meaning of the term growth (fortwachsen) of a vascular bundle equivocal. If it means that the already existing elongated cells become transformed into vascular bundles, it describes no peculiar process of growth—the vascular bundles were already to be distinguished in their elementary condition; but if it means that the cells themselves, of which the vascular bundles are composed, are produced subsequently, originating above first and proceeding downwards, this is I believe erroneous. It is necessary to bear in mind the essential distinction between monocotyledonous axes with and without a cambium circle, in order to understand these structures. Where no cambium exists there are no other new cells formed besides those in the point of the bud; but where there is cambium, all development, and so also the development of new vascular bundles in the stem, proceeds upwards and outwards; never, so far as I have been able to observe, downwards or towards the interior. The lowest and innermost cells are always the oldest, never the upper or outer (of course excluding the bark, to which alone an endogenous growth can be ascribed). I must therefore distinctly assert that in the Palms, as in all Monocotyledons, the lower end of an older vascular bundle never reaches down into an internode lower than that in which the lower end of its first rudiment originated."

The following is a summary of the nature of axial structures, and the names given to the various parts of which they are composed:—

1. Duration.

A. Annual. Stem (*Caulis*).
Internodes (*Internodia*).
a. Only existing in the beginning of the period of vegetation, fugacious (*Internodia fugacia*).
b. Enduring the whole period (*Internodia annua*).
c. Only existing in the latter part of the period of vegetation (*Internodia serotina*).
B. Perennial. Trunk (*Truncus*).

2. Position on the Soil.

A. Above ground (*Epigæus*).
B. Under ground (*Hypogæus*).

3. Form.

A. Developed Internodes (*Internodia elongata*).
B. Undeveloped Internodes (*Internodia abbreviata*).
C. Disciform expanded Internodes (*Internodia disciformia*).
D. Concavely expanded Internodes (*Internodia concava*).
N.B. Rigid, pointed, leafless, or defoliated Internodes are called Spines (*Spinæ*); soft, curling, and thus climbing round foreign objects, Tendrils (*Cirrhi, Capreoli*).

4. Various Internodes of the same Axis.

A. Bearing true Leaves and Branches (*Caulis* and *Truncus*).
N.B. Sometimes no leaves are developed (*Axis aphyllus*), or they fall off from the *truncus*, mostly at the end of the first year (*Axis denudatus*). The stem may grow out from the terminal bud of an embryo, as in the simple stem, or out of a trunk. A stem produced from a trunk might be called *Scapus*; but this is a wholly superfluous term.
B. Bearing only bracts, bracteoles, or flowers, Peduncle (*Pedunculi*); in a compound inflorescence the internode bearing a single flower is called the Pedicel (*Pedicellus*). *Receptaculum* is a superfluous expression in the *Synantheræ*. *Pedunculus disciformis, conicus*, &c., is simpler and more correct. Also in *Ficus, Pedunculus concavus*.
C. Internodes between calyx and pistil, Receptacle (*Torus*), e. g. in some *Rosaceæ, Torus disciformis* (in *Potentilla*), *Torus concavus* (in *Rosa*).
a. Internodes between calyx and stamens (e. g. in *Rubus*), or calyx and corolla (e. g. in *Passiflora*), the Disc (*Discus*), e. g. *planus* (in *Geum*), *D. tubulosus* (in *Cereus grandiflorus*).
b. Internodes between corolla and stamens, Androphore (*Androphorum*), e. g. *A. elongatum* (in *Cleome*).
c. Internodes between stamens and pistil, Gynophore (*Gynophorum*), e. g. *G. conicum* (in *Rubus*).
D. Internodes between calyx and seed-buds, as a hollow disc inclosing the seed-buds, Inferior Germen (*Germen inferum*), e. g. in *Synantheræ, Orchidaceæ*.
E. Internodes between stamens and seed-buds, as a plate with the borders curved inward together, in the cavity of which the seed-buds occur, Stalk-Pistil (*Pistillum cauligenum*). In *Liliaceæ* and *Leguminosæ* (?).
F. End of the stalk in the germen, as support of the seeds, Spermophore (*Spermophorum*), in Seed-Buds (*Gemmulæ*). (For the parts of these see below, under the Seed-Bud).

5. As to the Nodes.

A. With Imperfect Nodes (*Caulis, Truncus*).
B. With Perfect Nodes.
a. Stalk (*Culmus*).
b. Stem (*Calamus*).

N.B. It is exceedingly useful to mark this distinction by definite terms: but then we must name the stalk of the *Caryophylleæ*, most *Umbelliferæ* and *Labiatæ*, *Culmus;* the stem of *Bambusa*, *Calamus*, *Piper*, *Aristolochia*, &c., *Calamus*. In other respects the expressions *culmus* and *calamus* have no sense, since it could only be defined as a stalk, such as occurs in the plants to which such a stalk is ascribed, the former in some Grasses, the latter in some *Cyperaceæ*.

6. Different Axes of Compound Plants.

A. Main Axis produced from the terminal bud of the embryo (*Caulis vel Truncus primarius*).

B. Secondary Axis, produced from axillary or adventitious buds (*Caulis vel Truncus secundarius*).

N.B. Still connected with the main axis, called Branch or Twig (*Ramus*).

C. Ramification of the Axis (*Ramificatio*). Ramification of the *Pedunculus* (*Inflorescentia*).

D. Secondary Axis growing along underground, and its secondary axes alone rising above the soil, Root-Stock, Rhizome (*Rhizoma*).

N.B. For Secondary Axes which lie upon the earth, because they are too weak to stand erect, there are some special terms, but these appear to me superfluous:—*Flagellum*, *Stolo*, *Sarmentum*, Runner, Sucker, which are sometimes to be distinguished by the foliation, sometimes by the rooting, now one way and now another, and again may be different from the *Caulis repens*, *humifusus*, *prostratus*, *procumbens*, *decumbens*, *sarmentaceus*, and all the rest of this manufactory of words, aud yet cannot be separated by any characters.

E. It is useful to discriminate, according to the ramification and duration,

a. The simple plant, the lateral buds of which are flowers (*Herbula*) e. g. *Cuscuta*, *Myosurus:*

b. The branched stalk, Herb (*Herba*), e. g. *Anagallis*, *Veronica verna*.

c. With underground stems, stalks above ground, Undershrub (*Suffrutex*), e. g. *Aconitum*, *Napellus*, *Pæonia officinalis*.

d. Stem branched from below, without predominance of the main stem, Bush (*Frutex*), e. g. *Prunus spinosa*, *Juniperus Sabina*.

e. Trunk, the lower branches of which soon die, and which only bears a crown, Tree (*Arbor*), e. g. *Pyrus terminalis*, *Fagus sylvatica*.

N.B. We also reckon among trees those stems also which branch from below upward, but in which the main axis is developed in far the greatest proportion, and may readily be traced to the summit, e. g. *Populus dilatata*, *Abies excelsa*. These might even be called *Arbor fruticosa*.

If the great mass of Exogens are distinctly known from Endogens by their peculiar manner of growth and by the arrangement of their woody matter, they are not less clearly defined by external marks.

Their leaves have the veins ramifying from the midrib, or ribs if there are several, in so intricate a manner as to give the appearance of irregular net-work. Their veins never run parallel with each other without ramifications; for if, as sometimes happens, they appear to do so, it will be found that the appearance is confined to the principal veins or ribs, and that the secondary veins between them ramify in the usual way. The leaves are moreover in most cases articulated with the stem, leaving behind them a clean scar when they die, not rotting away and hanging upon the stem in the form of a ragged sheath, as is common in Endogens. Moreover they are frequently furnished with stipules, an unusual circumstance in Endogens.

The flowers of Exogens are usually constructed upon a quinary type; that is, they have 5 sepals, 5 petals, aud 5 stamens, or some power of that number; now and then they vary to a type of 4, or they exceed the number 5; but we very rarely find the ternary structure of Endogens present in them. If, as in *Anonaceæ*, *Berberaceæ*, and other orders, the sepals and petals follow a ternary type, the number 3 is lost in the stamens or the ovary. The natural order *Menispermaceæ* is the only one among Exogens in which the ternary type regularly pervades all the parts of the flower.

In their manner of growth they rarely resemble Endogens. The consequence of the ramification of the veins is to give their leaves a broad and rounded figure, the effect of which upon their general

Exogenous Vegetation.

appearance is to produce the rounded lumpish aspect that we recognise in all the trees naturally inhabiting this country. In no known instance does the stem grow by the development of a single terminal bud; so that we never find in this class the columnar aspect of palm-trees [GYMNOSPERMS], unless the genus *Theophrasta* be considered an exception. Consequently a landscape consisting of nothing but Exogenous plants would resemble the imaginary sceno that forms the subject of the preceding cut.

The differences between Exogens and Endogens, thus strongly marked in the stem, leaves, and flowers, are connected with others in the embryo. [REPRODUCTION IN PLANTS; SEED.] In Exogens of the commou kind this orgau has two lobes, held together by a minute central body, the upper end of which, between the lobes, is the plumule or rudimentary stem, the lower the radicle or rudimentary root; the lobes themselves, or cotyledons, are rudimentary leaves. This structure is readily seen in a hazel-nut or a garden-bean; the deviations from it are few and unimportant as compared with those of Endogens. Three or a greater number of cotyledons may be present in a whorl, instead of two opposite to each other. Or one of the two cotyledons may be much smaller than the other, as in *Trapa;* or they may be deeply lobed, as in the garden-cress. But in all these cases the deviations are obviously reconcileable with the typical character of being Dicotyledonous.

When the embryo of an Exogen germinates, the radicle simply lengthens at its point, without having to break through the coat of the embryo; on this account Exogens have been named Exorhizal.

The result of this examination is, that the great class of Exogens has five important, and in some measure independent characters, by which its limits are settled.

1. The wood is exogenous.
2. The veins of the leaves are netted.
3. The fructification is formed upon a quinary or quaternary type.
4. The embryo is dicotyledonous.
5. The germination is exorhizal.

Hence Exogens have received two other names in allusion to such characters; they are commonly called *Dicotyledones;* and *Exorhizæ* is another but less common appellation. Moreover, they are the *Phanerocotyledoneæ* of Agardh, the *Anthophytæ* and *Carpophytæ* of Oken's school, the *Dichorgana* of Schultz, the *Phylloblastæ* of Reichenbach; not to mention other names still more obscure.

In consequence of imperfect development, and the abortion or multiplication of parts, mauy deviations occur from the above characters. But as in Endogens, so in these, there is uot in consequence any real difficulty in distinguishing Exogens from other plants. Suppose the stem to be so slightly formed, as in *Podostemaceæ* or the aquatic *Halorageæ*, as not to arrive at a state in which the exogenous arrangement is perceptible, we have the dicotyledonous embryo and the typical number of the floral organs to guide us. Let the leaves appear as scales, as in *Lathræa, Orobanche,* and the like; still there is the embryo or again the floral proportions. If the fructification is absolutely ternary as in *Menispermaceæ*, the organization of the stem, leaves, and embryo reveals the true nature of such plants. Or if the embryo is undivided, as in *Cuscuta*, and at the same time the veins of the leaves deficient, and all this with an incomplete formation of woody matter, then the number of parts iu the flower remains to prevent our falling into error. It is therefore always to be remembered, that the limits of this great class are not exclusively determined by one single character, but by a combination of five; a part of which may be occasionally exceptional or undiscoverable.

Liko all other natural assemblages, Exogens have many analogies with other parts of the vegetable kingdom. We have already adverted to the Podostemaceous order of this class representing distinctly the Pistiaceous order, or at least *Lemna* among Endogens. *Piperaceæ* are distinct analogies here to the *Araceæ* of Endogens, *Chenopodiales* to *Glumosæ*, and possibly *Menispermaceæ* to *Smilaceæ*.

Whatever uses there may be in the vegetable kingdom are to be found in this class, which comprehends four-fifths of the natural orders, and probably not much less than the same proportion of species. Timber, in particular, is their exclusive produce, aud if corn has no direct analogy in Exogens, at least a substitute for it is furnished by the potato and the cassava.

Considering the very great numbers of Exogens—they may be rated at 50,000 or 60,000 at a low computation—it is not surprising that it should be here that the systematic botanist experiences his great difficulties. Comparatively no embarrassment worth notice occurs in the arrangement of Endogens; but in Exogens the difficulties are so great as to have hitherto baffled the most acute writers. We do not mean with regard to the natural orders themselves, for they are in general well understood and defined: our observation applies to a collocation of the orders, or in other words, to the construction of groups of a secondary value which shall be as natural and as well defined as the orders themselves. In a recent enumeration we find no fewer than 231 orders of Exogens. It is obviously impracticable to study so large a number of combinations without breaking them into groups, and accordingly various methods have been proposed.

Jussieu, adopting to a certain extent the views of his predecessors, considered—1st, the separation of the petals, 2nd, their combination, or 3rd, their absence, of primary consequence; and adding to this, 4th, the separation of the sexes in flowers having no petals, he formed the four groups of—1st, Polypetalous; 2nd, Monopetalous; 3rd, Apetalous; and 4th, Diclinous plants. The first three of these he again subdivided accordiug as their stamens or their corolla grew under the ovary (hypogyuous), upon the calyx (perigynous), or upon the ovary (epigynous); then the mouopetalous epigynous group was subdivided into plants having united stamens and those having them distinct; the result being eleveu classes, which were placed by Jussieu in the following order:—

			Class.
Apetalous	Stamens epigynous		1
	Stamens perigynous		2
	Stamens hypogynous		3
Monopetalous	Corolla hypogynous		4
	Corolla perigynous		5
	Corolla epigynous	anthers uuited	6
		anthers distinct	7
Polypetalous	Stamens epigynous		8
	Stamens hypogynous		9
	Stamens perigynous		10
Diclinous			11

This was however so artificial a distribution, that botanists soon found it as unsatisfactory as it was simple. Various changes have therefore been recommended from time to time, some of which are the following:—

In 1813, De Candolle, dropping the names of all Jussieu's classes, and abolishing many of them, proposed to arrange as follows the 113 orders of Exogens with which he was at that time acquainted.

			Class.
Polypetalous	Petals hypogynous (*Thalamifloræ*)		1
	Petals perigynous (*Calycifloræ*)		2
Monopetalous	Corolla perigynous	*Corollifloræ*	3
	Corolla hypogynous		4
Apetalous		(*Monochlamydeæ*)	5

Thus the classes were reduced from eleven to five, which was a defect; but those which remainod were supposed to be more natural, which would have been an advantage. Five years afterwards, in his 'Regni Vegetabilis Systema Naturale,' he added the names inclosed within parentheses, and he broke up the *Thalamifloræ* into five cohorts, but without stating what orders he arranged under them. We do not find that he ever pursued the subject farther. Since that period this great botanist has occupied himself with the special study of the natural orders, and the public has derived no advantage from his general views, which is much to be regretted.

In 1825, Professor Agardh of Lund, afterwards bishop of Carlshad, proposed a great change iu tho subordination of Exogens, retaining the priuciples of primary division recognised by Jussieu and De Candolle, but forming them into twenty subdivisions, defined by various characters analogous to those by which the orders themselves are circumscribed. This, we believe, is the first step of any consequence towards putting Exogens into a more natural grouping than that of Jussieu. In many respects the subdivisions are, as far as they go, unobjectionable; but they have excited scarcely any attention among systematic botanists. The necessity however of some better method of subordination than that of Jussieu and De Candolle has become evident to everybody; and attempts have been made to effect this by Drs. Bartling, Schultz, Von Martius, and others on the continent, and by Dr. Lindley in this country. The last named author has successively developed his system in his 'Nixus Plantarum,' the 'Penny Cyclopædia,' article Exogens, his 'Natural System of Botany,' and his 'Vegetable Kingdom.' We shall here give an analysis of Dr. Lindley's arrangement of Exogens, as given in the last mentioned work. Whatever may be its defects they are rather inherent to the subject than attributable to any want of knowledge or judgment in the author, as it undoubtedly displays the largest acquaintance with the details of the structure of this class of plants that has yet been displayed by any writer on systematic botany. The following is an analysis of the class of Exogens:—

Alliances of Exogeus.

Sub-Class I. Diclinous Exogens.

Flowers ♂ ♀, without any customary tendency to ⚥.

I. AMENTALES.—Flowers in catkins, achlamydeous or monochlamydeous. Carpels superior. Embryo small, with little or no albumen.

Casuarinaceæ.—Ovules 1 or 2, ascending. Radicle superior.
Betulaceæ.—Ovule 1, pendulous. Radicle superior.
Altingiaceæ.—Ovules 00. Seeds winged.
Salicaceæ.—Ovules 00. Seeds cottony.
Myricaceæ.—Ovule 1, erect. Radicle superior.
Elæagnaceæ.—Ovule 1, ascending. Radicle inferior.

II. Urticales. — Flowers scattered, monochlamydeous. Carpel single, superior. Embryo large, lying in a small quantity of albumen.

Stilaginaceæ.—Radicle superior. Ovules twin, suspended. Embryo straight, albuminous. Anthers 2-lobed, with vertical fissures.

Urticaceæ.—Radicle superior. Ovule solitary, erect. Embryo straight, albuminous. Juice limpid. Stipules small, flat.

Ceratophyllaceæ.—Radicle inferior. Embryo exalbuminous. Plumule many-leaved, large.

Cannabinaceæ.—Radicle superior. Ovule solitary, suspended. Embryo hooked, exalbuminous.

Moraceæ.—Radicle superior. Ovules solitary, suspended. Embryo hooked, albuminous.

Artocarpaceæ.—Radicle superior. Ovule solitary, erect or suspended. Embryo straight, exalbuminous. Juice milky. Stipules large, convolute.

Platanaceæ.—Radicle inferior. Embryo albuminous. Plumule minute. Juice limpid. Stipules large, deciduous.

III. Euphorbiales.—Flowers scattered, monochlamydeous. Carpels consolidated, superior. Placentæ axile. Embryo surrounded by abundant albumen. (Albumen occasionally absent.)

Euphorbiaceæ.—Ovules definite, suspended, anatropal. Radicle superior.

Gyrostemoneæ.—Ovules definite, suspended, campylotropal. Radicle inferior. Albumen mealy.

Scepaceæ.—Ovules definite, suspended, anatropal. Radicle superior, ♂, amentaceous.

Callitrichaceæ.—Ovules definite, suspended, amphitropal. Radicle superior.

Empetraceæ.—Ovules definite, ascending, anatropal. Radicle inferior.

Batideæ.—Ovules solitary, ascending, ♀, naked, combined into a succulent cone.

Nepenthaceæ.—Ovules 00, ascending. Radicle inferior. Seeds scobiform.

IV. Quernales. — Flowers in catkins, monochlamydeous. Carpel single, superior. Embryo large, lying in a small quantity of albumen.

Corylaceæ.—Ovary 2- or more celled. Ovules pendulous or peltate.

Juglandaceæ.—Ovary 1-celled. Ovule solitary, erect.

V. Garryales. — Flowers monochlamydeous, sometimes amentaceous. Carpels inferior. Embryo minute, in a large quantity of albumen.

Garryaceæ.—Flowers amentaceous. Leaves opposite, stipulate.

Helwingiaceæ.—Flowers fascicled. Leaves alternate, stipulate.

VI. Menispermales. — Flowers monochlamydeous. Carpels superior, disunited. Embryo surrounded by abundant albumen.

Monimiaceæ.—Albumen copious, solid. Seeds pendulous. Embryo small, external. Stamens perigynous.

Atherospermaceæ.—Albumen copious, solid. Seeds erect. Anthers opening by recurved valves.

Myristicaceæ.—Albumen copious, ruminated. Sepals united into a valvate cup.

Lardizabalaceæ.—Albumen copious, solid. Seeds parietal. Embryo minute.

Schizandraceæ.—Albumen copious, solid. Seeds pendulous. Embryo minute, internal. Stamens hypogynous.

Menispermaceæ.—Albumen sparing, solid. Seeds amphitropal. Embryo large.

VII. Cucurbitales.—Flowers monochlamydeous. Carpels inferior. Placentæ parietal. Embryo without albumen.

Cucurbitaceæ.—Fruit pulpy. Placentæ strictly parietal. Monopetalous.

Datiscaceæ.—Fruit dry. Placentæ strictly parietal. Apetalous.

Begoniaceæ.—Fruit dry. Placentæ projecting and meeting in the axis. Monodichlamydeous.

VIII. Papayales.—Flowers dichlamydeous. Carpels superior, consolidated. Placentæ parietal. Embryo surrounded by abundant albumen.

Papayaceæ.—Corolla monopetalous; ♀, without scales.

Pangiaceæ.—Corolla polypetalous; ♀, with scales in the throat.

Sub-Class II.—Hypogynous Exogens.

Flowers ☿, or ♂ ☿ ♀. Stamens entirely free from the calyx and corolla.

IX. Violales.—Flowers monochlamydeous. Placentæ parietal, or sutural. Embryo straight, with little or no albumen.

Flacourtiaceæ.—Flowers scattered, apetalous, or polypetalous. Petals and stamens both hypogynous. Leaves dotless, or with round dots only.

Lacistemaceæ.—Flowers in catkins, apetalous, scaly, polygamous. Stamens unilateral.

Samydaceæ.—Flowers scattered, apetalous, tubular, hermaphrodite. Leaves marked with both round and linear transparent dots. Stamens perigynous.

Passifloraceæ.—Flowers polypetalous or apetalous, coronetted. Petals perigynous, imbricated. Stamens on the stalk of the ovary. Styles simple, terminal. Seeds arillate. Leaves stipulate.

Malesherbiaceæ.—Flowers polypetalous, coronetted. Petals perigynous, imbricated. Stamens on the stalk of the ovary. Styles simple, dorsal. Seeds without aril. Leaves without stipules.

Moringaceæ.—Flowers polypetalous. Calyx many-leaved. Petals perigynous. Anthers 1-celled. Fruit stipitate, consolidated, siliquose. Seeds without albumen. Stamens perigynous.

Violaceæ.—Flowers polypetalous. Calyx many-leaved. Petals hypogynous. Stamens all perfect. Anthers crested and turned inwards. Fruit consolidated. Seeds albuminous.

Frankeniaceæ.—Flowers polypetalous. Calyx tubular, furrowed. Petals hypogynous, unguiculate.

Tamaricaceæ.—Flowers polypetalous. Calyx many-leaved. Petals hypogynous. Styles distinct. Fruit consolidated. Seeds 00, basal, comose, without albumen.

Sauragesiaceæ.—Flowers polypetalous. Calyx many-leaved. Petals hypogynous. Stamens partly sterile and petaloid. Anthers opposite; the petals naked, turned outwards. Fruit consolidated. Seeds albuminous.

Crassulaceæ.—Flowers polypetalous or monopetalous. Calyx many-leaved. Petals hypogynous. Fruit follicular, apocarpous.

Turneraceæ.—Flowers polypetalous. Petals perigynous, contorted. Styles forked. Leaves exstipulate.

X. Cistales.—Flowers monochlamydeous. Placentæ parietal or sutural. Embryo curved or spiral, with little or no albumen.

Cistaceæ.— Stamens not tetradynamous, generally indefinite. Flowers ⅘ or ⅘. Seeds with albumen. Fruit closed up.

Brassicaceæ.—Stamens tetradynamous. Flowers ⁴⁄.

Resedaceæ.—Stamens not tetradynamous, definite. Flowers not tetramerous. Seeds without albumen. Fruit usually open at the point.

Capparidaceæ.—Stamens not tetradynamous. Flowers 4. Seeds without albumen. Fruit closed up.

XI. Malvales. — Flowers monochlamydeous. Placentæ axile. Calyx valvate in æstivation. Corolla imbricated or twisted. Stamens definite or 00. Embryo with little or no albumen.

Sterculiaceæ.—Stamens columnar, all perfect. Anthers 2-celled, turned outwards.

Byttneriaceæ.—Stamens monadelphous, in most cases partly sterile. Anthers 2-celled, turned inwards.

Vivianiaceæ.—Stamens free. Disc none. Seeds with albumen. Embryo curved. Petals permanent. Calyx ribbed.

Tropæolaceæ.—Stamens free. Disc none. Seeds without albumen. Embryo amygdaloid.

Malvaceæ.—Stamens columnar, all perfect. Anthers 1-celled, turned inwards.

Tiliaceæ.—Stamens free, on the outside a disc. Seeds with albumen. Embryo straight.

XII. Sapindales. — Flowers monochlamydeous, unsymmetrical. Placentæ axile. Calyx and corolla imbricated. Stamens definite. Embryo with little or no albumen. Stamens rarely 00.

Tremandraceæ.—Flowers complete, partially symmetrical. Calyx valvate. Anthers 2-4-celled, opening by pores.

Polygalaceæ.—Flowers complete (irregular) unsymmetrical. Petals naked. Anthers opening longitudinally. Carpels 3. Seeds winged. (In one case the ovary is adherent.)

Vochyaceæ.— Flowers complete, unsymmetrical, very irregular. Petals naked. Anthers opening longitudinally. Carpels 3. Seeds winged.

Staphyleaceæ.—Flowers complete, unsymmetrical. Petals usually with an appendage or 0. Anthers opening longitudinally. Carpels 3. Seeds usually arillate, wingless.

Sapindaceæ.—Flowers complete, unsymmetrical. Petals usually with an appendage or 0. Anthers opening longitudinally. Carpels 3. Seeds usually arillate, wingless.

Petiveriaceæ.—Flowers apetalous. Carpels solitary.

Aceraceæ.—Flowers complete, unsymmetrical. Petals naked or 0. Anthers opening longitudinally. Carpels 2. Seeds without an aril.

Malpighiaceæ.—Flowers complete, partially symmetrical. Calyx imbricated. Petals naked, stalked. Ovules hanging by cords. Stigmas simple. Embryo usually convolute.

Erythroxylaceæ.—Flowers complete, partially symmetrical. Calyx imbricated. Petals with an appendage. Ovules sessile, pendulous. Stigmas capitate. Embryo straight.

XIII. Guttiferales. — Flowers monochlamydeous. Placentæ axile. Calyx imbricated. Corolla imbricated or twisted. Stamens 00. Embryo with little or no albumen. Stamens sometimes definite in number.

Dipteraceæ.—Leaves simple, alternate, with large convolute stipules. Flowers symmetrical. Petals equilateral. Calyx unequal, permanent, winged. Anthers beaked. Fruit 1-celled; 1-seeded.

Ternstromiaceæ.—Leaves simple, alternate, without stipules, or with very small ones. Flowers symmetrical. Petals equilateral. Anthers versatile. Seeds few or single. Stigmas on a long style.

Rhizobolaceæ.—Leaves digitate, opposite. Flowers symmetrical. Petals equilateral. Stigmas sessile. Seeds solitary. Embryo with an enormous radicle.

Clusiaceæ.—Leaves simple, opposite, without stipules. Flowers symmetrical. Petals equilateral. Anthers adnate, beakless. Seeds solitary or few. Stigmas sessile, radiating.

Marcgraviaceæ.—Leaves simple, alternate, without stipules. Flowers unsymmetrical. Petals equilateral. Anthers versatile. Seeds innumerable, minute. Stigmas sessile.

Hypericaceæ.—Petals oblique, glandular. Seeds numerous, naked. Styles long, distinct.

Reaumuriaceæ.—Petals oblique, glandless. Seeds few, shaggy. Styles long, distinct.

XIV. Nymphales.—Flowers dichlamydeous. Placentæ axile or sutural. Stamens 00. Embryo on the outside of a very large quantity of mealy albumen. A part have no albumen.

Nymphæaceæ—Carpels united into a many-celled fruit, with dissepimental placentæ.

Cabombaceæ.—Carpels distinct. Albumen copious. Torus absent.

Nelumbiaceæ.—Carpels distinct. Albumen 0. Torus honeycombed, very large.

XV. Ranales.—Flowers monodichlamydeous. Placentæ sutural or axile. Stamens 00. Embryo minute, inclosed in a large quantity of fleshy or horny albumen.

Magnoliaceæ.—Carpels distinct. Stipules large, convolute. Corolla imbricated. Albumen homogeneous.

Anonaceæ.—Carpels distinct. Stipules 0. Corolla valvate. Albumen ruminate.

Dilleniaceæ.—Carpels distinct. Stipules 0. Corolla imbricated. Albumen homogeneous. Seeds arillate.

Ranunculaceæ.—Carpels distinct. Stipules 0. Corolla imbricated. Albumen homogeneous. Seeds without an aril.

Sarraceniaceæ.—Carpels consolidated. Calyx permanent. Placentæ axile.

Papaveraceæ.—Carpels consolidated. Calyx deciduous. Placentæ usually parietal.

XVI. Berberales.—Flowers monodichlamydeous. Placentæ sutural, parietal, or axile. Stamens definite. Embryo inclosed in a large quantity of fleshy albumen.

Droseraceæ.—Flowers regular and symmetrical. Placentæ parietal. Stamens alternate with the petals, or twice as many.

Fumariaceæ.—Flowers irregular and unsymmetrical. Placentæ parietal. Stamens opposite the petals.

Berberidaceæ.—Flowers regular, symmetrical. Placentæ sutural. Stamens opposite the petals. Anthers with recurved valves.

Vitaceæ.—Flowers regular, symmetrical. Placentæ axile. Stamens opposite the petals. Anthers opening longitudinally.

Pittosporaceæ.—Flowers regular, symmetrical. Placentæ axile and parietal. Stamens alternate with the petals. Ovules ascending or horizontal. Corolla imbricated.

Olacaceæ.—Flowers regular, symmetrical. Placentæ axile. Stamens alternate with the petals. Ovules pendulous. Corolla valvate.

Cyrillaceæ.—Flowers regular, symmetrical. Placentæ axile. Stamens alternate with the petals, if equal to them in number. Ovules pendulous. Corolla imbricated.

XVII. Ericales.—Flowers dichlamydeous, symmetrical in the ovary. Placentæ axile. Stamens definite. Embryo inclosed in a large quantity of fleshy albumen. Stamens occasionally adherent to the corolla.

Humiriaceæ.—Flowers polypetalous. Stamens all perfect, monadelphous. Anthers 2-celled, with a long membranous connective.

Epacridaceæ.—Flowers monopetalous. Stamens all perfect, free. Seeds with a firm skin. Anthers 1-celled, opening longitudinally.

Pyrolaceæ.—Flowers half-monopetalous. Stamens all perfect, free. Seeds with a loose skin. Embryo at the base of the albumen.

Francoaceæ.—Flowers polypetalous. Stamens half-sterile and scale-like, free. Seeds with a firm skin.

Monotropaceæ.—Flowers half-monopetalous. Stamens all perfect, free. Seeds with a loose skin or wing. Embryo at the apex of the albumen.

Ericaceæ.—Flowers monopetalous. Stamens all perfect, free. Seeds with a firm or loose skin. Anthers 2-celled, opening by pores.

XVIII. Rutales.—Flowers monodichlamydeous, symmetrical. Placentæ axile. Calyx and corolla imbricated, if present. Stamens definite. Embryo with little or no albumen. Occasionally ♂ ♀.

Aurantiaceæ.—Fruit consolidated, succulent, indehiscent. Petals imbricated. Stamens free, or nearly so. Leaves dotted.

Amyridaceæ.—Fruit consolidated, hard, dry, somewhat valvular. Petals valvate. Stamens free. Leaves generally dotted.

Cedrelaceæ.—Fruit consolidated, capsular. Stamens deeply monadelphous or free. Seeds numerous, winged.

Meliaceæ.—Fruit consolidated, berried, or capsular. Stamens deeply monadelphous. Seeds few, wingless. Leaves dotless.

Anacardiaceæ.—Fruit apocarpous. Ovule single, suspended by a cord rising from the base of the carpel.

Connaraceæ.—Fruit apocarpous. Ovules collateral, ascending, orthotropal, sessile.

Rutaceæ.—Fruit finally apocarpous, few-seeded, with the pericarp separating in two layers. Ovules sessile, pendulous. Flowers ⚥.

Xanthoxylaceæ.—Fruit finally apocarpous, 1-seeded, with the pericarp separating in two layers. Ovules sessile, pendulous. Flowers ♂ ⚥ ♀.

Ochnaceæ.—Fruit finally apocarpous, 1-seeded, with the pericarp not laminating, and a succulent conical torus.

Simarubaceæ.—Fruit finally apocarpous, 1-seeded, with the pericarp not laminating, and a dry inconspicuous torus. Albumen wanting. Leaves alternate, without stipules.

Zygophyllaceæ.—Fruit finally apocarpous, few-seeded, with the pericarp not laminating, and a dry inconspicuous torus. Albumen present. Leaves opposite, with stipules.

Elatinaceæ.—Fruit finally apocarpous, many-seeded. Flowers polypetalous.

Podostemaceæ.—Fruit finally apocarpous, many-seeded. Flowers apetalous, very imperfect.

XIX. Geraniales.—Flowers monodichlamydeous, symmetrical. Placentæ axile. Calyx imbricated. Corolla twisted. Stamens definite. Embryo with little or no albumen.

Linaceæ.—Flowers symmetrical. Styles distinct. Carpels longer than the torus. Seeds with little or no albumen.

Chlænaceæ.—Flowers regular, unsymmetrical, with a permanent cup-like involucre. Stamens monadelphous. Albumen abundant.

Oxalidaceæ.—Flowers symmetrical. Styles distinct. Carpels longer than the torus. Seeds with abundant albumen.

Balsaminaceæ.—Flowers very irregular and unsymmetrical, without an involucre. Stamens distinct. Albumen none.

Geraniaceæ.—Flowers usually symmetrical. Styles and carpels combined round a long-beaked torus.

XX. Silenales.—Flowers monodichlamydeous. Placentæ free, central. Embryo external, curved round a little mealy albumen. Carpels more than one, completely combined into a compound fruit. Some slightly perigynous, others ♂ ♀.

Caryophyllaceæ.—Calyx and corolla usually both present and symmetrical (4 and 4, or 5 and 5), the latter conspicuous. Ovules amphitropal. Leaves opposite, without stipules.

Illecebraceæ.—Calyx and corolla usually both present and symmetrical (4 and 4, or 5 and 5), the latter rudimentary. Ovules amphitropal. Leaves with scarious stipules.

Portulacaceæ.—Calyx and corolla both present and unsymmetrical (2 and 5), the latter usually conspicuous. Ovules amphitropal. Leaves alternate, succulent, without stipules.

Polygonaceæ.—Calyx only present, but often coloured. Ovules orthotropal. Nut usually triangular.

XXI. Chenopodales.—Flowers monochlamydeous. Placentæ free, central. Embryo external, either curved round or applied to the surface of a little mealy or horny albumen. Carpels solitary, or if more than one distinct. Some slightly perigynous, others ♂ ♀.

Nyctaginaceæ.—Sepals united into a long (often coloured) plaited tube which separates from its base, the latter becoming hard, and forming a spurious pericarp.

Phytolaccaceæ.—Sepals separate, flat. Stamens alternate with the sepals, or 00. Carpels several (or 1).

Amarantaceæ.—Sepals separate or nearly so, flat. Stamens opposite the sepals. Anthers often 1-celled. Ovary 1; often several-seeded. Flowers scarious, surrounded by imbricated bracts.

Chenopodiaceæ.—Sepals separate or nearly so, flat. Stamens opposite the sepals. Anthers 2-celled. Ovary 1; always 1-seeded. Flowers herbaceous, naked.

XXII. Piperales.—Flowers achlamydeous. Embryo minute, on the outside of a large quantity of mealy albumen. Occasionally ♂ ♀.

Piperaceæ.—Carpel solitary. Ovule erect. Embryo lying in vitellus. Leaves opposite or alternate, with or without stipules.

Chloranthaceæ.—Carpel solitary. Ovule suspended. Embryo naked. Leaves opposite, with intermediate stipules.

Saururaceæ.—Carpels several, distinct. Ovule erect. Embryo lying in vitellus. Leaves alternate with stipules.

Sub-Class III. Perigynous Exogens.

Flowers ⚥ or ♂ ⚥ ♀. Stamens growing to the side of either the calyx or corolla. Ovary superior, or nearly so.

XXIII. Ficoidales.—Flowers monodichlamydeous. Placentæ central or axile. Corolla, if present, polypetalous. Embryo external, and curved round a small quantity of mealy albumen.

Basellaceæ.—Petals absent. Sepals distinct. Fruit inclosed in a membranous or succulent calyx. Carpel single, solitary. Seed erect.

Mesembryaceæ.—Petals numerous, conspicuous. Carpels several, consolidated.

Tetragoniaceæ.—Petals absent. Carpels several, consolidated.

Scleranthaceæ.—Petals absent. Sepals united into a tube. Carpel single, solitary. Fruit inclosed in the hardened calyx tube.

XXIV. Daphnales.—Flowers monodichlamydeous. Carpel solitary. Embryo amygdaloid, without albumen.

Thymelaceæ.—Anthers bursting lengthwise. Apetalous or polypetalous. Ovule solitary, suspended. Calyx imbricated.

Proteaceæ.—Anthers bursting lengthwise. Apetalous. Ovules erect. Calyx valvate.

Lauraceæ.—Anthers bursting by recurved valves. Leaves perfect. Fruit naked.

Cassythaceæ.—Anthers bursting by recurved valves. Leaves mere colourless scales. Fruit buried in a succulent permanent calyx.

XXV. Rosales.—Flowers monodichlamydeous. Carpels more or less distinct. Placentæ sutural. Seeds definite. Corolla, if present, polypetalous. Embryo amygdaloid, with little or no albumen.

Calycanthaceæ.—Flowers consisting of numerous imbricated scales. Cotyledons convolute.

Chrysobalanaceæ.—Flowers polypetalous (or apetalous), nearly or quite regular. Carpel solitary. Style proceeding from the base of the ovary.

Fabaceæ, or *Leguminosæ*. — Flowers polypetalous or apetalous, paphoriaceous (or leguminous). Carpel solitary, with the style proceeding from the apex of the ovary.

Drupaceæ.—Flowers polypetalous, regular, drupaceous. Carpel solitary, with the style proceeding from the apex of the ovary.

Pomaceæ.—Flowers polypetalous, regular. Carpels adhering to the calyx by their back.

Sanguisorbaceæ.—Flowers apetalous. Carpel solitary, inclosed in a hardened calyx-tube, forming a false pericarp.

Rosaceæ.—Flowers polypetalous. Carpels free from the calyx, and quite or nearly so from each other.

XXVI. Saxifragales.—Flowers monodichlamydeous. Carpels consolidated. Placentæ sutural or axile. Seeds 00. Corolla, if present, polypetalous. Embryo taper, with a long radicle, and little or no albumen.

Saxifragaceæ.—Styles distinct. Leaves alternate.

Hydrangeaceæ.—Styles distinct. Leaves opposite, without stipules.

Cunoniaceæ.—Styles distinct. Leaves opposite, with large interpotiolar stipules.

Brexiaceæ.—Styles consolidated. Calyx many-leaved. Albumen 0. Leaves alternate.

Lythraceæ.—Styles consolidated. Calyx tubular, permanent, with the petals in the margin. Albumen 0. Leaves opposite.

XXVII. Rhamnales.—Flowers monodichlamydeous. Carpels consolidated. Placentæ axile. Fruit capsular, berried, or drupaceous. Seeds definite. Embryo amygdaloid, with little or no albumen.

Penæaceæ.—Flowers apetalous. Ovary composed of 4 carpels. Calyx tubular, with definite divisions. Cotyledons consolidated.

Aquilariaceæ.—Flowers apetalous. Ovary composed of 2 carpels. Calyx tubular, with a definite number of divisions. Cotyledons amygdaloid.

Ulmaceæ.—Flowers apetalous. Ovary composed of 2 carpels. Calyx imperfect, and irregularly divided at the edge. Cotyledons thin and leafy.

Rhamnaceæ.—Flowers polypetalous. Calyx valvate. Stamens opposite petals. Seeds erect.

Chailletiaceæ.—Flowers polypetalous. Calyx valvate. Stamens alternate with the petals. Seeds pendulous.

Hippocrateaceæ.—Flowers polypetalous. Calyx imbricated. Stamens (3), monadelphous.

Celastraceæ.—Flowers polypetalous. Calyx imbricated. Stamens ⅘, distinct.

Stackhousiaceæ.—Flowers monopetalous. Stamens episepalous.

Sapotaceæ.—Flowers monopetalous. Stamens epipetalous. Ovules ascending. Radicle short. Cotyledons amygdaloid.

Styracaceæ.—Flowers monopetalous. Stamens epipetalous. Ovules in part at least suspended. Radicle long. Cotyledons leafy.

XXVIII. Gentianales. — Flowers dichlamydeous, monopetalous, symmetrical. Placentæ axile or parietal. Embryo minute, or with the cotyledons much smaller than the radicle, lying in a large quantity of albumen.

Ebenaceæ.—Stipules 0. Stigmas simple, sessile, radiating.

Aquifoliaceæ.—Stipules 0. Stigmas simple, at the end of a manifest style. Placentæ axile. Seeds definite, pendulous. Corolla imbricated.

Apocynaceæ.—Stipules 0. Stigmas collected into a massive head, expanded at the base in the form of a ring or membrane, and contracted in the middle. Albumen sometimes 0.

Loganiaceæ.—Leaves opposite, with intervening stipules.

Diapensiaceæ.—Stipules 0. Stigmas simple, at the end of a manifest style. Placentæ axile. Seeds indefinite, peltate. Stamens interpetalous.

Stilbaceæ.—Stipules 0. Stigmas simple, at the end of a manifest style. Placentæ axile. Seeds definite, erect. Corolla valvate. Flowers unsymmetrical.

Orobanchaceæ.—Stipules 0. Stigmas simple, at the end of a manifest style. Placentæ parietal. Flowers didynamous.

Gentianaceæ.—Stipules 0. Stigmas simple, at the end of a manifest style. Placentæ parietal. Flowers regular.

XXIX. Solanales.—Flowers dichlamydeous, monopetalous. Placentæ axile. Fruit 2-3-celled. Embryo large, lying in a small quantity of albumen.

Oleaceæ.—Stamens free, 2 or 4.

Solanaceæ.—Stamens free, 5. Placentæ axile. Embryo terete.

Asclepiadaceæ.—Anthers and stigmas consolidated into a column.

Cordiaceæ.—Stamens free, 5. Placentæ axile. Cotyledons leafy, folded longitudinally.

Convolvulaceæ.—Stamens free, 5. Placentæ basal. Cotyledons leafy, doubled up.

Cuscutaceæ.—Stamens free, 5. Placentæ basal. Embryo filiform, spiral.

Polemoniaceæ.—Stamens free, 5. Placentæ axile. Cotyledons straight, plano-convex.

XXX. Cortusales.—Flowers dichlamydeous, monopetalous, symmetrical. Placentæ free. Central embryo lying among a small quantity of albumen. Occasionally monochlamydeous or polypetalous.

Hydrophyllaceæ.—Stamens alternate with the petals. Styles 2. Inflorescence circinate.

Plumbaginaceæ.—Stamens opposite the petals. Fruit membranous, 1-seeded. Styles 5. Stem herbaceous.

Plantaginaceæ.—Stamens alternate with the petals. Style 1. Inflorescence straight.

Primulaceæ.—Stamens opposite the petals. Fruit capsular, many-seeded. Style 1. Stem herbaceous.

Myrsinaceæ.—Stamens opposite the petals. Fruit indehiscent, drupaceous. Style 1. Stem woody.

XXXI. Echiales.—Flowers dichlamydeous, monopetalous, symmetrical or unsymmetrical. Fruit nucamentaceous, consisting of several 1-seeded nuts, or of clusters of them separate or separable. Embryo large, with little or no albumen. (Very rarely hypogynous.) Regular-flowered orders passing from Solanals.

Jasminaceæ.—Flowers regular, ⅔, unsymmetrical. Stamens 2. Fruit 2-lobed. Stigma naked.

Salvadoraceæ.—Flowers regular, symmetrical. Stamens 4. Fruit simple. Stigma naked.

Ehretiaceæ.—Flowers regular, symmetrical. Stamens 5. Stigma naked. Nuts 4. Confluent inflorescence circinate.

Nolanaceæ.—Flowers regular, symmetrical. Stamens 5. Nuts 5 or ⅘. Stigma naked. Inflorescence straight.

Boraginaceæ.—Flowers regular, symmetrical. Stamens 5. Nuts 4 or ⅔. Stigma naked. Inflorescence circinate.

Brunoniaceæ.—Flowers regular, symmetrical. Nut solitary. Stigma indusiate. (Stamens hypogynous.) Irregular-flowered. Orders passing into Bignoniads.

Lamiaceæ.—Flowers irregular, unsymmetrical. Nuts 4. Ovule erect.

Verbenaceæ.—Flowers irregular, unsymmetrical. Nuts confluent. Ovules erect.

Myoporaceæ.—Flowers irregular, unsymmetrical. Nuts confluent. Ovules pendulous. Anthers 2-celled.

Selaginaceæ.—Flowers irregular, unsymmetrical. Nuts confluent. Ovules pendulous. Anthers 1-celled.

XXXII. Bignoniales.—Flowers dichlamydeous, monopetalous, unsymmetrical. Fruit capsular or berried, with its carpels quite consolidated. Placentæ axile or parietal, or free central. Embryo with little or no albumen.

Pedaliaceæ.—Placentæ parietal. Fruit bony or capsular. Embryo amygdaloid. Radicle short.

Gesneraceæ.—Placentæ parietal. Fruit capsular or baccate. Embryo with minute cotyledons. Radicle long.

Crescentiaceæ.—Placentæ parietal. Fruit succulent, hard-shelled. Embryo amygdaloid. Radicle short.

Bignoniaceæ.—Placentæ axile. Seeds winged, sessile, without albumen. Cotyledons large, leafy.

Acanthaceæ.—Placentæ axile. Seeds wingless, attached to hard placental processes, without albumen. Cotyledons large, fleshy.

Scrophulariaceæ.—Placentæ axile. Seeds albuminous. Cotyledons scarcely larger than or not so large as the radicle.

Lentibulariaceæ.—Placentæ free. Central seeds minute, without albumen. Cotyledons much smaller than the radicle.

Sub-Class IV. Epigynous Exogens.

Flowers ⚥ or ♂ ⚥ ♀. Stamens growing to the side of either the calyx or corolla. Ovary inferior, or nearly so.

XXXIII. Campanales.—Flowers dichlamydeous, monopetolous. Embryo with little or no albumen.

Campanulaceæ.—Ovary 2 or more celled. Anthers free, or half united. Stigma naked. Corolla valvate, regular.

Lobeliaceæ.—Ovary 2 or more celled. Anthers syngenesious. Stigma surrounded by hairs. Corolla valvate, irregular.

Goodeniaceæ.—Ovary 2 or more celled. Anthers syngenesious or free. Stigma indusiate. Corolla induplicate.

Stylidiaceæ.—Ovary 2 or more celled. Stamens and styles united into a column. Corolla imbricated.

Valerianaceæ.—Ovary 1-celled. Corolla imbricated. Anthers free. Ovule pendulous. Albumen none.

Dipsacaceæ.—Ovary 1-celled. Corolla imbricated. Anthers free. Ovule pendulous. Seeds albuminous.

Calyceraceæ.—Ovary 1-celled. Corolla valvate. Anthers syngenesious. Ovule pendulous. Seeds albuminous.

Asteraceæ.—Ovary 1-celled. Corolla valvate. Anthers syngenesious. Ovule erect. Albumen none.

XXXIV. Myrtales.—Flowers dichlamydeous, polypetalous. Placentæ axile. Embryo with little or no albumen. (Occasionally monochlamydeous.)

Combretaceæ.—Ovary 1-celled. Ovules pendulous. Leaves dotless. Seeds without albumen. Cotyledons convolute.

Alangiaceæ.—Ovary 1-celled. Ovules pendulous. Leaves dotless. Seeds albuminous. Cotyledons flat.

Chamælauciaceæ. — Ovary 1-celled. Ovules ascending. Leaves dotted. Embryo fused into a solid mass.

Haloragaceæ.—Ovary with more than 1 cell. Flowers polypetalous or apetalous. Calyx open, minute. Stamens definite. Ovules pendulous. Cotyledons minute. (Occasionally 1-celled.)

Onagraceæ.—Ovary with more than 1 cell. Flowers polypetalous or apetalous. Calyx valvate. Stamens definite. Ovules horizontal or ascending. Cotyledons flat, much larger than the radicle.

Rhizophoraceæ.—Ovary with more than 1 cell. Flowers polypetalous. Calyx valvate. Stamens indefinite. Cotyledons flat, much shorter than the radicle, which germinates before the fruit falls.

Belvisiaceæ.— Ovary with more than one cell. Flowers monopetalous, coronated. Calyx valvate. Stamens indefinite, monadelphous. Cotyledons amygdaloid.

Melastomaceæ.—Ovary with more than 1 cell. Flowers polypetalous. Calyx imbricated. Stamens definite. Anthers rostrate. Leaves usually dotless.

Myrtaceæ.—Ovary with more than 1 cell. Flowers polypetalous or apetalous (or valvate). Calyx imbricated. Stamens 00. Anthers oblong. Leaves usually dotted.

Lecythidaceæ.—Ovary with more than 1 cell. Flowers polypetalous. Calyx valvate or imbricated. Stamens 00, in part collected into a fleshy hood. Anthers oblong. Leaves dotless.

XXXV. Cactales.—Flowers dichlamydeous, polypetalous. Placentæ parietal. Embryo with little or no albumen.

Homaliaceæ.—Sepals and petals distinct. Stamens opposite the petals. Styles separate. Ovules pendulous.

Loasaceæ.—Sepals and petals distinct. Stamens scattered. Styles confluent. Ovules pendulous. Seeds albuminous.

Cactaceæ.—Sepals and petals numerous, indistinguishable. Stamens scattered. Styles confluent. Ovules horizontal. Seeds without albumen.

XXXVI. Grossales.—Flowers dichlamydeous, polypetalous. Seeds numerous, minute. Embryo small, lying in a large quantity of albumen.

Grossulariaceæ.—Fruit pulpy. Placentæ parietal.

Escalloniaceæ.—Fruit capsular. Pacentæ axile. Style and stamens definite. Calyx imbricated.

Philadelphaceæ.—Fruit capsular. Placentæ axile. Styles disunited. Stamens 00. Calyx valvate.

Barringtoniaceæ.—Fruit pulpy or fibrous. Placentæ axile. Style 1. Stamens 00. Calyx imbricated.

XXXVII. Cinchonales. — Flowers dichlamydeous, monopetalous. Embryo minute, lying in a large quantity of albumen.

Vacciniaceæ.—Stamens epigynous. Anthers opening by pores.

Columelliaceæ. — Stamens epipetalous, bursting longitudinally. Anthers sinuous. Flowers unsymmetrical.

Cinchonaceæ. — Stamens epipetalous, bursting longitudinally. Anthers straight. Leaves with interpetiolar stipules.

Caprifoliaceæ. — Stamens epipetalous, bursting longitudinally. Anthers straight. Fruit consolidated. Leaves without stipules.

Galiaceæ.—Stamens epipetalous, bursting longitudinally. Anthers straight. Fruit didymous. Leaves verticillate, without stipules.

XXXVIII. Umbellales.—Flowers dichlamydeous, polypetalous. Seeds solitary, large. Embryo small, lying in a large quantity of albumen.

Apiaceæ.—Fruit didymous, with a double epigynous disc.

Araliaceæ.—Fruit not didymous, without a double epigynous disc, 3 or more celled. Pentamerous flowers. Corolla valvate. Leaves alternate, without stipules. Anthers turned inwards, opening lengthwise.

Cornaceæ.—Fruit not didymous, without a double epigynous disc, 2 or more celled. Tetramerous flowers. Corolla valvate. Leaves opposite, without stipules.

Hamamelidaceæ.—Fruit not didymous, without a double epigynous disc, 2-celled. Corolla imbricated. Leaves alternate, with stipules. Anthers with deciduous valves.

Bruniaceæ.—Fruit not didymous, without a double epigynous disc, 3- (or 1-) celled. Corolla imbricated. Leaves alternate, without stipules. Anthers turned outwards, opening lengthwise.

XXXIX. Asarales.—Flowers monochlamydeous. Embryo small, lying in a large quantity of albumen.

Santalaceæ.—Ovary 1-celled. Ovules definite, with a coated nucleus.

Loranthaceæ.—Ovary 1-celled. Ovules definite, with a naked nucleus.

Aristolochiaceæ.—Ovary 3-6-celled. Ovules 00.

On this arrangement Dr. Lindley makes the following general remarks :—

"The office of reproduction is, after that of sustaining life, the most essential in the economy of plants and animals, and therefore the modifications which are found in the organs of reproduction may be expected to furnish the best characters for classification, after those of nutrition. The latter have been already employed as the foundations of the classes, as far as they appear susceptible of being so applied; the former, consisting of the stamens and pistil, have been little used for the classes, and appear to present as many modifications as are required for secondary divisions. That was the opinion of Linnæus, who adopted them in the construction of the classes and orders of his sexual system; but he mainly relied upon their number, which is a circumstance of little or no importance, and where that was done his classification proved useless; but in those parts of the system in which he made use of other circumstances, as in his *Monadelphia*, *Diadelphia*, *Tetradynamia*, *Didynamia*, *Syngenesia*, &c., his divisions ceased wholly or in part to be artificial, and although in some instances modified, still correspond essentially with the natural orders of modern botanists. Nor did the importance of the stamens and pistil escape the keen eye of Jussieu, who relied upon them very much in the construction of his ingenious system. In the first place he separated from all other Exogens those which have the stamens in one flower and the pistil in another, and he called them Diclinous, and by this process he brought together a collection of natural orders corresponding with the Monœcious and Diœcious plants of Linnæus. No one can doubt that this was a judicious step, and upon the whole the plants collected in the Diclinous division resemble each other more than they resemble anything else; but he excluded a large number of truly Diclinous plants, which are scattered over other parts of his classification, and this has led to the idea that the distinction itself was a bad one, an opinion in which I formerly concurred; but a more careful examination of it since, and an extensive acquaintance with the vegetable kingdom, has entirely convinced me that we have no available characters for breaking up Exogens into primary groups, or sub-classes, superior to those of separated and united sexes, that is to diclinism and hermaphroditism. Not that they are without exceptions; to employ the forcible language of Jussieu himself:—'Ut in præcedente serie nonnullas diclinis hermaphroditis commixtas plantis admittit exceptæ, sic in diclinum ordines quædam irrepunt hermaphroditæ; consentiente aut jubente naturâ, quæ stabiliores interdum eludit regulas, nonuunquam instabilis ipsa aut abstrusis legibus obtemperans.' ('Gen. Pl.' 384.) But if what are called polygamous plants, that is to say, such as have a rudimentary pistil in the male flowers, and rudimentary stamens in the female flowers, are regarded as being hermaphrodite, as they surely are, and the idea of a diclinous structure is limited to cases of a total separation of the stamens and the pistil, these exceptions are reduced to a small and unimportant number of no moment in a classification. For this reason then the Diclinous sub-class of Jussieu is still preserved and increased by modern discoveries, and improved by the expulsion of such plants as *Piper*, *Gnetum*, *Ulmus*, and others, which belong to hermaphrodite orders, or have other affinities than those suggested by Jussieu. In this way Exogens are broken up into two groups, the one Diclinous and the other Hermaphrodite. The latter is divided by almost everybody into Polypetalous, Monopetalous, and Apetalous sub-classes, following the old systematists who knew of little beyond external characters, and had small acquaintance with any plants except those of Europe. But all experience shows, what reason seems to indicate, that no great natural combinations can be effected by such distinctions. Exceptions to the constancy of such characters are endless; there is probably not one polypetalous order that is not also apetalous, and many of them are even monopetalous, of which Rueworts, Houseleeks, Anonads, Leguminous plants, Milkworts, and many more afford familiar examples. The apetalous orders are occasionally polypetalous, as in many genera of Buck-Wheats and Daphnad's. The monopetalous structure becomes polypetalous in all but a very few cases, even indeed in such natural orders as the Primworts; and it even disappears altogether, as in Oliveworts and

Primworts. Nor is it probable that characters derived from the calyx and corolla should be of the very highest value; for in the first place those organs are physiologically identical, their distinction having no real existence except in certain special instances; and in the next place the importance of them to the act of reproduction can hardly be considerable, when we find that plants are multiplied quite as well in their absence as in their presence, and even that, as in the Violet, some Leguminous plants, the common Apple, &c., which habitually produce them, seeds are matured as freely when they are partially away as when in a state of high development. For this reason the calyx and corolla are here rejected as organs suited for distinguishing the primary groups, or the sub-classes of Exogens. We are not however justified in assuming that the calyx and corolla are never of any high importance in plants, and therefore, while they are objectionable as forming the basis of a classification per se, they are recognised as having a real value in connection with the stamens. If the stamens have no adhesion to either calyx or corolla, then it may be assumed that the latter organs may be dispensed with, and for this reason the first sub-class of hermaphrodite Exogens is characterised by the stamens standing entirely clear of the floral envelopes, or being, in the language of Jussieu, hypogynous. But if there is any adhesion between the stamens and either the calyx or corolla, it may equally be assumed that the one organ is in some way necessary to the other; for this reason the perigynous character is admitted as a valid mark of a sub-class; not however a slight and inappreciable adhesion, but a real and manifest union of the parts; and it is considered immaterial whether the stamens grow on the petals or the calyx, provided they grow on one of them.

"Beyond this we have that further degree of adhesion, to which Jussieu gave the name of Epigynous, consisting of a union not only of the calyx or corolla to the stamens, but of all those organs to the sides of the ovary. This, in which it may be supposed that a higher degree of necessity for the incorporation of the floral organs exists than in the former case, is taken as the distinctive mark of a third sub-class of hermaphrodite Exogens, so that the sub-classes are established on the following grounds:—

Flowers absolutely unisexual . . .	I. DICLINOUS.
Flowers hermaphrodite:—	
Stamens not adhering to either calyx or corolla	II. HYPOGYNOUS.
Stamens adhering to either calyx or corolla	III. PERIGYNOUS.
Stamens, calyx, and corolla all adhering to the side of the ovary	IV. EPIGYNOUS.

"This it may be said is essentially the old plan of Jussieu; but there is this material difference between the method now proposed and that of the great chief of the French school; that what he treated as a secondary character is made primary; while his primary distinction of polypetalous, monopetalous, and apetalous structure is treated quite as a subordinate consideration, as it surely deserves to be. If the classification thus obtained be attentively studied it will be found to offer many entirely new combinations, while others of universally recognised truth are not disturbed by it. Of these new combinations there are few to which any serious objection seems to apply, and it is believed that the larger part of them are more opposed to our prejudices than to truth. Not that I have the presumption to suppose that they will meet the universal approval of botanists. What method of classification ever has or ever can be? So long as there are points of view from which a survey may be taken of the vegetable kingdom, so long will there be conflicting opinions as to the way in which the objects that meet the eye can best be grouped.

"In former attempts at redistributing the natural orders of Exogens, I had proposed to throw into one sub-class all those in which the embryo is very small, as compared with the albumen in which it is imbedded, and I still think that this peculiarity is of as much importance among plants as the being oviparous or viviparous among animals. But although I do not at present see a reason for retracting my former opinion on that subject, yet I do see that the time is hardly come for carrying out such a principle satisfactorily; and therefore, instead of employing it for the character of a sub-class, it has only been used as a means of limiting alliances.

"Although, from the complicated nature of the affinities of plants, no hope can be reasonably entertained of securing an unbroken line of transition from one end to the other of the series in which the various groups must necessarily be treated of, yet it will be found that the method here proposed offers very few considerable gaps in the chain of relationship.

"Commencing with the Amental Alliance, which seems to stand in near relation to the Joint Firs (*Gnetaceæ*), among Gymnosperms, the passage to the Urtical and Euphorbial is too plain to require explanation; of the latter the Quernal and Garryal may be regarded as epigynous, forming the first without albumen, the second with an abundance of it. Nutmegs in the Menispermal Alliance then fit in; and the twining Menispermads may be taken as an aticipation of Cucurbitals, of which the Papayal Alliance is an offset a little out of the direct line of succession. Even to the latter however an analogue is found among Violals, in the form of Bixads and Samyds; thence Turnerads conduct us directly into the Cistal Alliance.

"At this point we quit the debateable ground of affinities, and passing necessarily through Malvals, Sapindals, and Guttiferals, we reach the Nymphal Alliance through Tutsans. Here however the chain is evidently broken, and probably the sequence is wrong. The Water-Shields (*Cabombaceæ*), among Nymphals, pass directly into the Ranal Alliance by way of the Crow-Foots, whence Poppy-Worts join Fume-Worts in the Berberal Alliance. At this place Cyrillads appear to form a connecting link with Humiriads among Ericals, and the latter pass directly into the Rutal Alliance by the intervention of such plants as *Correa*. From Rutals the passage is easy to the Geranial, Sileual, and Chenopodal Alliances, which suddenly stop with the Peppers; this is however a doubtful case of affinity, although such a plant as *Batis* may seem to justify the approximation. At the point now reached the perigynous sub-class is penetrated by way of the Ficoidal Alliance, which might be almost united with the Chenopodal. Scleranths, among Ficoidals, seem to present a transition to Salvadorads in the Daphnal Alliance, of which again a part of the Rosal Alliance is almost a polypetalous form. From Rosals to Saxifragals, and then by way of *Brexia* to Rhamnads, is but a step. At this point the Gentianal Alliance is entered by way of Holly-Worts, and we quit it by moving from Gentian-Worts into the Solanal Alliance. The Cortusal, Echial, and Bignonial Alliances may be passed without any obstacle, and thus we reach the end of the perigynous sub-class. Gesner-Worts in the Bignonial Alliance fit on to Goodeniads, among the Campanals, of the epigynous sub-class. These join Myrtals through Myrobalans on the one hand, and Napoleon-Worts on the other. From Myrtals we pass to the Cactal Alliance, which may be theoretically considered a parietal condition of the former, so near do the Onagrads of the former approach the Loasads of the latter group. This brings us to Barringtoniads and other orders collected in the Grossal Alliance. The Cinchonals are entered by way of Bilberry-Worts, and quitted through the Stellate plants, which evidently touch Umbellifers in the Umbellal Alliance. At this point a passage is effected into the last alliance, that of Asarals, by way of Witch-Hazels and Sandal-Worts, till the whole line is finally closed by the Birth-Worts. These singular plants with their ternary flowers seem to have an uncontestable relationship to Yams among Dictyogens, and thus the circle of affinities eventually returns into itself.

"Each of the sub-classes consists of alliances which have also in many instances a strong lateral relation; so that in order to obtain a clear idea of their mutual correspondence it is necessary to place them side by side as well as in succession. This is very obvious in the following instances:—

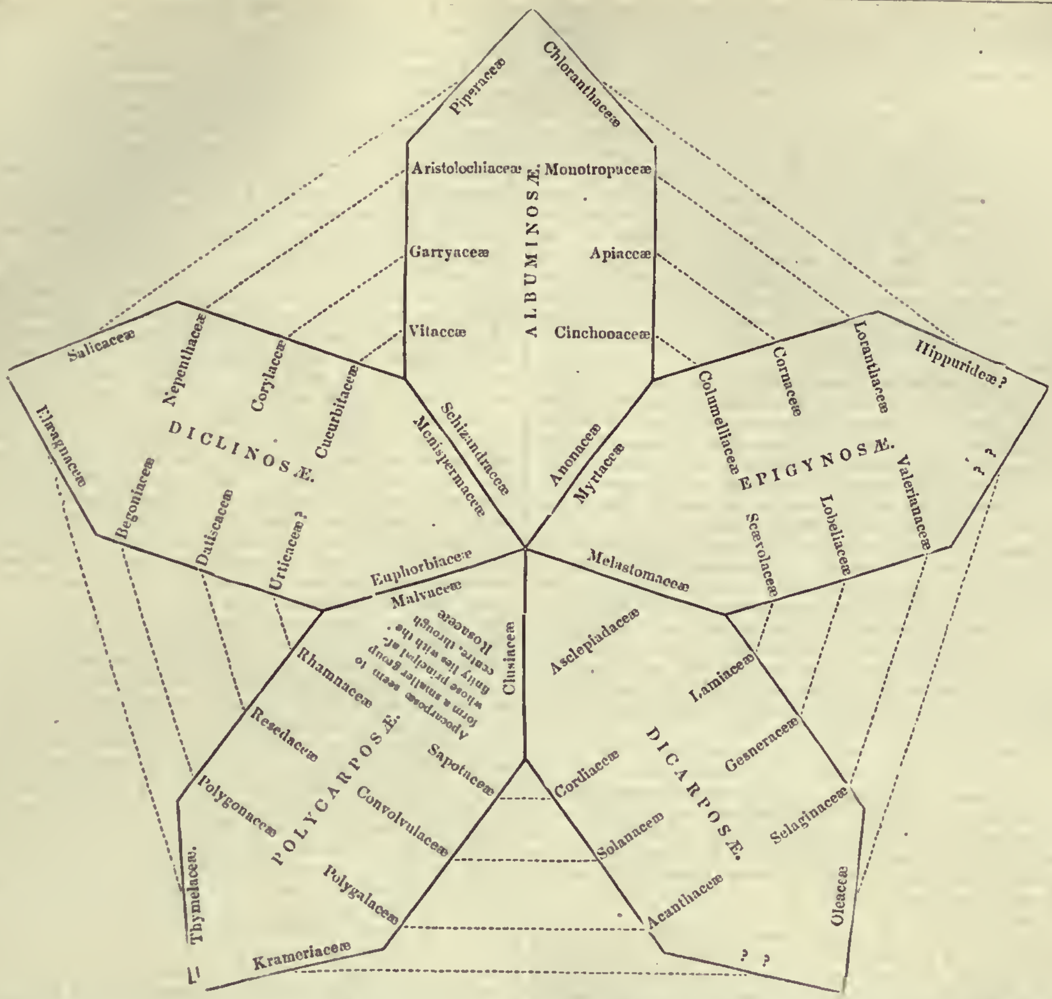
Diclinous.	Hypogynous.	Perigynous.	Epigynous.
Urticales . . .	*Chenopodales* .	*Ficoidales* . . .	
Euphorbiales . .	*Malvales* . .	*Daphnales* . . .	
Menispermales .	*Ranales* . . .	*Saxifragales* . .	*Myrtales.*
Cucurbitales . .	*Violales* . . .	*Bignoniales* (*Crescentia*). . .	*Campanales.*

"This abundantly shows how hopeless it is to express the real affinities of plants by any other means than a map or some such contrivance, and that all sequences will of necessity be inadequate to explain in any considerable degree the position in which natural orders really stand with relation to each other."

An attempt at arranging the orders according to the system then adopted by Dr. Lindley, was made in the 'Penny Cyclopædia;' and we subjoin it on the next page as a specimen of how complicated affinities may be expressed upon a flat surface. A series of irregular solid spheres would perhaps express the affinities of the orders better.

That these groups are all perfect in themselves, or nearly so, is sufficiently proved by *Albuminosæ*, the sequence of whose orders may be expressed as follows; the orders included in the diagram being marked with *:—

1. *Anonales.*—*Magnoliaceæ*
   Winteraceæ
   Dilleniaceæ
   Berberaceæ
   **Anonaceæ*
   Monimiaceæ
   Atherospermaceæ
   Myristicaceæ
   **Schizandraceæ*
2. *Ranales.*—*Nymphæaceæ*
   Hydropeltideæ
   Nelumbiaceæ
   Ranunculaceæ
   —*Podophylleæ*
   Papaveraceæ
   —*Fumarieæ*
   Francoaceæ (?)
   Sarraceniaceæ
   Cephalotaceæ
   Droseraceæ
3. *Primulales.*—*Primulaceæ*
   Myrsinaceæ
   Ebenaceæ (?)
   Aquifoliaceæ (?)
4. *Gentianales.*—*Apocynaceæ*
   Spigeliaceæ
   Gentianaceæ
5. *Loganiales.*—*Loganiaceæ*
   Potaliaceæ
6. *Cinchonales.*—*Caprifoliaceæ*
   **Cinchonaceæ*
   Lygodysodeaceæ
   Galiaceæ
7. *Umbellales.*—**Apiaceæ*
   Araliaceæ
8. *Pittosporales.*—**Vitaceæ*
   Olacaceæ
   Pittosporaceæ
9. *Grossales.*—*Grossulaceæ*
   Bruniaceæ
   Escalloniaceæ
10. *Lathræales.*—*Pyrolaceæ*
    **Monotropaceæ*
    (?) *Orobanchaceæ* (?)
11. . . . .—**Garryaceæ*
12. . . . .—**Aristolochiaceæ*
13. *Piperales.*—**Piperaceæ*
    Saururaceæ
    **Chloranthaceæ*



For further information on the subject of natural arrangements the student should consult Dr. Lindley's 'Vegetable Kingdom.'

EXORHIZÆ. [EXOGENS.]

EXO'STEMMA (from ἔξω, without, and στέμμα, a crown) a genus of Plants belonging to the natural order *Cinchonaceæ*. It has an obovate 5-toothed calyx; a corolla with a terete tube, and a 5-parted limb with linear segments; the anthers linear, exserted; the capsule crowned by the calyx, dehiscing from the apex through the dissepiments into two half-fruits; the seeds girded by a membranous entire border. The species are trees or shrubs, with lanceolate oval short-stalked leaves, and stipules solitary on each side of the petioles.

E. Caribæum, Quinquina Piton, Sea-side Beech, has ovate-lanceolate acuminated glabrous leaves; axillary 1-flowered pedicles, rather shorter than the petioles; the calyx bluntly 5-toothed; the style and stamens about equal in length to the corolla. It is a tree about twenty feet high, and a native of the Caribbee Islands, Guadaloupe, St. Domingo, Jamaica, Santa Cruz, and Mexico. This plant is the *Cinchona Caribæa* of Jacquin and the *C. Jamaicensis* of Wright. The capsules before they are ripened are very bitter, and produce a burning itching when applied to the nostrils and lips. The bark is also bitter, and possesses a tonic, febrifuge, and emetic action on the system, but it does not appear to have either quinine or cinchonine in its composition. The bark is generally smooth and gray on the outside. Its flavour, according to Dr. Wright, is at first sweet, with a mixture of the taste of horse-radish and aromatic oils, but afterwards it becomes excessively bitter and disagreeable. When examined by the microscope it presents innumerable shining crystalline points, which, according to Guibourt, are some principle peculiar to the bark.

E. floribunda, Quinquina of St. Lucia, has elliptic acuminated glabrous leaves; peduncles terminal, corymbose; flowers smooth; the teeth of the calyx short, acute; the capsules turbinate. It is a native of the West India islands, among woods by the side of torrents. It is the *Cinchona floribunda* of Swartz; *C. Sanctæ Luciæ* of David, *C. montana* of Badier, and *C. Luciana* of Vittmann. The bark is similar to the last, and used as a substitute for the Peruvian bark, but Pelletier and Caventou discovered no quinine or cinchonine in any part of the plant.

E. Souzanum, Quinquina de Piauhi, has leaves obovate or ovate, acute, smooth; the corymbs few, flowered, terminal; the capsules scarcely an inch long, obovate, compressed, the valves usually 4-nerved; the seeds transversely oblong, with a broad wing all round. This plant is a native of Brazil, and is used as a substitute for the Peruvian bark. Buchner found in it an alkaloid, which he called Esenbeckine, on the supposition that this plant was an *Esenbeckia*. The alkaloid was probably cinchonine.

E. Peruvianum is the *Cinchona Peruviana* of Poiret. It has ovate-oblong acute leaves, rounded at the base, the upper sessile and cordate. It is a tree ten or twelve feet high, and grows in the colder parts of Peru, on the declivities of the Andes, between the river Chota and the village of Querocotillo, 3000 feet above the level of the sea. The bark is very bitter, and has a sweetish taste, with a nauseous smell. There are several other species of *Exostemma*, which have also been used as cinchona barks, but the above are those which are best known.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica;* Bischoff, *Medicinisch-Pharmaceutische Botanik.*)

EYE. The organs appropriated to the sense of sight are distributed very extensively, yet with that frugality which always regulates the operations of nature in the construction of animals. All the active species which live in the light are furnished with them; the rest are disqualified to possess as well as to profit by them, by their limited powers of locomotion, or by constant residence in the dark. In conformity with this rule, to which there are few if any exceptions, these organs are occasionally associated with the lowest types of animal development, and are sometimes absent in the highest. Thus some radiated animals, most of the articulated tribes, and many of the mollusca, have manifest organs of vision, and some of them are of the most curious and artificial construction; on the other hand, the mole and the shrew-mouse, both vertebrated animals, and belonging to the highest order of that class, the mammalia, are blind. They have eyes, it is true; but those of the mole are not larger than the head of a pin, and are unprovided with optic nerves; and the equally imperfect eye of the shrew is covered with skin, from which hair grows as on the rest of the body. Hence, even in the absence of further evidence, we might conclude that if these animals have any perception of light, it can only be sufficient to warn them back to their haunts when by any accident they emerge to the day. But it is more probable that they do not see at all; and that these rudimentary organs, like the male nipple, exist only in conformity with the general model of vertebrated construction.

The structural peculiarities of the eye, as well as the presence of that organ, may be inferred with more certainty from the circumstances of an animal than from the place it occupies in any zoological scale: in fact, no part has a closer relation to the habits and mode of existence. The eye may be simple or compound, single or multiplied, fixed or moveable: it may be encased in a hard transparent shell; or lie deeply imbedded within the protection of a bony socket; or project from the surface of the head at the extremity of a sensitive and retractile horn: it may be adapted for near or distant, oblique or direct, vision; for seeing in a strong or a weak light, in a dense or in a rare medium; or it may be formed so as to accommodate itself to each of these conditions in its turn; and these peculiarities will all be found upon examination to be in strict accordance with the exigencies of the animal. Mere difference in bodily size, and the proportionate reduction or increase in the bulk of the eye, is sufficient to constitute a reason for a difference in its structure, and may suggest an explanation when such discrepancies are observed to exist in animals otherwise alike.

Yet with all the varieties in configuration to which we have alluded, it is rather in form than in substance that the eyes of animals differ from each other. The organ has always a common purpose, and is essentially the same in all cases: that is, we find an assemblage of the same fundamental parts, generally arranged in the same order, even when our powers of observation are assisted by the microscope, and until all traces of organisation are lost in extreme tenuity of texture and the transparency which results from it. And although there are refinements in the structure of the organ of which we do not know the purpose, and certain delicate adjustments in the exercise of the faculty of which we do not know the instruments, yet upon the whole we can deduce the principles upon which the eye is constructed, and assign the uses of its several parts with great certainty from our knowledge of optical and physiological laws.

The human eye is the most complete type of this organ, and the structure and functions of the human eye will be here more particularly described, with occasional remarks upon the structure of the eyes of the lower animals.

The object, or what may be called the general problem, of the human eye, is to combine distinctness and extent of vision with the security and maintenance of the organ, and the utmost convenience in using it. The parts associated for these purposes are the orbits, or sockets, of the eye; the optic nerve; the eyeball, or globe, with its contents, and the external muscles which move and suspend it; the eyelids; the lachrymal apparatus; the nerves and vessels which supply these parts, and the mass of fatty and cellular substance which isolates and supports them.

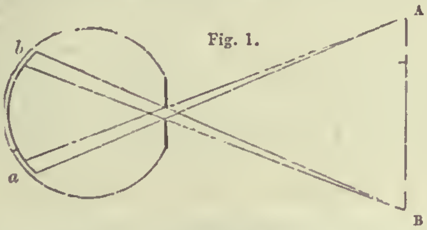
Orbits.—The eyes with their appendages are lodged in two symmetrical roomy cavities in the skull, completed in front by the eyelids, but elsewhere entirely circumscribed by bone, the office of which it need hardly be said is to protect them from injury, and from any pressure that might embarrass the perfect freedom and precision of their movements. These cavities are called the Orbits, Orbital Fossæ, or Sockets of the eye. Seven bones of the cranium or face, which we need not enumerate, enter into the composition of each. They are separated from each other in their whole depth, which is about two inches, by the posterior chambers of the nose. They are conical in shape, or, more strictly speaking, pyramidal, and obscurely quadrangular. The apex is directed backwards; the base, about an inch and a quarter in width, is directed forwards, with a considerable inclination outwards or towards the temple. The margin is less prominent at the outer side than elsewhere, so that when viewed laterally it presents a wide semicircular notch, with the concavity forwards. One object of the divergence of the orbits, and of this retreating curvature of the outer margin, is obviously to increase the extent of vision. If the point of the finger be held before the eye, and carried gradually back towards the ear, it will be observed that in consequence of this arrangement it can be seen long after it has got behind a vertical plane touching the front of both eyes, which taken together are thus enabled to sweep over an angle of about 320°, or 20° on each side behind the tangent plane. Above and below, the edge is undercut as well as prominent, and the socket is therefore a little wider within than at the margin itself, so that it slightly overhangs the eyeball at these points. The inner or nasal sides pass directly backwards and are parallel to each other, and the roof is horizontal; consequently the conical form of the cavity arises from the inclination of the outer side and floor. In the angle between these sides, and in that between the first and the roof, there are two long irregular slits. The former opens into the deep hollow between the temple and the back of the upper jaw; it is called the foramen lacerum inferius, or spheno-maxillary fissure, and gives passage to a branch from the fifth pair of nerves, which, piercing the bone, passes beneath the floor of the orbit, and emerges upon the cheek through a hole just beneath the lower edge of the orbit, about a third part from the inner angle of the eye. The other slit, which is called the sphenoidal fissure, or foramen lacerum superius, opens into the cavity of the head, and transmits another branch of the fifth pair, which passing within the orbit along the roof comes out through an opposite notch in its upper margin, and is distributed upon the forehead and upper lid. These branches of the fifth pair, called the supra and infra-orbitary nerves, are the most frequent seats of that excruciating affliction the tic-douloureux. Through the sphenoidal fissure are likewise transmitted the ophthalmic veins, and all the other nerves except the optic destined to the eye and its appendages. A third opening, which is circular, called the foramen opticum, of the size of a large quill, and leading also from the cavity of the skull, gives passage through the sphenoid bone to the ophthalmic artery and the optic nerve. It is directed obliquely outwards and forwards, and is situated at the apex or back part of the orbit, in the angle between the nasal side and the roof. In the same angle, close to the margin, that is, just within the corner of the eye near the nose, there is a deep groove leading into the lachrymal canal, to which we shall have occasion to recur hereafter.

Optic Nerves.—The Optic Nerves, arising at the back part of the brain, with which they have extensive and important connections, not only where they seem to originate in the corpora quadrigemina, but throughout the whole of the first part of their course within the cranium, pass horizontally forward above the floor of that cavity, converging towards each other till they meet, when they become closely united. It is probable that they not merely meet but cross each other, the greater part, if not the whole, of the nerve from the right side of the brain going to the left eye, and vice versâ. It has been ingeniously supposed by Dr. Wollaston ('Phil. Trans.,' 1824), in order to account for some singular phenomena of disordered and healthy vision, that this decussation or crossing takes place only with respect to those parts of each nerve which lie towards the other; so that each supplies the outer half of one eye and the inner half of the other. This he conceives would explain, among other things, the correspondence between the homologous points of the two eyes, which may be defined as those points which see the same object at the same time. It is scarcely possible to verify such speculations by dissection, from the softness and apparent homogeneity of the parts. In fish the optic nerves cross each other entirely without touching; and in man, when the sight of one eye has been lost, the nerve beyond the point of union within the cranium has been observed to be wasted or diseased on the side opposite to that of the affected eye. [BRAIN; NERVE.] Beyond the point of junction the nerves again diverge from each other, and passing into the optic foramen become invested in a tough, flexible, and fibrous sheath, which is a tubular production of the strong membrane called the dura mater which lines the cavity of the skull. The outer part of this sheath is reflected off as the nerve enters the orbit, and expanding, adheres to the bony surface of that cavity throughout, becoming its periosteum. The nerves, continuing to diverge, reach the eyeball after a somewhat tortuous course of an inch in length. The curvature and laxity of the optic nerve give facility to the movements of the globe, and preserve the delicate structures within it as well as the nerve itself from the injurious effects of tension. Its length is such as to allow the eyeball to project slightly beyond the edge of the socket in front, and to afford space behind for the action of the muscles which move it, and a suitable distance between their points of attachment. Including the thickness of the sheath, it is about one-sixth of an inch in diameter. It does not consist like other nerves of a bundle of distinct fibres, but of a medullary pulp inclosed in minute transparent tubes. The sheath is pierced half an inch from the globe by a vessel called the arteria centralis retinæ, which accompanied by several small veins reaches the axis of the nerve, and passes with it into the interior of the eye. The nerve does not enter the back of the globe exactly in the axis of vision, but about the fifth part of an inch from it, in a horizontal line, on the inner or nasal side, and subtending an angle of about 23° at the centre of the eye. At this point the dimensions of the sheath are suddenly contracted, and it terminates in a thin cul-de-sac pierced with minute holes or pores, hence called the lamina cribrosa (sieve-like plate). Through these pores the pulp of the nerve, divested of its tubular involucra, passes into the interior of the globe in divided portions; but immediately re-uniting expands at the back of the eye into a delicate cup-shaped membrane, with the concavity directed forwards. This expansion of the optic nerve is called the Retina; it is the most important part of the eye, having a peculiar and exclusive sensibility to the impressions of light, of which immediate notice is conveyed from it along the collected nerve to the brain. All other parts of the mechanism of vision are subordinate to this; and their whole office, independently of the conservation of the organ as a part of a living body, is to regulate the quantity of light admitted into the eye, and to distribute it in such a way upon the surface of the retina that the impression, which if immediately received would be confused and general, may be an exact counterpart of the visible surface of the object.

Mechanism of Distinct Vision.—The most elementary fact that we know respecting light is, that it proceeds in straight lines or rays from every point of a luminous or illuminated body. A sensitive surface or retina presented nakedly to such a body would therefore intercept innumerable cones or pencils of light, each diverging from a different point of the object. But each point of the retina must also be considered in that case as the apex of a cone of rays converging upon it from every part of the object; and it is manifest that the various impressions thus received upon the same point at the same time would be undistinguishable from each other. All therefore that we can conceive to be communicated to the mind by the sum of such indefinite impressions over the whole retina, is a knowledge of the prevailing colour of the object, and possibly a general idea of its direction. But if there were more objects than one, or that one had parts or magnitude, even this inconsiderable addition to the mere sense of light and colour would be impossible. The confusion resulting from the simultaneous impressions of a multitude of pencils of light on the same surface would be partly removed if the seat of perception were placed at the bottom of a cavity capable of being turned to each object or each part of the same object in succession, inasmuch as this would prevent the interference of rays proceeding from parts not actually under contemplation; but an indistinctness would still remain in proportion to the magnitude of the field of view, only remediable by narrowing the cavity to a merc-capillary tube, upon the inconvenience of which we need not enlarge.

Let us consider what would be the effect of a very simple addition to the cavity. We will suppose it to be closed in front by a dark screen, perforated with a small central hole as in the section represented in *fig.* 1.

Fig. 1.

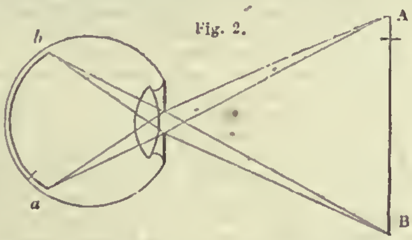


In this case pencils of rays crossing each other from A and B, the top and bottom of an object, would impinge at *a* and *b* upon different parts of the retina. By this means the advantages of a large and a small field of view would be combined, a distributed impression of the object would be produced, and its several parts would be seen separately and in their proper relative situations. The effect may be easily shown by holding a card, pierced with a smooth circular hole, near a taper, and throwing the spectrum upon a wall at a little distance. Such a screen is termed the Iris.

But still the rays from each point of the object would be diffused over a space instead of being collected upon a separate point of the surface, and the impressions of contiguous pencils would in some degree overlap and confuse each other. This inconvenience might be lessened by contracting the opening, but another cause of indistinctness would then be introduced in the diminished admission of light.

Both evils might be avoided if a lens of a proper construction were fixed behind the screen (as in *fig.* 2). Pencils diverging from single points of the object would thus be admitted through the opening, which we will call the Pupil, and would be made to converge to single points on the surface, and the impression would now be an exact counterpart of the object, A being distinctly seen in its true place and direction from *a*, and B from *b*.

Fig. 2.



But additional provisions would be necessary to bring this arrangement to the requisite degree of perfection. In the first place the retina must be adjusted to correspond in shape with the focal distance of the lens. This purpose might be accomplished if the walls of the cavity were composed of flexible materials, by interposing a transparent fluid between the lens and the retina, which, by its uniform distension, would constrain the latter to take and retain the form of a portion of a sphere.

Again, although the diagram has been otherwise drawn for an obvious reason, our arrangement hitherto supposes the object to be very small, and to be seen directly in front of the eye; but if oblique as well as direct pencils are to be brought to a focus, that the lateral vision may be also distinct, a second refracting body, of a proper form, must be placed in front of the lens. This may be done very conveniently, with the further advantage of completing the cavity, by adding a transparent portion to its walls in front of the screen, to be likewise distended with fluid in order to keep it in the shape of a segment of a sphere. (*Fig.* 3.)

It is also desirable that the back of the screen and the interior of the cavity should be blackened, that the rays may be extinguished after impact upon the retina, lest any internal reflection should interfere with the impressions on other parts. The expediency of this provision is always kept in view in the construction of optical instruments, and may be made evident by looking at a bright object through a polished metal tube. The colouring-matter is called the Pigmentum Nigrum, or simply the Pigment. [PIGMENT.]

Fig. 3.

The only remaining artifice to secure the perfection of the organ that need be mentioned in this synopsis of its most essential provisions, is to endow the pupil with the faculty of contraction and enlargement according to the quantity of light. If it were of a constant size, more light would be concentrated upon the retina from a bright or a near object than from one comparatively distant or faintly illuminated; and as the sensibility of the retina must remain the same, the disproportion would occasion dimness of sight in one case and dazzling in the other, and might even impair the nerve.

We have thus imagined all the parts to be built up in succession that are of primary importance (as far as we know) in the construction of an organ of distinct vision, and the figure to which we have arrived might pass as a tolerably correct diagram of the human eye.

The laws of light and sensation require that there should be a general type in the structure of these parts, and a mutual relation among them as to density, form, and position. But this does not preclude much variety; a difference of position, for instance, may be, and frequently is, compensated by a corresponding difference in form or density either of the same or other parts. Hence the problem of distinct vision has many solutions, each perfect in its kind. In fact, nothing can be more diversified in unimportant particulars, or more uniform in those which are essential, than the interior constitution of the eye in different animals: it is never precisely the same in any two species, however closely they may be allied; but we constantly find the retina, the lens, and the pigment, and generally the iris, inclosed of course in some kind of capsule, transparent in front, and partly occupied by complementary fluids. To this there are some exceptions, which however we believe to be only apparent. Thus the larvæ of many insects, some of the microscopic animalcules, and species of *Mollusca*, have red or black spots upon their surface, which are undoubtedly eyes, and are thought by some to be little more than expansions of an optic nerve beneath a thin coloured membrane to absorb the light, and in some unknown way to distribute its impressions; whilst others consider them as a congeries of extremely minute but perfectly-formed eyes of the usual construction, of which the pigment alone is visible from its opacity and abundance.

Globe.—The Globe, or Eyeball, contains the parts immediately concerned in vision. It consists of very unequal portions of two spheres of a different size, which have a common circular intersection in a transverse vertical plane, much nearer the front than the back of the eye. The iris, or coloured screen, perforated centrally by the pupil, nearly occupies the situation of this imaginary plane, but is, strictly speaking, behind it. The posterior and larger portion is circumscribed by the sclerotic membrane, except in front, where it may be considered as bounded by the iris: it is rather less than an inch in diameter, and constitutes about five-sixths of the surface of the globe. (*Fig.* 4, *a.*) The included space is occupied by the choroid membrane and retina, the vitreous and crystalline humours, the ciliary body and processes, and a small part of the aqueous humour. The anterior portion, which forms about a quarter of a sphere, thirteen-twentieths of an inch in diameter (*fig.* 4, *b*), and occupies the remaining sixth

Fig. 4.

part of the surface of the globe, contains the rest of the aqueous humour, and is bounded in front by the transparent and slightly-prominent disc set in the sclerotic like a watch-glass in its metallic rim, and known as the Cornea, from its horny texture. Its transverse chord, or the diameter of the circle of union between the cornea and sclerotic is nine-twentieths, or nearly half an inch in length.

The globe derives its firmness to the touch from the distension of the contained fluids: its capability to bear that distension, which insures the permanence of its shape, is due to the flexible but strong and inelastic outer covering or tunic, consisting, as we have said, of the sclerotic and cornea.

Sclerotic. (*Fig. 5, a.*)—The Sclerotic Membrane is so called from its toughness (σκληρός, hard, rigid). It may be considered as an expanded prolongation of the sheath of the optic nerve, which it resembles in its interwoven fibrous texture. Its inner surface is continuous with the lamina cribrosa already mentioned. Immediately around this part it is about an eighth of an inch thick, and gradually becomes thinner as it approaches the cornea, which it slightly overlaps. The two structures are not separated by an abrupt line, but are blended together, and adhere so closely that they cannot be torn asunder without great force. The thin glistening tendons of the muscles which move the globe, or rather their smooth outer laminæ are spread over and incorporated with the sclerotic in front, approaching each other till they unite near its junction with the cornea. They render it somewhat thicker in this situation than in the spaces between them or behind the line where they begin to be inserted. This front part of the capsule of the eye is called the tunica albuginea, from the whiteness characteristic of all tendinous parts. When boiled the sclerotic yields gelatine. Under the microscope it is found to consist of true connective tissue, the fibrils of which can be easily demonstrated by teasing or treating transverse sections with acetic acid. Numerous fine elastic elements pervade the connective tissues of the sclerotic, of the same form as in tendons and ligaments, that is, as a net-work. During life the elements of this net-work appear to possess cavities and fluid contents, which according to Virchow form a kind of nutritive system. The vessels are very few in this membrane, and are derived chiefly from the ciliary arteries and those of the muscles of the eyeball. Nerves have been recently described in the sclerotic, but their existence, according to Kölliker, is doubtful.

Fig. 5.

Conjunctiva.—The albuginea is defended from contact with the air by a transparent mucous membrane, continuous with that which lines the interior of the eyelids. It is called the conjunctiva reflexa, or adnata, to distinguish it from the conjunctiva propria of the lids. It is very loosely connected to the sclerotic at first to facilitate the movement of the globe: as it advances forward it becomes more closely attached to the albuginea; and hence extending to the cornea adheres intimately to its margin and over its whole surface. The conjunctiva is the most sensitive external part of the body to all painful impressions, except cold, especially where it invests the cornea. The smallest particle of foreign matter in contact with it gives intolerable pain, and makes the act of winking to clear it away imperative; and hence its chief and most essential use as part of the delicate organ of which it may be considered as the guardian. If the nerve which supplies it with sensibility be divided or injured, incidental causes of irritation are suffered to produce their injurious effects unheeded, and the eye soon becomes inflamed, ulcerates, and is destroyed.

Cornea. (*Fig. 5, b.*)—The Cornea is somewhat thicker than the sclerotic except at the back of the eye, is equally tough, though rather more flexible, and of a much closer and more even texture. Its inner surface is concave, and nearly parallel to its outer surface; it is however rather thicker in the middle than elsewhere, and the general statement that it has no share in effecting the convergence of incident rays on account of the parallelism of its surfaces is therefore not quite correct. It is covered externally, as we have already mentioned, by the conjunctiva, and is lined internally by a delicate elastic membrane called the Membrane of Descemet or Demours. The bulk of the tunic, or cornea proper, consists of several layers which slide upon each other when the membrane is rubbed between the finger and thumb, and are separated in the natural state by a limpid fluid contained in a delicate cellular structure. This fluid gives plumpness to the outer surface, which is represented by some authorities to be not exactly spherical, but of that kind which would be formed by the revolution of an ellipse of small excentricity about its long axis.

The cornea proper consists of a fibrous substance closely allied to connective tissue, but which, according to Müller, yields when boiled, not gelatine, but chondrin. Its elements, pale bundles 0·002‴—0·004‴ in diameter, in which, at least when teased out, finer fibrils are usually perceptible, sometimes more, sometimes less distinctly, are united into flat bundles. These bundles, which have their flat sides always parallel with the surface of the cornea, decussate in various directions, and exhibit, if not complete lamellæ, yet a distinctly laminated structure, owing to which the cornea is very readily torn and penetrated in the direction of its surfaces, and with great difficulty in that of its thickness.

The conjunctival lining of the cornea is composed principally of a soft laminated epithelium 0·023‴—0·050‴ thick, in which the deeper layers of cells are elongated and placed vertically upon the cornea, whilst the middle ones are more of a rounded form; and as they approach the surface pass into a layer 0·008‴—0·01‴ thick, corresponding to the horny layer of the epidermis, composed of plates 0·01‴—0·14‴ in size, though still nucleated and soft.

The Membrane of Descemet or Demours, as the inferior layer of the cornea is called, consists of an elastic membrane rather laxly attached to the corneal tissue, and of an epithelium on its inner surface. The former is as clear as glass, brilliant, quite structureless, easily lacerable though tolerably firm, and so elastic that when it is raised from the cornea by the scalpel and forceps, by boiling in water, or by maceration in alkalies, under which treatment as under reagents in general it does not lose its transparency, it always rolls up strongly and towards the front. Towards the border of the cornea it passes into a peculiar system of fibres, first described by Bowman. This set of fibres is continued from the cornea on to the iris, where they form the ligamentum iridis pectinatum of Huek, the pillars of the iris of Bowman. The epithelium of the membrane of Demours, which in man frequently does not retain its perfect condition, consists of a single layer of polygonal cells, with extremely fine and pale granular contents and round nuclei. This layer ceases towards the border of the cornea, but isolated indications of its existence may be found along the pillars of the iris.

Although in the embryo of man and the sheep a rich capillary plexus of vessels exists in the conjunctiva, the cornea in the adult human being is nearly non-vascular. It is nevertheless not unfavourably circumstanced for nutrition. Wounds in it rapidly unite; portions of the epithelium, or even of the fibrous layer, are speedily restored when removed; and ulcers are filled up from the bottom with new corneal substance. Fatty deposits in its tissue, particularly in its cellular elements, producing a yellow zone, first accurately described by Mr. Edwin Canton, and called Arcus senilis, or Gerontoxon Nerves, have been described in the cornea by Schlemm; they are derived from the nervi ciliares, and penetrate the sclerotic at its anterior border, and thence enter the fibrous layer of the cornea. They are readily found at the margin of the sclerotic in the form of 24—36 finer and thicker twigs, but scarcely exceeding 0·02‴ in size.

Chorioid or Choroid Membrane. (*Fig. 5, c, fig. 6*).—We have now to consider the internal tunics of the eye, the first of which is the Choroid, or more properly Chorioid Membrane, so called from some resemblance in the flocculence of its outer surface to the chorion, or external investment of the ovum. This is a thin soft dark-brown structure in contact with or lining nearly the whole concave surface of the sclerotic. It may be said to originate around the entrance of the optic nerve, which passes through it before it expands into the retina; and it terminates in the posterior margin of the ciliary ligament, circle, or more properly muscle (*fig.* 5, *i*)—a flattened band of gray matter, about the seventh part of an inch in breadth, attached to the sclerotic internally near its junction with the cornea. In these situations the two membranes adhere with some firmness; they are elsewhere connected by vessels which pierce the outer and ramify upon the inner membrane, and by the filaments of a fine intermediate cellular tissue. But the connection is so slight that it may be readily broken by gentle inflation with a blow-pipe insinuated through a puncture in the sclerotic, without injury to the fragile texture of the choroid. The choroid consists almost entirely of a multitude of minute vessels, curiously interlaced, and communicating freely with each other. It is supplied with blood by 15 or 20 branches of the ophthalmic artery, which pierce the sclerotic round the entrance of the nerve, and are at first distributed externally on the posterior part of the sphere; but they finally pass inwards, and terminate in a close and uniform vascular expansion over the whole concave surface. This is called the tunic of Ruysch, who erroneously considered it as a distinct membrane. The innumerable veins of the choroid, or venæ vorticosæ, are arranged with great elegance and regularity in arched and drooping branches, like the boughs of the weeping willow; they are very conspicuous upon the outer surface, above the first exterior ramifications of the arteries. (*Fig.* 6.) They unite in four or five common trunks, which emerge through the sclerotic at equal intervals behind the middle of the eye-ball. The outer surface of the choroid is somewhat rough and flocculent; the inner surface, upon which the retina is expanded, is delicately smooth and even. Both are abundantly covered with the pigment, which is secreted by every part of the choroid, and pervades its loose and porous texture.

Fig. 6.

The sclerotic partly removed, and the rest turned back, showing the Choroid Coat and Iris. *a*, optic nerve.

The choroid may thus be divided into three layers: 1, an external brown soft lamella supporting the ciliary nerves and long ciliary vessel, and in front containing the ciliary muscle—the outer pigment layer; 2, the less deeply coloured proper vascular layer, with the larger arteries and veins; and 3, a colourless, delicate, internal layer, containing an extremely abundant capillary plexus, the membrana choris-capillaris, which however does not extend farther in front than the ora serrata. The tissue of which the choroid is composed, independent of its vessels and nerves and the ciliary muscle, is intermediate between elastic and connective tissue. Bowman was the first to demonstrate the true muscular structure of the ciliary ligament or muscle as it is now more properly called.

Pigment.—In man this matter is of a deep-brown colour, in most other animals it is black, and hence is very commonly called the Pigmentum Nigrum. It appears under the microscope to consist of almost regularly hexahedral contiguous cells, 0·006‴—0·008‴ in diameter, 0·004‴ thick, disposed in an elegant mosaic manner, in which the large quantity of brownish-black pigment usually prevents the nucleus being apparent as more than a clear spot in the interior. It adheres very loosely, so that when the surfaces covered with it are drawn to and fro in water, it becomes diffused, and may be washed off. The choroid thus treated is found to be of the same whitish or gray colour which characterises the ciliary ligament. In the natural state of the parts, not only the choroid, but the cellular tissue on its external surface, and the inside of the sclerotic, are deeply stained by the pigment, which shows through, and occasions the bluish tint of the white of the eye in persons of delicate complexion. But on the inner surface of the choroid the pigment is retained by an expansion finer than a spider's web, yet of close texture, which may be called after its discoverer the membrane of Dalrymple. By this means the transparency of the retina is preserved. It is probable that this membrane of the pigment is of a serous kind, and that it is reflected at the optic and ciliary margins of the choroid, and passes over the whole posterior surface of the retina—thus doubly defended from absolute contact with the pigment. The choroid is not the only part which secretes this colouring matter. It is found in equal or greater abundance upon the back of the iris, on the surfaces of the ciliary processes, and in fact wherever it is wanted to facilitate vision. The pigment cells are absent in the eyes of albinos, as well as, at any rate partially, in the region of the tapetum in animals.

In many animals, especially the nocturnal and carnivorous tribes, the pigment is deficient at the bottom of the eye, and the surface of the choroid in that situation presents a brilliant colour and almost metallic lustre. This is called the Tapetum (tapestry of divers colours). It is of various shades of blue, green, and yellow; sometimes changeable like shot silk, and sometimes of a silvery whiteness. The tint occupies various proportions of the surface; it is most brilliant immediately opposite the pupil, and passes gradually into the dark hue of the pigment. There is no vestige of a tapetum in the human eye. The use of it is not well known. It probably causes the animal to see better in the dusk and less clearly in the day, by reflecting the rays a second time through the retina. This reflection from a very effective concave mirror produces a strong convergence of the rays which come back through the pupil, and is the cause of the well-known glare of the eyes of cats and other animals seen in an obscure light from that particular distance at which the emerging rays are most completely brought to a focus upon the eye of the observer. The breadth of this luminous appearance arises from the great dilatation of the pupil under the circumstances in which it is seen.

Retina.—The optic nerve, having entered the interior of the globe through the sclerotic and choroid membranes, forms a slight prominence at the point of union of its several portions, and thence spreads out in the form of a fine transparent membrane over the whole concave surface of the choroid, embracing the translucent body called the Vitreous Humour. Towards the choroid it appears to consist of a mere homogeneous pulp, not very different from the medullary matter of the brain; but it is undoubtedly most elaborately and minutely organised. Towards the vitreous humour it has the structure of a most delicate vascular web, consisting of innumerable ramifications of the central artery (which, as we have already mentioned, accompanies it into the interior of the globe) and of its associated veins. Its name may have been derived from the net-work formed by the visible branches of these vessels; at least it is not otherwise applicable to the structure of the membrane. The distribution of the central artery may be made visible to an observer in his own eye by a curious experiment first suggested by Purkinjé. One eye being steadily directed to a surface of some uniform dark or neutral tint, such as a wall painted of a lead colour, and the other eye closed by the hand, the flame of a small wax-taper is to be slowly waved round and round, so as to be brought at every turn at a little distance over the front of the eye. The central artery will gradually come into view, at first obscurely, and afterwards more clearly. The experiment succeeds best after the experience of several trials on successive nights. The form is such as might be expected from a branching net-work of vessels: the lines are dark, with bright edges on a faintly illuminated ground. There are other modes of making the experiment, which show the appearance more distinctly, but they are less simple. The retina terminates anteriorly in a thin scalloped edge, fitting into corresponding irregularities called the ora serrata in the posterior margin of the ciliary body. (*Figs.* 5, *l*; 9, *d*.) Exactly opposite the pupil there is a bright yellow spot, fading gradually off at the edges, and having a black point in the centre precisely where the axis of direct vision intersects the back of the eye. (*Fig.* 5, *n*.) This central point was believed by its discoverer, Soemmering, to be an actual deficiency of the substance of the retina; and it is generally called in consequence the foramen of Soemmering. But it is now known to be merely a central absence of the yellow colour of that part of the retina rendered conspicuous by the pigment seen through the ordinary transparent texture. These appearances are lost very shortly after death, and are replaced by a minute fold, into which the retina gathers itself, reaching from the place of the central point to the prominence which marks the union of the divided portions of the nerve. The use of this yellow spot and central point, and of the tendency of the retina to assume a folded shape in this situation is not understood.

The microscopic construction of the retina has been recently studied by Pacini, Kölliker, and Müller. Although of variable thickness in all parts it may be divided into the five following layers:—

1. The layer of rods and cones called the bacillar layer.
2. The granular layer.
3. The layer of gray nerve-substance.
4. The expansion of the optic nerve.
5. The limitary membrane.

"The bacillar layer, stratum bacillorum, seu membrana Jacobi, presents a very remarkable structure, being composed of innumerable rod-like and conical corpuscles, disposed with the utmost regularity, and reflecting the light very strongly. With the exception of H. Müller, this structure in animals has been understood quite erroneously, and even in man it has been but very superficially known. It consists of two elements, the rods (bacilli) and the cones (coni), which together constitute a single layer 0·036‴ thick at the bottom of the eye, more anteriorly 0·024‴, and quite in front not more than 0·015‴ in thickness. In general these bodies are so arranged that the more numerous rods have their largest ends directed outwards, whilst the cones are disposed in the reverse direction, whence the latter when imperfectly examined appear to constitute an inner, distinct, thinner layer, lying between the inner extremities of the 'rods.'" (Kölliker.)

The granular layer is composed of opaque granular corpuscles, reflecting the light tolerably strongly, of a round or oval figure, and 0·002‴—0·004‴ in size, sometimes looking like free nuclei, sometimes like minute cells almost entirely filled by large nuclei.

The layer of cineritious cerebral substance is pretty sharply defined on the side of the granular layer, and less so towards that of the fibres of the optic nerve, between the elements of which it penetrates more or less. It is composed of a finely granular matrix, corresponding exactly with that of the gray substance on the surface of the cerebrum and cerebellum, and of numerous nerve-cells scattered in it.

The expansion of the optic nerve. This nerve after quitting the brain and till it reaches the eye presents the same conditions as in the ordinary nerves. Within the canal of the sclerotic and as far as the colliculus nervi optici, the optic nerve retains its white colour, and presents dark-bordered tubules, but from that point onwards its elements become perfectly clear, yellowish or grayish, and transparent, like the finest tubules in the central organs, measuring on the average not more than 0·0006‴—0·0008‴; some it is true are occasionally larger. What chiefly distinguishes these from other pale nerve-terminations, is the absence of nuclei in their course, a somewhat greater refractive power, and the frequent occurrence of varicosities, which two latter particulars would seem to indicate, if not exactly a nerve-medulla, as in the common nerves, still the existence of partially semi-fluid and perhaps fatty contents, and assimilate the nerve-fibres of the retina to the most delicate elements of the cerebrum. The nerve-fibres radiate on all sides from the colliculus nervi optici, and constitute a continuous membranous expansion, which extends as far as the ora serrata retinæ, and presents very considerable interruption only in the situation of the macula lutea.

The limitary membrane is a delicate membrane, 0·0005‴ thick, intimately united with the rest of the retina, which when that structure is teased out, and on the application, is frequently detached in large threads, and then appears perfectly structureless. On its inner aspect towards the hyaloid membrane, when the retina is folded, flattened cell-nuclei are occasionally perceptible, which certainly cannot be referred to an epithelium, and Kölliker thinks not to the vitreous lens either, as the latter is always separable from the retina.

The nature of the rods and cones in the bacillar layer have been much discussed. It has been supposed that they are the terminations of the optic fibres. There are however difficulties in the way of this theory; "among which," says Kölliker, "not the least is the circumstance that although the 'rods' and 'cones' are certainly fifty times more numerous than the fibres of the optic nerve, yet the radiating fibres arising from the former, on their passage into the optic fibres, subdivide, and as it must probably be assumed, are continuous with several of them." "I look upon the 'rods' and 'cones,'" he continues, "which may also be said to correspond in all chemical characters with the nerve-fibres of the retina, and the whole of the radiating fibre-system of the retina, as true nervous elements; and venture at the same time to broach the bold supposition, founded upon a less established basis, that the 'rods' and 'cones' are the true percipients of light, and that they communicate their condition to the fibres of the optic nerve, by means of the direct or indirect connection of their fibrous processes with the former, through which again the impressions are conveyed to the sensorium." He thinks that the optic fibres in the nervous expansion of the retina do not perceive light, for the following reasons:—1. That the point of the retina, where those fibres alone are found, is not sensible to light. 2. The optic fibres are superimposed upon each other in such numbers that it is impossible they should perceive light, inasmuch as each luminous impression, owing to the transparency of the fibres, must in any case always affect many of them, and consequently would of necessity give rise to confused sensations. 3. Because this part of the retina in which there is no continuous layer of nerve-fibres on the inner surface, that is to say the 'yellow spot,' is the most sensitive to luminous impressions. Under this notion the import of the 'rods' and their remarkable arrangement would be intelligible, and the almost inexplicable correspondence in the size of the images of the smallest distinguishable interspaces between two objects, with the diameter of the 'rods' and 'cones,' be placed in its true light.

Vitreous Humour. (*Figs.* 5, *e*; 7 *d*.)—The part next in order to be described is the vitreous humour, behind which the retina is disposed. It is a transparent fluid of semigelatinous consistence and high refractive power, constituting about five-sixths of the bulk of the globe. It consists of a fluid differing in no great degree from water, contained in a cellulated structure called the hyaloid membrane (ὕαλος, glass), from its perfect translucency. The minute cells are connected together; for if the external part be punctured, the fluid contained in them gradually drains away. This cellular structure is so delicate and fragile that it is almost impossible to obtain it separately; but the membranous partitions are rendered slightly opaline by strong spirit or diluted acids, and may thus be made evident. It is condensed into a membrane of a firmer consistence upon the surface, which serves the general purpose of a containing capsule for the vitreous humour, and is strong enough to cause it to preserve its shape in some degree when the stronger tunics of the eye are removed. There is a narrow tubular dimple of some depth in the vitreous humour opposite the entrance of the nerve, lined by a trumpet-shaped production into it of the external membrane, called the hyaloid canal. (*Fig.* 5.) It serves to transmit a branch of the retinal artery and associated veins for the nourishment of the capsule of the lens in the fœtus, and perhaps also of the hyaloid membrane, and of the substance of the lens itself. There can be no doubt that the vitreous humour is secreted by the surfaces of the hyaloid cells, but this fœtal artery is the only vestige of a vascular arrangement yet discovered in the part.

Fig. 7.

This figure, from the work of Zinn, represents the Vitreous Humour in its hyaloid membrane. The lens, imbedded in its upper surface, is surrounded by the canal of Petit. The dark border beyond is the plaited portion of the hyaloid membrane called the zone of Zinn, stained with the pigment left by the ciliary body, which in the natural state of the parts rests upon that portion of the surface of the hyaloid. The outer edge of the zone is marked by a waved outline, corresponding with the ora serrata of the ciliary body.

a, crystalline lens; *b*, canal of Petit; *c*, zone of Zinn; *d*, vitreous humour.

The zone of Zinn, or zonula Zinnii, is that portion of the hyaloid membrane which is continued to the border of the lens, where it becomes blended with the capsule of that body. In doing this it splits into two lamellæ, the posterior of which is blended with the capsule of the lens, and the anterior connected with the ciliary processes which are attached to the capsule of the lens a little in front of its margin. Between the two lamellæ and the border of the lens there is left a space surrounding the latter in an annular manner, and in a transverse section of a triangular form. This is the canal of Petit. The darker colour of the zone of Zinn appears to depend on the existence of pigment-cells belonging to the choroid, which are situated principally in the folds in which the processus ciliares were contained, and give the whole zone a striped aspect. On the inner side of this layer lies a single layer of clear very frequently pale polygonal nucleated cells of 0·006‴—0·012‴ in size, but which is never entire, being always partially removed together with the ciliary processes on which Henle and others have noticed it.

Lens, or Crystalline Humour. (*Figs.* 5, *f*; 7, *a*; 8.)—The crystalline lens (κρύσταλλος, crystal) is imbedded in a deep depression in the front of the vitreous humour, a little nearer the nasal than the temporal side of the globe. It has the form and function of a double convex lens. The surfaces may be considered as portions of two unequal spheres, the anterior being considerably flatter than the posterior. The diameter of the sphere of which the former is a segment is about eight-twelfths, of the latter five-twelfths of an inch. The thickness of the lens, measured in the axis of vision, is about the sixth part of an inch, and its transverse diameter is about twice that length. (*Fig.* 4, *c c*, *d d*.) In refractive power it is superior to the other transparent substances contained in the eye. Its consistence is gelatinous, increasing in density from the circumference towards a central nucleus, which has the tenacity of soft wax. It is composed of an infinite succession of thin concentric laminæ, arranged with the utmost regularity one within another like the coats of an onion; and every such stratum or elliptic shell is made up of a series of exquisitely minute fibres laid side by side, forming three septa like the cloves of an orange, of which the bounding or cleavage planes diverge from the axis of the lens at angles of 120° in the manner represented in the annexed figure. (*Fig.* 8.) If the lens be hardened in strong spirit, the result of this curious arrangement is, that it partly cleaves into three portions made up of layers which may be peeled off one after another, each further separable to a certain extent into its component parallel fibres. The spirit not only hardens the crystalline humour, but renders it opaque; and the same effect is produced by plunging it in boiling water, as every one must have observed in the eyes of dressed fish. In fact it consists chiefly of the transparent substance called albumen found in eggs, and is coagulated by heat in the same way. The lens is similarly constructed in the eyes of other *Mammalia*; and analogous, though not identical, arrangements are observed in other classes. In fish the fibres we have spoken of are curiously hooked together by fine teeth, resembling those of a saw. We chiefly owe the discovery of these facts respecting the intimate structure of the lens to the labours of Leeuwenhoek, Young, and Brewster, whose writings may be consulted for much further interesting information on the subject. The crystalline lens is inclosed in a transparent and highly elastic membranous capsule, represented in *fig.* 5 by a white line, to the regulated pressure of which the preservation of its true shape, so important to the purposes of vision, is mainly attributable. There is no analogous structure in the body, except the internal lining of the cornea already mentioned, which closely resembles it in its function with reference to the surface of the aqueous humour. When the lens is hardened in spirit or boiling water, this capsule retains its nature; and if peeled off, shrivels up and curls upon itself. It may be easily detached with a piu from the hard spherical lens of a boiled fish, and will be found still possessed of its peculiar qualities of transparency and elasticity. The capsule is firmly attached to the hyaloid membrane behind, from which it is not easy to separate it neatly. Whether it has any further conuection than that of mere contact with its own contents, is not easy to show, or to doubt; but the nature of that connection, if any exists, might be expected to be obscure, considering that both the parts are diaphanous, and one of them almost liquid at the surface of contact. Indeed it has been supposed that a small quantity of limpid fluid was actually interposed between the lens and its capsule, but this is now shown to be the result of imbibition after death.

Fig. 8.

Magnified view of the Crystalline Lens, showing its laminated and fibrous structure, and the direction of its planes of cleavage.

The capsule of the lens when examined under the microscope is found to consist of two elements, the proper capsule and epithelium. The former is a perfectly structureless and transparent highly elastic membrane, inclosiug the lens on all sides as if moulded to it, and parting it from the neighbouring structures. The epithelium is placed on the inner surface of the capsule towards the lens, liniug the anterior half of the capsule, with a single layer of beautifully clear polygonal cells, of 0·006‴—0·01‴, with round nuclei. The lens itself consists entirely of elongated flat hexahedral elements, 0·0025‴—0·005‴ broad and 0·009‴—0·0014‴ thick, of a perfectly transparent aspect, very flexible and soft, and having a considerable degree of toughness, which have usually been described as the fibres of the lens, although they are nothing more than thin-walled tubes with clear viscous albuminous contents, which when the tubes are torn escape from them in the form of large irregular drops, aud consequently might suitably be described as the tubes of the lens. These bodies become opaque by the application of all agents that coagulate albumen, as uitric acid, alcohol, heat, chromic acid, and creosote. In caustic alkalies and acetic acid they are quickly dissolved. The coucentric laminæ, which consist of these tubes, are not regularly defined layers, aud never consist of a single stratum of tubes. The course of the tubes in the separate lamellæ is in general such that both the superficial and the deeper in the centre of the lens radiate towards the margins, and then curve round upon the other surface anterior or posterior, but in such a way that no fibre extends through the entire semicircumference of tho leus, or reaches, for instance, from the middlo of the anterior surface to that of the posterior. More precisely described, the tubes on the anterior and posterior surfaces of the lens do not proceed exactly to the middle, but terminate in a stelliform fissure (*fig.* 8) which exists in that situation.

Aqueous Humour.—This fluid, in no respect distinguishable from water except in holding a minute proportion of several saline ingredients in solution, occupies the space between the lens and the cornea. The iris divides this space into two unequal portions called the anterior and posterior chambers of the eye, and so closely approaches the lens that near the margin of the pupil the two surfaces are separated by a mere film of aqueous humour. The cavity is lined throughout by a serous membrane, which secretes and limits the fluid, aud prevents it from acting injuriously upon subjacent parts of importance. At least a membrane of this kind may be peeled off in some animals; its existence in the hnman eye is rather a matter of infercuce than proof.

Iris. (*Figs.* 5, *h*; 9, *b*.)—In speaking of the choroid we have already adverted to the flattened ring called the ciliary ligament or muscle (*fig.* 5, *i*), which connects it in front with the sclerotic. The iris arises from the auterior margin of this ring, and is extended, as we have seen, across the aqueous humour in the form of a thiu partition with a round aperture, or pupil, of variable size in the centre, or a little nearer the inner side, the function of which, we need hardly repeat, is to regulate the quantity of light admitted into the eye, by contracting when it is in excess, and dilating when it falls short of the due amount.

The external appearance of the iris is too familiar to need a particular description. It is covered iu front with a glistening polished membrane. The brilliancy of the eye depeuds in a great measure upon the light reflected by this surface, and is lost when its smoothness and transparency are impaired by inflammation. The posterior surface of the iris is called the uvea. (*Fig.* 9, *b*.) It is thickly coated with pigment, which is prevented from diffusing itself in the aqueous humour by a membrane liko that on the choroid. Such a provision is particularly needed here ou account of the quick movements of the part in a watery fluid. The colouring matter of the iris has much analogy with the pigment. Like that substance it forms no part of the texture it pervades; and when the outer membranes are removed by maceration iu water it may be washed away. Both have a relation in quantity as well as in depth of tint to the complexion and colour of the hair. In the negro tho iris is of so dark a hue that it can scarcely be distinguished from the pupil; while in the white rabbit and other albinoes, including the human variety, where the pigment is entirely wanting from some origiual malformation, the substance of the iris is transparent, and reflects only the pink colour of the circulating blood. Such eyes are dazzled by a strong light, and probably see better than others in tho dusk. The iris, if minutely injected, appears, like the choroid, to be composed almost entirely of vessels. It is principally supplied by the two long ciliary arteries (*fig.* 6) which pierce the sclerotic about half an inch from the optic uerve on either side; and passing between that membrane and the choroid divide near the edge and in the substance of the ciliary muscle, and are wholly distributed to the iris. Their branches are disposed in two conspicuous circles on the front surface, one near the outer or ciliary margiu, the other uot far from the pupil. But though the iris resembles the choroid in vascularity, it differs essentially from it in other respects. It is richly supplied with nerves, which proceed to the iris and are distributed upon it much in the same way as the arteries, and are the medium of its sympathy with the retina, and the source of its irritability. It also possesses a peculiar contractile power, which is dependent on smooth muscular fibres of precisely the same kind as those found in the ciliary muscle of the choroid. These fibres are disposed circularly in front and at the fore edge, and in a radiated form behind. (*Fig.* 9, *b*.) (See Lister on the Contractile Tissue of the Iris, 'Quarterly Microscopical Journal,' vol. i.)

Fig. 9.

a, pupil; *b*, uvea, or back part of the iris; *c*, processes of the ciliary body; *d*, ora serrata of the ciliary body, to which a few shreds of the vascular web of the retina remain attached.

Pupil. (*Fig.* 9, *a*.)—The pupil iu the human eye is bounded by a sharp well-defined circular edge. In other animals its shape is subject to mauy varieties which may often be explained by a reference to their habits and circumstances. In fish it is generally crescentic or imperfectly quadrangular. In herbivorous animals, which often continue to browse during the night, it is oblong and obliquely transverse, as in the horse and sheep. In most serpents and many rapacious quadrupeds, both aquatic and terrestrial, the pupil though large and round at night is a mere vertical slit when seen by day, especially in the smaller species of each geuus, as in the common cat. It is curious that in the larger cats, as the lion and tiger, as well as in some of the larger four-footed reptiles, tho pupil again becomes circular. In all birds, we believe, the pupil is round; and it may be observed that, with few exceptions, they all sleep after night-fall. In the few nocturnal species, as the owls, the pupil is very large though still round, and these birds always shun the day. The long uarrow pupil is in fact a provision for a greater variation in sizo than tho circular form permits, and is generally found in those animals which roam at night and also see well by day. Wheu abseut in such animals the bulk of the organ is commouly sufficient to secure the admission of a sufficient quantity of light after sunset without this provision. In the fœtus the pupil is closed by a vascular film called the membrana pupillaris, one function of which is precisely that of the centering of a bridge to support and extend it during the process of its construction. A tubular film of the same kind has been lately discovered by Müller stretched between the margin of tho pupil and the ciliary body. Both these films are absorbed before birth.

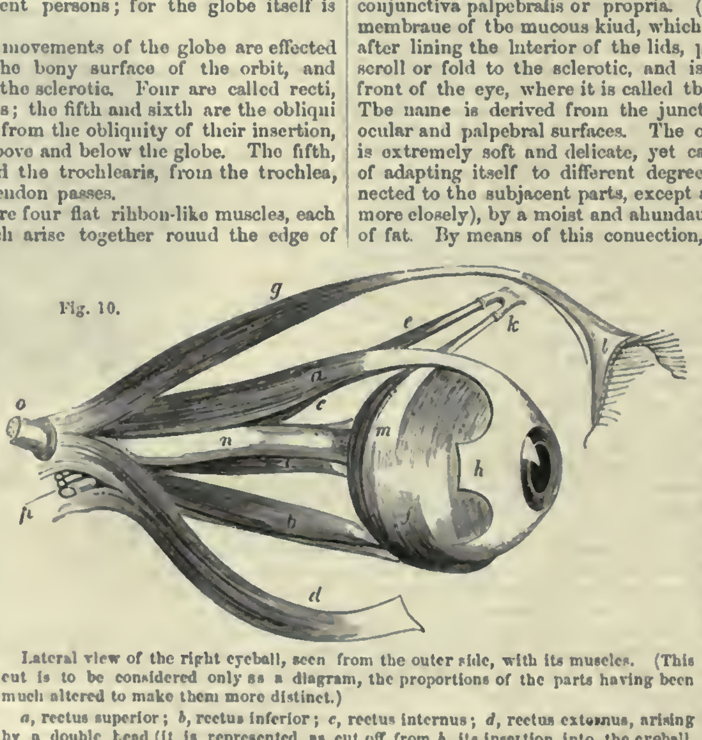
Ciliary Body and Processes. (*Figs.* 5, *l*; 9, *d*, *c*.)—Upon the compressed anterior surface of the vitreous humour where it curves inwards from the sclerotic towards the lens, rests the ciliary body, a thin, dark, annular band, about the fifth part of an inch in breadth, consisting of a frill of flat converging plaits, which encircle but do not reach the circumference of the lens. The posterior aspect is concave, and adheres loosely over the rounded vitreous humour; the front is convex, and is firmly attached to the whole breadth of the ciliary ligament, and to a small portion of the back of the iris near its junction with the ligament. It appears to be a continuation of the inner layer of the choroid, or tunic of Ruysch, but is rather thicker, and resembles it in extreme vascularity. The medullary matter of the retina terminates, as we have seen, at the indented posterior margin (ora serrata) of this membranous band. The ciliary body is everywhere thickly coated and pervaded with pigment, except at the extremities of about seventy minute unattached points which fringe the inner margin, and radiate towards the lens like the florets of a marigold round its central disc. These are the ciliary processes. (*Figs.* 5, *k*; 9, *c*.) They are separated from the uvea by the fluid of the posterior chamber, and are received behind into corresponding depressions in the vitreous humour.

Appendages of the Globe.—The Eyeball, of which we have thus described the contents, is lodged in the cavity of the orbit, a little nearer the inner than the outer side. In front, where the protection of bone is wanting, the two moveable and muscular eyelids supply a sufficient defence, and contribute, by their gentle and constant pressure, to keep the eye in that state of equilibrium between opposite forces upon which the steadiness and precision of its rapid motions in a great measure depend. The space in the socket not occupied by the globe and its appendages is completely filled by a cushion of soft fat, contained in elastic membranous cells, which permits the free movement of the several parts, while it keeps them separate, and affords them all, as well as the globe itself, a suitable and uniform support. Varieties in the quantity of this substance, in the capacity of the orbit, and in the development of the lids, determine the different degrees of prominence and of apparent size observed in the eyes of different persons; for the globe itself is nearly of the same size in all.

Muscles of the Eyeball.—The movements of the globe are effected by six muscles arising from the bony surface of the orbit, and inserted into different parts of the sclerotic. Four are called recti, that is straight or direct muscles; the fifth and sixth are the obliqui superior and inferior, so called from the obliquity of their insertion, and their respective positions above and below the globe. The fifth, or superior oblique, is also called the trochlearis, from the trochlea, or pulley, through which the tendon passes.

The recti (*fig.* 10, *a*, *b*, *c*, *d*,) are four flat ribbon-like muscles, each about half an inch broad, which arise together round the edge of the foramen opticum, and embrace the nerve at its exit from the skull. They end in broad thin glistening tendons, attached to the sclerotic at four equidistant points, about a quarter of an inch from the edge of the cornea, above, below, and on either side. Hence they are designated as the superior, inferior, internal, and external straight muscles. We have already explained how the outer surfaces of their tendons are blended, and form the tunica albuginea. Each turns the pupil towards the side of its insertion; and it is easy to see how by their single actions, or by a proper combination of two that are contiguous, the pupil may be turned in any required direction. The rectus externus, from its position on the diverging side of the orbit, is necessarily the longest of these muscles. It has also a double origin, arising not only in common with the rest from the edge of the optic foramen, but also from the edge of the sphenoid fissure, and arches over several nerves which enter the orbit by that passage (*p*). The superior oblique or tochlearis (*e*) is a round tapering muscle, which arises near and on the nasal side of the rectus internus (*c*), and ends in a smooth round tendon. The pulley (*k*) through which this tendon passes is a small loop of cartilage fixed to the roof of the orbit towards the nasal side, just within the margin. In this situation the tendon is enveloped in a lubricated extensible sheath called bursa mucosa; thence spreading into a thin fan-like expansion, it is reflected obliquely backwards and outwards between the globe and the tendon of the rectus superior (*a*), and is inserted into the back part of the sclerotic at a point (*m*) intermediate between the optic nerve and the insertion (*h*) of the rectus externus, and nearer the former. Its separate action turns the pupil downwards and outwards. The inferior oblique (*f*) arises broad within the lower edge of the orbit towards the nasal or inner side, and passing obliquely backwards over the tendon of the rectus inferior (*b*), is attached to the sclerotic at the outer and back part opposite the insertion of the trochlearis. It directs the pupil upwards and outwards, supposing the eye to look originally straight forwards: if the pupil be inclined either way, to the nose or to the temple, the inferior oblique increases that inclination, being equipoised as to lateral action when the eye is slightly turned inwards, as in reading. But its tendency is always to turn the pupil upwards. To a certain extent the same remark is applicable (mutatis mutandis) to the action of the antagonist muscle, the superior oblique, which if exerted at the same time would counteract the tendency upwards, so that both taken together would keep the eye in that easy position so often assumed by man and animals in looking without much effort yet steadily at near objects, as in taking food, reading, and most other quiet occupations. The position we mean is that in which the axes of vision are directed slightly towards each other and a little downwards, and the eyeballs are gently pressed against the lids and by them, and thus are kept in a convenient and steady equilibrium. When the oblique muscles act together with force, they hold the eyeball firmly against the lids and to the nasal side of the orbit. One or both of these muscles, as well as the rectus externus, are supposed to be endowed with certain automatic or involuntary actions, very useful in the economy of vision. Their functions in this and other respects have given occasion to much curious disquisition.

Fig. 10.



Lateral view of the right eyeball, seen from the outer side, with its muscles. (This cut is to be considered only as a diagram, the proportions of the parts having been much altered to make them more distinct.)

a, rectus superior; *b*, rectus inferior; *c*, rectus internus; *d*, rectus externus, arising by a double head (it is represented as cut off from *h*, its insertion into the eyeball, and turned aside to show the parts behind it); *e*, obliquus superior, a round and tapering muscle terminating in a round tendon, which passes through a pulley or loop (*k*), and is reflected under the flat tendon of the rectus superior, and, becoming flat, is inserted at (*m*) into the sclerotic; *f*, obliquus inferior coming round over the tendon of the rectus inferior from the front and inner edge of the orbit, near the inner corner of the eye, and inserted into the sclerotic opposite the insertion of the superior oblique; *g*, levator palpebræ superioris, ending in a flat tendon, which is inserted into (*l*) the crescentic tarsal cartilage of the upper lid; *o*, *n*, the optic nerve; *p*, the nerves of the 3rd, 5th, and 6th pair, which pass between the two heads of the rectus externus. The rest of their course is not shown.

The Eyelids or Palpebræ. (*Figs.* 11, 12, 13.)—The textures which enter into the composition of the eyelids are included between a soft external skin and a moist smooth internal surface, called the conjunctiva palpebralis or propria. (*Fig.* 13, *a a*.) The latter is a membrane of the mucous kind, which, as we have already mentioned, after lining the interior of the lids, passes across in a loose circular scroll or fold to the sclerotic, and is reflected back again over the front of the eye, where it is called the adnata or conjunctiva reflexa. The name is derived from the junction thus effected between the ocular and palpebral surfaces. The outer skin of the eyelids, which is extremely soft and delicate, yet capable to a considerable extent of adapting itself to different degrees of extension, is loosely connected to the subjacent parts, except at the margin (where it adheres more closely), by a moist and abundant cellular tissue, entirely devoid of fat. By means of this connection, when the upper lid is raised and these under-lying parts are retracted under the edge of the orbit, the superfluous skin is gently drawn after them, and is disposed of conveniently under the brow (supercilium). The eyelids meet, when closed, by two narrow flat surfaces, accurately applied to each other, called their ciliary or tarsal margins. These epithets are respectively derived from the tarsi, or thin concave and crescentic shells of smooth and elastic cartilage which give form to the lids, and firmness and outline to their opposed edges (*fig.* 10, *l*); and from the lashes or cilia, which grow in several rows at the margins of both lids, from their extreme outward verge, and in the direction of the flat surfaces. The angles in which the margins of the eyelids meet towards the nose and temple are called the canthi. The outer canthus is kept in its place during the motions of the part by a tendinous expansion or aponeurosis, which, adhering to the thin crescentic edges of both tarsi on their outer or convex surface, attaches them, and most closely on this (the temporal) side, to the margin of the orbit. It is called the broad ligament of the tarsi. The nasal extremities of the tarsi are confined to the side of the nose by two slips which are given off behind from the tendon of the orbicular muscle.

Muscles of the Eyelids.—Immediately beneath the subcutaneous cellular tissue there is a broad layer of muscular fibres arranged elliptically round the transverse fissure of the eyelids, the disposition of which is well shown in *fig.* 12. The office of this muscle, which is called the orbicularis, is to close the lids; and it is capable of acting under certain circumstances with great force. It is collected at the inner angle or canthus of the eye into a round short tendon, which is attached in that situation to the bone. Elsewhere it is connected with the skin and aponeurotic expansions of the face and forehead. It is also connected with the occipito-frontalis muscle, which elevates the eye-brows and with the corrugator supercilii, which wrinkles and knits them in the act of frowning. A

The edges of the fold which passes to the sclerotic are seen loose and floating; *b*, lachrymal gland; *c*, orifices of the lachrymal ducts; *d*, tendon of the elevator muscle of the upper lid; *e e*, parallel rows or clusters of the Meibomian glands; *f*, the semilunar fold of the conjunctiva at the inner canthus, which is the rudiment of the third eyelid of birds and other animals. Near *f*, on the right, are seen the two puncta lachrymalia.

person acquainted with mechanics will have no difficulty in perceiving the advantage derived from the oblique, or, as it might almost be called, the incidental action of the orbicularis in closing the lids, to the edges of which its fibres are parallel. A more direct application of muscular force would have been more powerful; but the actual arrangement secures a rapidity incomparably more conducive to the function of the eyelids, which is to cleanse and moisten the surface of the eye.

Levator Palpebræ Superioris.—Below the orbicularis, in the upper lid, is the broad tendon of the muscle which elevates the upper lid. (*Figs.* 13, *d*; 10, *g*.) This muscle arises from the edge of the optic foramen, just above the rectus superior, and passing over it along the roof of the orbit, forms the thin tendon we have mentioned, which is inserted into the inner surface or rather the thin upper edge of the tarsal cartilage. There is no such provision for depressing the lower lid, which is rendered unnecessary by its inferior extent. Moreover the muscle we have just described sufficiently answers the purpose, by pressing down the globe, and causing it to slide a little forwards; as may be easily felt if a finger be placed against the lower lid when the eye is close, and suffered to remain while the upper lid is slowly raised.

Meibomian Glands. (*Fig.* 13, *e, e*).—Between the tarsus of either lid and the conjunctiva are disposed numerous vertical rows of minute whitish grains, which appear through the semi-transparent mucous membrane, and occupy an elliptic space, taking both lids together, of about half an inch in width, exactly in front of the globe. These are called the Meibomian glands, from their discoverer. They secrete an unctuous matter which passes into tubes centrally placed in each row, and exudes from as many minute orifices on the ciliary margin of the lid. (*Fig.* 11, *c*). There are about forty of these parallel clusters in the upper lid: in the lower there are not so many, nor are they individually so long. We need not dilate upon the use of this secretion, which often collects in a sensible quantity upon the edges of the lids during sleep, especially when the glandular action is excited by slight inflammatory irritation of the part. The palpebral conjunctiva, already described, immediately covers these glandular corpuscles. The caruncle, a small red prominence at the inner angle of the eye (*fig.* 11, *d*) consists of a number of similar bodies.

Lachrymal Apparatus. (*Figs.* 13, 14).—At the upper and outer part of the interior of the eyelid are several minute orifices (*fig.* 13, *c*), generally seven in number, arranged in a half circle, which lead into the secretory ducts of the lachrymal gland. (*Figs.* 13, *b*; 14, *e*.) This is a white flattened lobulated body, of the size of a large bean, lodged in a depression just within the margin of the orbit, and covered externally by the orbicular muscle. The function of this gland is to secrete the tears; and is probably always going on, although not in a degree sufficient to be remarked, except in weeping, or when some foreign body or acrid vapour stimulates the surface of the eye, and by sympathy excites the gland to unusual secretion.

Fig. 14.

a, the two puncta leading into the lachrymal ducts; *b*, the common entrance of these ducts into the lachrymal sac; *c*, the head of the lachrymal sac; *d*, the narrow portion of the sac, or membranous lachrymal canal passing downwards to the nose; *e*, the lachrymal gland.

The involuntary actions of the rectus externus and inferior oblique muscles, to which we have alluded, are supposed to have a relation to the lachrymal secretion. In the act of winking, the eye-ball is thrown up in an outward direction, as it would be by the action of these muscles, which not only brings the cornea into the vicinity of the ducts, but makes pressure upon the gland, while it relatively increases the rapidity with which the lids, drawn in winking towards the fixed nasal tendon are swept over the surface of the globe. That there is such a movement however produced is certain: the motion of the prominent cornea may be felt by the finger gently pressed upon the half-shut lid if it be completely and suddenly closed. The approximation of the lids towards the nose in winking is one of several provisions by which offending particles or superfluous fluids are brought to the inner canthus of the eye to be protruded or absorbed. In this situation there is a vacant space partly occupied by the caruncle, called the lacus lachrymalis (*fig.* 11, *d*); it is a sort of reservoir or rather sink for the tears. Above and below, at the entrance to this space where the ciliary margins terminate, there is a small prominence on the inner edge of both (*figs.* 11, *a*; 14, *a*), centrally punctured by small orifices. These are the puncta lachrymalia. Their inward aspect is well shown in *fig.* 13. They are the emunctories of the eye; and their function is to absorb the fluids presented to them, and convey them by two converging canals (*fig.* 14, *a*) to the lachrymal sac (*fig.* 14, *c*), which they enter by a common orifice (*fig.* 14, *b*). This is a membranous bag about as large as a kidney-bean lodged in a groove in the lachrymal bone, behind the tendon of the orbicular muscle. The lachrymal sac entering a vertical channel in the bone at the end of the groove is narrowed into the lachrymal canal (*fig.* 14, *d*), and passes directly downwards into the inferior meatus or chamber of the nose, which it enters on the outer side by a slit in the mucous lining. It is not exactly understood in what way the puncta absorb—whether by capillary attraction or by some vital force of suction. The side of the lachrymal sac is connected with the tendon of the orbicularis, which may aid in producing the effect by suddenly drawing its membranous surfaces apart. We all know the effect of repeated winking when the eyes are filled with tears.

Nervous and Vascular Constitution of the Eye.—Enough has been already said, for general information, with respect to the blood-vessels distributed to the eyeball, and it is not necessary to mention those which supply the appendages. With respect therefore to vascular arrangements we have only to add, that although there are abundant proofs of the existence of an active absorption within the globe, no lymphatic vessels especially destined to that function have been hitherto found in it. The optic or second cerebral nerve has been already described. All the straight muscles, with the exception of the rectus externus, the inferior oblique, and the levator palpebræ, are supplied by the third nerve. The fourth is wholly distributed to the trochlearis, and the sixth to the rectus externus. The orbicular muscle is supplied, like most of those of the face, by the portio dura of the seventh pair. All these, except the optic, are muscular or motor nerves. The fifth nerve supplies the whole organ in common with many other parts with ordinary sensation. Any account of the intricate nervous constitution of the iris would be here quite out of place. The third and sixth nerves are mainly concerned in it. Thus of the ten cerebral nerves, the second, third, fourth, and sixth are wholly, and the fifth and seventh partially distributed to the organ of vision; a fact which may give some idea of the elaborate organisation and varied exigencies of the parts which compose it.

Comparative Anatomy of the Eye.—The sense of sight is undoubtedly developed amongst the lowest class of animals, but it is difficult to point out the exact members of the series in which this faculty is first exercised. The moving zoospores of plants are attracted towards the light, and Ehrenberg regards as eyes the red spots seen in some organisms, such as *Volvox*, which are now regarded as plants. All anatomists are agreed on regarding the ocelliform spots situated at regular intervals along the margin of the disc of Pulmograde *Medusæ* as eyes. They are composed of a collection of pigmentary granules, superposed upon an enlargement of a nervous thread, which comes from the central circle of nervous matter in the animals. Similar spots have been observed at the extremities of the rays in the *Asteriadæ* by Professor E. Forbes. In many of the lower *Articulata* no higher development obtains. In the *Entozoa* no visual organ has been detected. Distinct eye-spots are seen in the Leeches, the *Rotiferæ*, and the Dorsibranchiate *Annelida*. Amongst the mass of *Mollusca* these organs are not observed. They are however very distinct in the Pectens and other swimming forms of Lamellibranchiate Mollusks.

"The eyes of most of the higher articulated animals are constructed upon the composite type, each of the masses that is situated upon either side of the head, being made up of an aggregation of simple eyes, every one of which is in itself a complete visual instrument, but is adapted to receive and to bring to a focus only those rays which come to it in one particular direction. In most insects each composite eye forms a large hemispherical protuberance, which occupies a considerable part of the side of the head, and when examined with a microscope, its surface is seen to be directed into a vast number of facets, which are usually hexagonal. The number of these facets, every one of which is the cornea of a distinct eye, is usually very great. Behind the cornea is a layer of dark pigment, which takes the place and serves the purpose of the iris in the eyes of the *Vertebrata*, and this is perforated by a central aperture or pupil, through which the rays of light which have traversed the cornea gain access to the interior of the eye. When a vertical section is made of one of these composite eyes, it is seen that each separate eye is the frustum of a pyramid, of which the cornea forms the large end or base, whilst the small end abuts upon a bulbous expansion of the optic nerve. The interior of this pyramid is occupied by a transparent substance which represents the vitreous humour, and the pyramids are separated from each other by a layer of dark pigment which completely incloses them, save at the pupillary apertures and also at a corresponding set of apertures at their smaller ends, where the pigment is perforated by the fibres of the optic nerve, of which one proceeds to each separate eye. Each facet of the common cornea or 'corneule' is usually convex on both its surfaces, and thus acts as a lens, the focus of which has been ascertained by experiment to be equivalent to the length of the transparent pyramid behind it; so that the image produced by the lens will fall upon the extremity of the filament of the optic nerve which passes to its truncated end. The rays which have passed through the several corneules are prevented from mixing with each other by means of the layer of black pigment which surrounds each cone; and thus no rays, except those which correspond with the axis of the cone, can reach the fibres of the optic nerve. Hence it is evident that each separate eye must have an extremely limited range of vision, being adapted to receive but a very small pencil of rays proceeding from a single point in any object; and as these eyes are usually immoveable, they would afford but very imperfect information of the position of surrounding objects, were it not for their enormous multiplication, by which a separate eye is provided (so to speak) for each point to be viewed. No two of the separate eyes, save those upon the opposite sides of the head which are directed exactly forwards, can form an image of the same point at the same time, but the combined action of all of them may give to the insect, it may be imagined, as distinct a picture as that which we obtain by a very different organisation. At any rate it seems certain, from observation of the movement of insects, that the vision by which they are guided must be very perfect and acute.

"Although the foregoing may be considered the typical structure of the eyes of insects, yet there are various slight departures from it in the different subdivisions of the class. Thus in some cases the posterior surface of each corneule is concave, and a space is left between it and the iris which seems to be occupied by a watery fluid or aqueous humour; in some instances again this space is occupied by a double convex body which seems to represent the crystalline lens; and there are cases in which this crystalline lens is found behind the iris, the number of eyes being reduced, and each individual eye being larger, so that the entire aggregate approaches, both in its structure and mode of action, to that of *Arachnida* and certain *Crustacea*. Besides their composite eyes, insects usually possess a small number of rudimentary single eyes resembling those of the *Arachnida*: these are seated upon the top of the head, and are called stemmata. Their precise use is unknown, but that they have considerable influence in the direction of the movements appears from the fact that, if the stemmata of a bee be covered with paint, on being let go it will fly continually upwards—a fact which seems related to those already mentioned in regard to the influence of visual sensations upon automatic movements. It is remarkable that the larvæ of insects which undergo a complete metamorphosis only possess simple eyes, the composite eyes being developed at the same time with the wings and other parts which are characteristic of the imago state during the latter part of the pupa condition. In the higher *Crustacea* the structure of the eyes is nearly the same as in insects; but the compound masses are not so large relatively to the bulk of the body, and the number of distinct eyes is not nearly so great. In the lower *Crustacea* however, as in *Myriapoda*, the visual organs much more closely approximate the type of structure which they present in the *Arachnida*; each aggregate mass being composed of a small number of simple eyes, of which every one has its own separate cornea as well as its own crystalline lens and vitreous humour, and these in some instances being altogether detached from each other. Among some of the Suctorial *Crustacea* the visual organs are altogether wanting in their state of full development, although they are uniformly present in their early condition; and the same may be said of the *Cirrhipedia*. Among *Arachnida*, which in this as in many other respects present an approximation to *Vertebrata*, we find a great reduction in the number of eyes, which are never more than eight in number (sometimes being only two), and are to be compared with the stemmata of insects rather than with their compound eyes. These eyes are sometimes collected into one mass on the summit of the cephalo-thorax, and are sometimes symmetrically and separately on the two sides of the median line. In the Scorpions we find two large eyes placed on the dorsal aspect of the cephalo-thorax near the median line, and three pairs of smaller ones, which are placed on the outer margins of the same division of the body. The larger eyes are described by Müller as each possessing a cornea which is convex anteriorly and concave posteriorly; and a nearly globular crystalline lens resembling that of fishes, whose anterior surface lies in the hollow of the cornea, while its posterior rests upon the vitreous humour, without being imbedded in it. The vitreous humour is a nearly hemispherical mass of soft granular matter, being almost flat in front and very convex behind; over its posterior surface is spread the retina, or expansion of the optic nerve; and this is covered by a thick layer of pigment which passes inwards in front of the vitreous humour so as to form a sort of iris, the pupillary aperture of which however exceeds the diameter of the crystalline lens. Among those classes which constitute the higher division of the Molluscous series in virtue of the possession of a distinct head, the presence of visual organs is by no means constant; many *Gasteropoda* and *Pteropoda* being destitute of them altogether, and others possessing ocelliform spots, which may be concluded to be rudimentary eyes from their similarity in position to the eyes of those which undoubtedly possess visual powers. The eyes are always very minute however in proportion to the bulk of the body, and in no instance do they possess a high type of structure; their general organisation indeed bears a close resemblance to that which has been described in the eye of the Scorpion. In the *Cephalopoda* we find the visual organs presenting a much larger size, and attaining a much higher grade of development, in accordance with their greater functional activity in directing the rapid and energetic movements practised by a large proportion of these animals. We here find nearly all the principal parts which are characteristic of the eye of higher animals, namely, a cornea, an anterior chamber filled with an aqueous fluid inclosed in a distinct capsule, a crystalline lens of globular form (as in fishes), a large posterior chamber filled with vitreous humour, a tough fibrous or sclerotic coat, a vascular choroid coat within this covered by black pigment upon its inner surface and retinal expansion. The relations of this last to the optic ganglion however are very peculiar. This ganglion is situated almost close to the back of the eye, and instead of transmitting a single optic nerve as in higher animals, it gives off a multitude of filaments which separately pierce the sclerotic coat, and then form a plexus between this and the choroid, which has been mistaken for the retina. The true retina however is a very thin lamella apparently composed of vesicular nerve-substance, which is found between the pigment and the membrane inclosing the vitreous humour; but the connection of this with the net-work of nerve-tubes on the outside of the pigmentary layer has not yet been made out. No proper iris exists in the eyes of the *Cephalopoda*, but its place is supplied by a partial prolongation of the sclerotic coat over the front of the crystalline, a central pupillary aperture being left. The cornea is not, like the true cornea of higher animals, a transparent continuation of the sclerotic coat, but is a modification of the general integument, analogous rather to the external or conjunctival layer of the cornea of *Vertebrata:* it is remarkable that in some *Cephalopoda* it should be perforated by an orifice of considerable size, through which the capsule of the crystalline lens projects into the external medium." (Carpenter, 'Principles of Physiology.')

The eyeballs of quadrupeds and other *Mammalia* resemble the human organ in structure, and differ from it, but not essentially, in form. This is not the case with the appendages. One of the most remarkable additions commonly found to the parts we have described is that of a strong retractor muscle in the shape of a hollow cone attached at the apex to the bottom of the orbit, and by the marginal base to the sclerotic, which it embraces, lying under the recti muscles. Its use is to draw back the eye in the orbit, a gesture which gives a very peculiar expression of hollowness to the organ in beasts of prey.

We subjoin the following account of the eye of the Common Owl (*Strix bubo*), chiefly for the purpose of explaining the pecten and the curious mechanism of the third eyelid, or nictitating membrane, in birds.

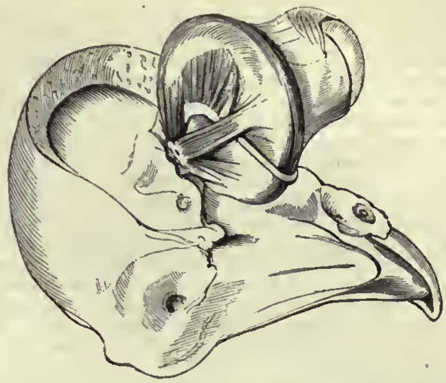
The general shape of the organ represented in the annexed figures resembles a bell. This arises from the disposition of a series of quadrangular bony scales (*fig.* 15, *a*) within the substance of the sclerotic, concave on their outer aspect, and overlapping and accurately fitted to each other. The rigidity thus communicated to the external case which contains the fluid media prevents their pressure from distending the eye into a spherical shape. The ciliary body (*fig.* 15, *b*) extends over the whole of this portion of the surface. A curious membrane called the pecten or comb (*fig.* 15, *c*), from some resemblance to that implement, projects through the choroid into the vitreous humour, and in some birds is attached to the side of the lens. In the owl it is comparatively short. It resembles a quadrangular piece of choroid folded backwards and forwards upon itself like the paper of a lady's fan. Of its use little is known. The foramen of Soemmering, described in the account of the human retina, is thought to be a rudiment of the pecten. In birds the retina has generally the yellow colour seen only partially in man round the central spot miscalled a foramen.

Fig. 15.

Horizontal section of the eye of the Common Owl (*Strix bubo*). *a a*, bony plates in the sclerotic; *b*, ciliary body; *c*, pecten.

At the back of the globe there are two muscles which originate from the sclerotic, and are applied to its curved surface round the

Fig. 16.



Head of the same bird. A portion of the bony margin of the orbit having been removed, the eyeball is turned forward so as to show the recti and other muscles.

entrance of the optic nerve. (*Fig.* 17, *a.*) The larger represents rather more than half of what if completed would be a broad circular ring. (*Fig.* 17, *b.*) It is called the quadratus. Attached by its wider edge near the margin of this part of the sclerotic, its fibres converge to the narrower edge, and terminate in a narrow tendon (*fig.* 17, *c*), perforated through its whole length like the hem of an apron. The second smaller muscle, called the pyramidalis from its shape (*fig.* 17, *d*), at an opposite part of the circumference. Its fibres converge, and are fixed into a long round tendon (*figs.* 17 and 18, *e*), which passes through the loop or hem (*c*) of the quadratus, and hence turning over the edge of the broad part of the sclerotic, is continued along the surface of its bell-shaped portion, where it passes through several thread-like loops or pulleys which keep it applied to the concavity, and round a bony point which projects from the surface, and is

Fig. 17.

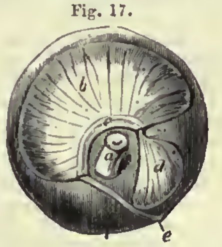


Fig. 18.

Fig. 17. Posterior view of the sclerotic of the same bird, showing the muscles of the nictitating membrane. *a*, optic nerve; *b*, quadratus muscle; *c*, its looped tendon; *d*, pyramidalis muscle; *e*, its tendon—having passed through the loop in that of the quadratus—turning over the edge of the sclerotic.

Fig. 18. Lateral view of the same part. *e*, the tendon of the pyramidalis, attached to the concave part of the sclerotic by tendinous loops, and passing round a prominent bony tubercle, is seen inserted into the nictitating membrane at *f*.

attached near the edge of the cornea to the edge of an elastic fold (*fig.* 18, *f*) of the conjunctiva, which is called the third eyelid or nictitating (that is, winking) membrane. It will be easily seen by the help of the figures, from this description, that the effect of the simultaneous contraction of the two muscles will be to draw the membrane with great rapidity, making it sweep over the surface of the cornea. It returns by its own elasticity with nearly equal quickness. A bird may be seen to use this mechanism twenty times in a minute; in fact, as often as it may be necessary to cleanse the surface of the eye. The colour of the membrane is milky; and it is seen to pass from the upper and inner to the outer and lower corner of the eye with the speed for which the act of winking is proverbial. There is a rudiment of this third eyelid in the human organ. It is a small crescentic fold of conjunctiva situated at the inner canthus behind the caruncle. (*Fig.* 13, *f.*) The haw is also a rudiment of it, in the eyes of quadrupeds; it is occasionally forced out by the pressure of the globe against the nasal side of the orbit, being unprovided with muscles.

Seat of Vision.—The retina in one sense is not the seat of vision. It is necessary to the perception that the impression of light should be received on another part not endowed with sensibility, namely the surface of the choroid; and that the vibration or other effect thus impressed should be transferred to the retina in front of that surface; for where the choroid is deficient at the entrance of the nerve, there is no perception of light. This may be easily shown by a very common and conclusive experiment. If two discs of white paper be fixed upon a wall at the distance of two feet from each other, and an observer, having closed one eye (the left), continues to gaze attentively at the left-hand disc, at the same time slowly retreating from the wall, he will for a time continue to see them both; the rays from the right-hand object entering of course laterally, and impinging upon the retina nearer and nearer to the entrance of the nerve as he goes backward. At length when he has reached the distance of about 6¼ feet from the wall, the right-hand object will suddenly disappear, and remain invisible (the observer still retreating) till he has gained a distance of about eight feet. During this period the spectrum has been passing over the circular aperture in the choroid through which the nerve enters. The insensible portion of the retina is found to extend horizontally over five degrees and a half of the angular range of vision. The eyes are generally unequal in power, and the experiment succeeds best in the weaker organ, in which the obscuration is more sudden and complete. In the experiment previously mentioned, showing the distribution of the central artery of the retina, the surface of the choroid is faintly illuminated through the transparent nervous expansion by what is called the dispersion of part of the light admitted through the pupil; but the rays thus scattered are locally intercepted by the opaque blood contained in the minute branches of the artery; hence, after several repetitions, when the eye has become accustomed to neglect the taper, and attend to the fainter internal illumination, the shadow of the vascular net-work upon the choroid becomes perceptible in dark lines.

Apparent Direction of Objects seen obliquely.—A body in motion, as a ball, striking the surface of another, impresses it in a line perpendicular to the surface at the point of impact. This rule appears to hold good with respect to the action of light upon the retina. Indeed if impressions of any kind be made upon it, the sensation is that of light, and the direction suggested is that of a line joining the centre of the sphere of which the retina forms a part with the point impressed,—in other words, a line perpendicular to it. This may be shown in several ways: if we excite the nerve by pressing far back upon the eyeball with the finger-nail, especially if the eye be closed or light otherwise excluded, a bright ring appears to be seen in a diametrically opposite quarter.

Erect Vision.—If the sclerotic and choroid be carefully removed under water from the back of an eye, an inverted picture of any object held before the cornea is seen upon the now milky surface of the retina. Hence the celebrated question raised in the age of philosophical barbarism, how is it that we see objects erect when the image on the retina is inverted? The question is an idle one, which is perhaps hardly worth answering. The mind judges of the apparent place of objects or of parts of an object by the direction of the impressions made upon the retina, not by the part of it which may happen to be affected by these impressions. The shadow of the central artery is an example of an impression necessarily received always upon the same parts; yet the apparent, or in other words the relative, place of the shadow will be found to vary with every movement of the eye.

Single Vision.—Another question, not so trivial as the last, has been raised with respect to single vision with two eyes, as the impression must be twofold. But perhaps it will not require an answer if the reader will try to imagine double vision of the same object, or rather of the same point, for the question resolves itself into that. Let the two supposed images approach each other, still remaining double, till they are in contact. Another step in the imaginary approximation, and they are one. The truth is, that both eyes see the object in the same place; and as two images, no more than two material substances, can occupy the same place at the same time, the impressions coincide and are single.

On the Development of the Organ of Vision.—The following remarks on this subject are from Professor Kölliker's 'Manual of Human Histology:'—

"The eyeball is not developed from a single point as a whole, but arises from the conjunction of formations, proceeding on one side from the central nervous system, on another from the skin, and thirdly from the parts lying between the two.

"In the Chick the primitive ocular vesicles arise before the commencement of the second day, from the primitive cerebral vesicle or the anterior cerebrum, in the form of two protrusions at first sessile, but afterwards having a hollow peduncle—the rudiment of the optic nerve. At the beginning of the third day the formation of the lens commences, from the skin of the face covering these vesicles by the thickening on the inner aspect and inversion of the epidermis, in consequence of which the anterior wall of the primitive ocular vesicle is also inverted, and becomes applied to the posterior wall, so that the cavity of the vesicle is wholly obliterated.

"Now, at first this secondary ocular vesicle encompasses the lens, which in the meantime has been separated by constriction from the epidermis, and comes into exact apposition with it beneath; like a cup subsequently however the vitreous body is developed between the two in a special new cavity. How the latter is formed has not yet been ascertained, although, as Schöler observes, it is most probable that it also grows in from the skin, in fact from the region below and behind the lens, and participates with the latter in the inversion of the primitive ocular vesicle. According to Remak, the retina is formed from the inner thicker wall of the inverted or secondary ocular vesicle, and from the outer and thinner, the choroid, from the anterior border of which the iris is not produced till afterwards. The sclerotic and cornea are applied from without upon the eyeball thus constituted, the former being to some extent a production of the skin. An interesting phenomenon is presented in the vessels existing in the fœtal eye, even in the transparent media. The vitreous body on its outer surface, between the hyaloid membrane and the retina, presents a tolerably wide meshed vascular plexus, which is supplied by branches of the arteria centralis retinæ, given off from it at its entrance into the eye, and anteriorly, at the border of the lens on the zonula Zinnii forms a vascular circle, the circulus arteriosus Mascagnii, from which again vessels are given off to the membrana capsulo-pupillaris presently to be described. Besides this, a special arteria hyaloidea, also derived from the central artery of the retina, runs in the so-called canalis hyaloideus, in a straight line through the vitreous body to the lens, and ramifies in the most elegant arborescent manner at very acute angles in a membrane closely applied to the posterior wall of the lenticular capsule. This is nothing else than a portion of an externally vascular capsule which at first very closely surrounds the lens, and in its anterior walls is supplied by the continuation of the hyaloid artery coming round the border of the lens towards the front, with which branches of the circulus arteriosus Mascagnii and of the anterior border of the uvea are connected. Afterwards, when the lens retreats from the cornea, with which it is at first in close apposition, and the iris buds out from the border of the uvea, the anterior wall of the vascular lenticular capsule is divided into two portions, one central and anterior, which, arising from the border of the iris, and connected with that membrane by vessels, closes the pupil, the membrana pupillaris; and another external and posterior, extending backwards from the same points on the border of the lens, the membrana capsulo-pupillaris. The latter becomes more and more distinct as the iris and aqueous chambers are developed, and the lens retreats until at last it represents a delicate membrane stretching across the posterior chamber.

"The venous blood from all these parts is returned through the veins of the iris and from the outer surface of the vitreous body, also through those of the retina, and perhaps through a vena-hyaloidea said to take the same course as the artery, but of the existence of which many authors doubt, and which I have never myself seen. With respect to the genetic import of the vascular capsule, nothing has as yet been ascertained. I find it to be composed of a homogeneous tissue, with a few scattered cells, and regard it as a structure corresponding to the cutis which in the formation of the lens is detached from the skin, together with a portion of the epidermis, and remains in the eye. The vitreous body then may be understood as modified subcutaneous connective tissue—a supposition not at all incongruous with the observations above adduced, and the more so because, as I have shown, all the subcutaneous connective tissue of the fœtus is at one time perfectly gelatinous, and, like the enamel organ, which also belongs to the same tissue, in specie strikingly resembles the vitreous body in aspect and consistence.

"Concerning the histological development of the eyes, the following only need be remarked. At an early period they consist in all their parts of formative cells of uniform size, which in process of time are metamorphosed into the various tissues. In the fibrous coat in the second and third month the cells are developed in the mode already described into connective tissue, and at the same time the distinction is set up between the cornea and sclerotic, which are at first externally exactly alike, and constitute only a single membrane. In the uvea the cells are for the most part employed in the formation of vessels; another portion goes to the formation of the inner and outer pigment layers, pigment granules being deposited in them at the commencement of the third month, whilst another is transformed into muscles, nerves, the epithelia and connective tissue of these membranes. The development of the nerve-cells and of the so-termed 'granules' from embryonic cells, may be readily traced. I have observed the same thing also with respect to the 'cones,' and I think that in the Frog it may be assumed with respect to the 'rods' likewise, that they are nothing but elongated cells; whilst in the *Mammalia* the formation of the rods and of the nerve-fibres themselves, has not yet been traced. The lens, lastly, is originally composed entirely of cells, which in course of time are transformed into the tubes.

"The precise nature of the processes attending these changes has not yet been investigated, although I agree with H. Meyer in the conclusion, that, since the tubes, both in the fœtus and child, present only a single nucleus, each of them is developed out of a single cell. These nuclei, taken as a whole, constitute a thin layer extending from the borders of the lens, through the middle of its anterior half, and slightly convex in front ('nuclear zone,' Meyer); the nuclei being smaller in the interior portions, and, as it were, in progress of solution, whence it may certainly be concluded that the lens increases by the apposition of thin layers from without. The formative-cells of the tubes of the lens are those which exist on the anterior half of the capsule, and the starting-point of the formation of the lenticular elements, according to my observation, is the entire anterior surface and the border of the organ. Nuclei are visible in the tubes even in the lens of the adult, as was known to Harting, though only at its margin."

EYEBRIGHT. [EUPHRASIA.]

F

FABA, a genus of Plants belonging to the natural order *Leguminosæ.* It has a tubular 5-cleft or 5-toothed calyx, with the two superior teeth shortest. The style is villous at the apex. The legume is large and coriaceous, lined with short hairs, and containing several large flat seeds. The leaves are almost without tendrils, and the stem is erect. The flowers are white or red.

F. vulgaris, the Common Bean, has thick leaves with 2-5 broad oval mucronate leaflets. It has semi-sagittate oval stipules, and the teeth of the calyx are almost linear.

This plant is much cultivated, and subject to considerable variety. Its seeds differ, being sometimes round and comparatively small, at other times large and flat. The flowers are mostly white, with a blackish-blue silky spot in the middle of the two lateral petals called wings. The Common Bean is said to be found wild in Persia, not far from the Caspian Sea, but it is one of those plants, which, having from time immemorial been cultivated by man, may have anywhere been introduced by his agency. It does not occur wild in the countries of Europe, where it grows most luxuriously under the care of man. For an account of the culture and properties of this plant and its uses, see BEANS, in ARTS AND SC. DIV.

FABACEÆ, *Leguminous Plants*, a name proposed by Lindley in his 'Vegetable Kingdom' for the natural order *Leguminosæ.* [LEGUMINOSÆ.]

FABOI'DEA, Mr. Bowerbank's generic title for Seed-Vessels found in the London Clay of Sheppey. ('Fossil Fruits of the London Clay.')

FÆCULA. [STARCH.]

FAGOPYRUM, a genus of Plants belonging to the natural order *Polygonaceæ.* It has a 5-parted perianth, 8 stamens, 3 styles, a 1-seeded trigonous nut, a central embryo, and large foliaceous contorto-plicate cotyledons. There is but one British species of this plant, the *F. esculentum.* This is the *Polygonum Fagopyrum* of Smith, and known as the common Buck-Wheat. It has an erect stem without prickles, the flowers in cymose panicles, 8 stamens, leaves cordate, sagittate, acute, a triquetrous acute nut, with entire angles. This is a valuable plant, as it grows on the worst and poorest soils, and is often sown as food for game. Though now admitted into the British Flora, there can be no doubt that it was originally a native of Persia and other Asiatic countries. It was introduced into Europe by the Crusaders; and hence in many parts of France, where it is commonly grown, is called Saracen Corn; and so much is it esteemed in Belgium, that M. Bory St.-Vincent says he was shown the tomb of the person who is reported to have first brought it into that country. [BUCK-WHEAT, in ARTS AND SC. DIV.]

(Babington, *Manual of British Botany;* Burnett, *Outlines of Botany.*)

FAGUS (from φάγω, to eat), a genus of Plants belonging to the natural order *Corylaceæ.* This order is characterised by its male flowers being arranged in catkins, and the female flowers being solitary or on spikes, and the fruit surrounded by a coriaceous involucre. The genus *Fagus* has its stamens in a globose catkin; the perianth 5-6-fid; the stamens 8 to 15 in number; the pistilliferous flowers are 2 together, and contained within a 4-leaved prickly involucre; the stigmas 3; the ovaries 3-cornered and 3-celled; the fruit is a nut, which by the suppression of the ovules and cells is only 1- or 2-seeded. The species are large handsome deciduous trees, natives of Europe, North and South America, and Australia. The best known species is the Common Beech, which is a native of Great Britain.

F. sylvatica, the Wood-Beech or Common Beech. It has ovate glabrous obsoletely-dentate leaves, ciliated on their margins. It is a tree varying from 60 to 100 feet in height. It is a native of various parts of Europe besides Great Britain, and a variety is found in North America. Loudon, in his 'Arboretum et Fruticetum Britannicum,' gives the following varieties:—

F. s. purpurea, the Purple-Beech, which has the buds and young shoots of a rose-colour.

F. s. cuprea, the Copper-Coloured Beech, in which the young shoots and leaves are of a paler colour than in the last.

F. s. foliis variegatis, the Variegated Beech, in which the leaves are white and red, interspersed with streaks of red and purple.

F. s. heterophylla, the Cut-Leaved Beech, in which the leaves are separated in various ways.

F. s. cristata, the Curled-Leaved Beech. The leaves are curled up in this variety.

F. s. pendula, the Weeping Beech, in which the branches are pendulous.

F. s. Americana, the White Beech. This is the American form of the Common Beech.

The Beech is remarkable for its smooth thin bark, which becomes white when fully exposed to the air. In the midst of it those knobs called embryo-buds, or abortive branches, are more often found than in any other tree. They are sometimes used by cabinet-makers and turners on account of their hardness. At the Great Exhibition of 1851 a chair was exhibited composed entirely of these knobs. The leaves are shining and thin, changing to a brown or russet colour in the autumn, and often remaining on the tree throughout the winter. Its branches are numerous, and its foliage so dense that other plants do not thrive under it; so that there is seldom any vegetation seen on the ground in a beech forest. The *Monotropa Hypopithys*, Bird's-Nest Orchis as it is called, is often found parasitical upon its roots. The fruits contain a nut or seed, which when ripe frequently drops out, leaving the husk upon the tree. The seeds are not disagreeable to the taste. Squirrels are fond of them, and are often found seeking them on these trees. The beech-trees in the forests of Germany generally attain the age of about 200 years. There is one in Windsor Forest which is supposed to have been in existence before the Norman Conquest.

The wood of the Beech-Tree when green is harder than that of any of our forest-trees. It is very generally used in the arts for all purposes where strength is required, and where the action of water is to be resisted. On the Continent, and especially in France, one of the most important uses of this wood is for making wooden shoes called sabots. They have the property of not absorbing water, and surpass the sabots of all other wood, except those made of walnut, which are much dearer.

As fuel the wood of the Beech is superior to that of most other trees. It is consumed for this purpose to a great extent in France and Germany. It burns rather rapidly, but throws out a great deal of heat, and makes a clear bright flame.

The fruit, the nut of which is called Beech-Mast in England, and la Faine in France, has a taste somewhat approaching to that of the hazel-nut. It forms an excellent food for swine, but the flesh of those which are fattened upon it does not keep so well as that of those fed on acorns. Beech-mast is sought after by wild animals, such as badgers, dormice, &c. Beech-oil, expressed from the nuts, is used in cooking, also for burning in lamps. For useful plantations the Beech is not highly prized; it is chiefly valuable as an ornamental tree for the park and the lawn. It is subject to the attacks of comparatively few insects; those which do infest it belong chiefly to the *Lepidoptera*, and are in the caterpillar state. The fungi which grow on the Beech in Great Britain are rather numerous: various species of *Agaricus, Boletus, Polyporus, Peziza, Stromatosphæria*, and *Stilbum* are mentioned. The most remarkable fungi growing beneath the Beech-Tree are—*Geoglossum viride, Helvella esculenta*, and *Morchella esculenta*, the common Morel. The last two species are celebrated luxuries for the table. *Morchella esculenta* grows in great abundance in the woods of Germany and France, particularly after any of the trees have been burned down. This having been observed, led in Germany to the practice of burning the trees in order to produce Morels, and consequently great numbers of them were destroyed till it was forbidden by law.

F. ferruginea, the American Ferruginous-Wooded Beech, is a North American timber-tree, so much resembling the common European Beech as to be considered by some to be only a variety of it. It has ovate acuminate thickly-toothed leaves, downy beneath, ciliate on the margin. The American Beech is easily known from the European one by its much shorter obtusely-pointed buds, with short roundish convex scales, which terminate almost abruptly, and are inclosed in numerous short loose scales. There are two varieties of this species—*F. Caroliniana* and *F. latifolia.*

F. obliqua, the Oblique-Leaved Beech, is a native of Chili. It has ovate-oblong oblique leaves, somewhat rhomboid, blunt, doubly serrated, entire at the base, attenuated into the petiole, somewhat downy.

F. betuloides, the Birchlike or Evergreen Beech, grows at Port Famine, Straits of Magalhaens, in the greatest abundance. It attains a very large size, trees of three feet in diameter being common, and there being many with trunks four feet in diameter. This Beech is also a native of Van Diemen's Land, where it is called the Myrtle-Tree by the colonists. It has ovate-elliptic leaves, obtuse, crenulate, leathery, shining, glabrous, round at the base, on short footstalks. The branches are divaricate, tortuous, brownish, the young ones pubescent, the leaves ciliate, alternate, from 4 to 10 lines long, and from 3 to 8 lines broad. The flowers are axillary. It is an evergreen tree, and forms vast forests in Tierra del Fuego, where it is a native.

F. antarctica, the Antarctic Beech, is a native of Tierra del Fuego.

F. Dombeyii, Dombey's or the Myrtle-Leaved Beech, is a tall tree, a native of Chili, where it is known by the name of Coigué, and furnishes excellent wood for the purposes of construction.

F. dubia, the Dubious Beech, is thought only to be a variety of *F. betuloides.* By some botanists, however, it is considered a distinct species, and is described as such.

FAHLORE, *Fahlerz*, Gray Copper Ore. Of this there are two varieties, the arsenical and the antimonial: the former occurs crystallised and massive. The primary form of the crystal is a cube, but the regular tetrahedron is the predominating crystal. Colour steel-gray, opaque. Lustre metallic. Specific gravity 4·8 to 5·1. Hardness 3·0 to 4·0, brittle. Cleavage parallel to the planes of the tetrahedron, very indistinct. Fracture conchoidal.

Massive Variety.—Amorphous. Structure granular to compact.

It occurs in Cornwall, Hungary, Saxony, &c. A specimen from Freiberg, analysed by Klaproth, yielded—

Arsenic	24·10
Copper	41·00
Iron	22·50
Sulphur	10·00
Silver	·40
Loss	2·00
	100

It frequently contains a much larger quantity of silver, and not uncommonly zinc.

Antimonial Fahlore.—It occurs crystallised in modified tetrahedrons. The colour dark lead-gray, approaching to iron-black, both externally and internally: not very brittle.

Analysis of a specimen from Kapnic by Klaproth:—

Antimony	22·00
Copper	37·75
Iron	3·25
Sulphur	28·00
Silver, and a trace of Manganese	·25
Zinc	5·00
Loss	3·75
	100

FAHLUNITE, *Tricklasite*, a Mineral consisting of silicate of alumina and other substances. It occurs crystallised and massive. The primary form of the crystal is a right rhomboid prism, but it usually occurs in imbedded, regular, hexagonal prisms. Colour yellowish, greenish, and blackish-brown. Nearly or quite opaque. Lustre resinous. Specific gravity 2·66. Hardness 5·0 to 5·5. Streak grayish-white. Cleavage perpendicular to the axis of the prism.

It is found at Fahlun in Sweden.

Before the blow-pipe alone it becomes gray, and fuses on its thinnest edges; with borax it melts slowly into a coloured glass.

According to Hissinger it consists of—

Silica	46·74
Alumina	26·73
Magnesia	2·97
Oxide of Iron	5·11
Oxide of Manganese	0·43
Water	13·50
	95·48

FALCIFERI. [AMMONITES.]

FALCO. [FALCONIDÆ.]

FALCON. [FALCONIDÆ.]

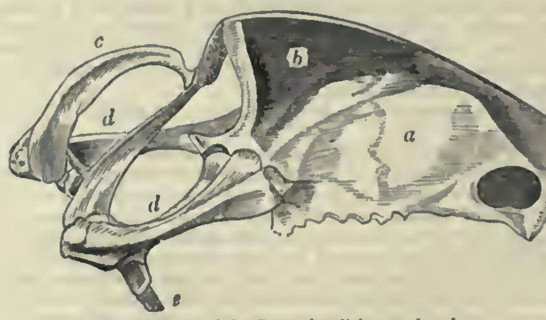
FALC'ONIDÆ, Leach's name for a family of Raptorial Birds, or birds of prey (Raptores of Illiger). In this family the destructive power is considered by all zoologists to be most perfectly developed; and we find in the birds composing it natural instruments for striking, trussing, and dissecting their prey, combined with a power of flight and strength of limbs equivalent to the necessities of the case, whether the prey be aërial, that is, whether it be the habit of the raptorial bird in question to strike down its quarry while the latter is in the act of flight, or whether the prey be terrestrial, or, in other words, captured on the ground. Of these natural weapons some idea may be formed from the cuts here given; and they are rendered still more

Bill of the Peregrine Falcon (*Falco peregrinus*).

formidable by the organisation of the whole animal, which is calculated to give them the greatest possible effect. The nails or claws, to be available, must be sharp; and in order that they may be kept in this state and fit for duty, there is a provision to enable the bird to prevent them from coming in contact with the ground or other foreign hard bodies; for the claws are retractile, not indeed in the same manner as those of the cats [FELIDÆ], which have the power of withdrawing or sheathing theirs within the integuments, but by a conformation which gives the bird of prey the power of elevating its claws at pleasure. The claws of falcons when sitting on stones or large branches of trees have often a cramped appearance; but this arises in most instances from the care of the bird so to arrange talons that their points may not be blunted against the perch.

Foot of the Peregrine Falcon (*Falco peregrinus*).

The power of flight, as Mr. Yarrell observes in his memoir 'On the Anatomy of Birds of Prey' ('Zool. Journ.,' vol. iii.), is one of the decided marks of the distinct organisation of birds; and, as one division of the first genus, *Falco*, appears to possess this power in the highest degree of perfection, he proceeds to consider the conditions necessary to produce such a degree. These, he observes, are large and powerful pectoral muscles; great extent of surface, as well as peculiarity of form in the wing; and feathers of firm texture, strong in the shaft, with the filaments of the plume arranged and connected to resist pressure from below. "A certain degree of specific gravity," continues Mr. Yarrell, "is necessarily imparted by large pectoral muscles, and the power of those muscles may be estimated by the breadth of the sternum and the depth of its keel, as affording extent of surface for the attachment of the large muscle by which the wing is depressed. As an illustration of this form the breast-bone of the Peregrine Falcon (*Falco peregrinus*) is represented, which exhibits the



Breast-bone of the Peregrine Falcon reduced.

a, the sternum; *b*, the keel; *c*, the furcula, or os furcatorius; *d d*, the clavicles; *e*, the scapula broken off.

breadth of the sternum, the depth of the keel, as well as the strength of the clavicles; and the power of flight peculiar to all the species of true falcons is still further illustrated by the form and substance of the os furcatorius, which is circular, broad, and strong, affording a permanent support to the shoulders. That the long and acuminated form of the wing in the true falcons, with each feather narrow, firm in consistence, the second the longest, and all gradually tapering to a point, is also best adapted for rapidity of motion, may be inferred from the example in the various species of the genera *Hirundo*, *Scolopax*, *Tringa*, *Charadrius*, *Procellaria*, *Sterna*, &c.; but that extent of surface and this peculiarity of form in the wing are not in themselves sufficient alone to afford rapid flight, is proved in the genus *Larus*, the species of which, though capable of exercising their immense pinions with graceful ease for hours in succession, without any apparent lassitude, are still incapable of rapid flight, for want of strong pectoral muscles. The numerous examples also furnished by the Gallinaceous tribe sufficiently evince that immense pectoral muscles are insufficient when coupled with a small round wing, and afford but a short flight, sustained with great labour, rapid in a small proportion only to the strength and repetition of the impulse, and accompanied by a vibration too well known to need further remark. So material also is the perfection of the feather in the genus *Falco*, that when any of those of the wing or tail are broken, the flight of the bird is so injured that falconers find it necessary to repair them. For this purpose they are always provided with pinion and tail-feathers accurately numbered, and the mode of uniting the more perfect feather to the injured stump is described in Sir John Sebright's excellent observations on hawking. The reader who is disposed to go farther back, will find in the 'Booke of Falconrie or Hawking,' &c. 'heretofore published by George Turbervile, Gentleman,' (Loudon, small 4to, 1611), the following chapters:—"Of Accidents that happen and light uppon a hawkes feathers, and first how to use the matter when a feather cannot be ymped." "The way and manner how to ympe a hawks feather, howsoever it be broken or bruised;" and four methods of operating, according to the circumstances, are detailed. "How to ympe the traine of a hawke beeing all broken, and never a feather whole or sound." Mr. Yarrell proceeds to observe that it is difficult to estimate the comparative rapidity of flight in different birds, and that our pigeons may appear to possess this advantage in a degree little inferior to the true falcons; but, he adds, the fact is that these birds are deficient in natural courage, and are unable, under circumstances, to avail themselves of those powers with which they are gifted.

"The bodies of all the species of true falcons when denuded of their feathers are triangular in form, broad at the shoulders and tapering gradually to the tail, the muscles of the thighs and legs of great size; but these characters are less prominent in the hawks, the bodies of which are more lengthened, the legs long and slender, the pectoral muscles smaller, the wing rounded in form, the fourth feather the longest, the wing primaries broad in the middle, the inner webs overlapping the feather next in succession, and emarginated towards the end. These two divisions of the genus *Falco*, although the latter are unequal to the former in powers, are remarkable for their bold character and rapid flight, their invariable mode of striking their prey on the wing, as well as the instinctive knowledge by which they are directed to destroy life, attacking the most vital part, and penetrating the brain with their sharp hooked beak either by one of the orbits where the bone is very thin or at the junction of the cervical vertebræ with the occiput.

"On comparing the bones of our two British eagles, the greater power of flight appears to belong to the *Albicilla*, that of prehension to the golden eagle, but both exhibit various indications of great strength.

"By an extended examination of the different species of buzzards and harriers it will be found that the characters described as necessary to produce rapid motion decline gradually. The sternum decreases in size, the keel loses part of its depth, the clavicles and furcula become more slight, while the form of the cranium, the loose ruffled feathers of the neck, as well as the general downy texture of the plumage, indicate the approach to the genus next in succession. Of the bones of the different species of the genus *Falco* generally it may be added that they are remarkable for their strength, such as are cylindrical being furnished with numerous transverse bony processes within the tubes, and the distribution of air throughout their internal cavities. The humerus is supplied with air through several orifices upon its inner and upper surface, and some difference will be found in the angle at which this bone is articulated with the clavicle to accomplish the ascending flight of the sky-lark, in contradistinction to the precipitous horizontal direction of the falcons. The thigh bone is also supplied with air by an orifice at the situation which answers to the front of the great trochanter; the large bones forming the pelvis, the vertebræ, sternum, furcula, clavicles, scapulæ, and even the ribs, are all furnished with apertures for the admission of air supplied from the various cells of the abdomen, sides, and thorax. This distribution of air to the bones does not seem however to be absolutely necessary for flight, since the young birds of our summer visiters appear to perform their first autumnal migration with perfect ease and celerity, at an age when the cavities of their bones are filled with marrow.

"The various characters of the feet are too obvious to require particular notice." (Yarrell.)

In the Museum of the Royal College of Surgeons in London the reader will find a preparation (Gallery, 522 A) of the stomach of the Golden Eagle. It is laid open so as to show the orifices of the numerous gastric glands of the proventriculus, the smooth lining membrane of the gizzard, and the valvular structure of the pylorus. The œsophagus is very wide, so that externally it appears to form one continued cavity with the proventriculus and stomach. John Hunter, in his 'Observations on Digestion' ('Animal Economy'), says, "There are few animals that do not eat flesh in some form or other, while there are many who do not eat vegetables at all; and therefore the difficulty to make the herbivorous eat meat is not so great as to make the carnivorous eat vegetables. Where there is an instinctive principle in an animal, directing it either to the one species of food or the other, the animal will certainly die rather than break through of its own accord that natural law; but it may be made to violate every natural principle by artificial means. That the hawk tribe can be made to feed upon bread I have known these thirty years; for to a tame kite I first gave fat, which it ate very readily, then tallow and butter, and afterwards small balls of bread rolled in fat or butter, and by decreasing the fat gradually it at last ate bread alone, and seemed to thrive as well as when fed with meat. This however produced a difference in the consistence of the excrements; for when it ate meat they were thin, and it had the power of throwing them to some distance; but when it ate bread they became firmer in texture, and dropped like the excrement of a common fowl. Spallanzani attempted in vain to make an eagle eat bread by itself; but by inclosing the bread in meat, so as to deceive the eagle, the bread was swallowed and digested in the stomach."

Mr. Yarrell observes that the œsophagus offers nothing peculiar beyond that of other birds not possessing the power of minutely dividing their food. It is plicated lengthways, allowing great extension, and its separation from the stomach is marked by a zone of gastric rings. The same author notices an opportunity which occurred to him of observing the castings or pellets of some eagles, which had been occasionally fed with dead pigeons. These castings showed that the vegetable food, such as peas, wheat, and barley, which had been swallowed by the eagles in the crops of the pigeons, remained entire, but somewhat enlarged and softened by heat and moisture. In these cases no part of the bones remained.

The intestines of the *Falconidæ* are in general short and large, but Mr. Yarrell remarks that the Osprey is an exception to this rule, and that to the thin membranous stomach of this bird there is attached an intestinal canal measuring 10 feet 8 inches in length, and in some parts scarcely exceeding a crow-quill in size. The canal in most of the species he adds, is in length, compared with that of the bird itself, as three to one; but in the Osprey it is as eight to one; and he observes that in the otter the intestinal canal is very long, equal in size, and without cæcal appendage; the seal too has long intestines with a small cæcum. Mr. Yarrell inquires therefore if it may not be concluded that the small quantity of nutriment which fish, as an article of food, is known to afford renders this extent of canal necessary in order that every portion may be extracted. The cæca of the *Falconidæ* amount to no more than minute rudiments.

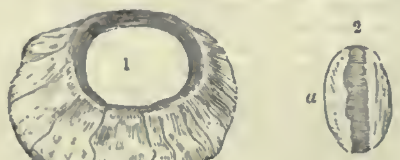
In the organs of respiration there is nothing very remarkable among the *Falconidæ*. The trachea is composed of two membranes inclosing between them numerous bony rings, forming a more or less perfect tube. The rings are strong and compressed. The point of divarication, the cross-bone, and bronchiæ constituting together the inferior larynx, are of the most common form, having but one pair of muscles attached; and the voice though powerful possesses, as might be expected, but little variation. (Yarrell.) *Falco musicus* seems however to be an exception, and it would be desirable to examine its trachea for the purpose of ascertaining whether it is not organised more after the fashion of that of the singing birds.

It might be expected that in the *Falconidæ* the soles of the feet and lower surfaces of the toes which come so closely into contact with the living prey would be endowed somewhat more largely with the sense of touch than those of birds which have no such habits; accordingly we find in the Museum of the College of Surgeons (Physiological Series) a preparation (No. 1400) of one of the feet of an eagle, with the cuticle removed, showing the papillæ and cushions of the cutis on the under surface of the foot.

In the same museum (No. 1482) will be found the tongue, larynx, and lower jaw of the Golden Eagle (*Aquila chrysaëtos*). The tongue is fleshy and large, divided into two lateral portions by a deep longitudinal furrow; at its base is a series of small retroverted spines arranged in the form of a chevron, between which and the larynx the surface is studded with the orifices of numerous glandular follicles: two rows of retroverted spines again occur behind the larynx. There is a row of glandular follicles on either side of the frænum linguæ, and a large cluster of similar orifices immediately anterior to it. The preparations Nos. 1483 and 1484 exhibit respectively the tongue and fauces of an Erne (*Haliæetus albicilla*) and the tongue and larynx of an Osprey (*Pandion haliæetus*).

A longitudinal section of the anterior part of the head of the Golden Eagle will be found in the same museum and series (No. 1538). The preparation shows the turbinated cartilages and cavity of the nose, together with part of the orbit and the air-cell continued from it anteriorly and situated below the nose. The parts are minutely injected, and the vascularity of the pituitary membrane covering the middle turbinated cartilage is well displayed. No. 1539 is a transverse section of the head of an Erne (*Haliæetus albicilla*), showing the convolutions of the middle turbinated cartilages, and the disposition of the pituitary membrane, which is thickest on the convex or mesial side of the convolutions. The air-cells in the superior maxillary bones, and their communications with those which are situated in front of the eyeball, are well seen in this preparation. Bristles have been inserted into the lachrymal ducts, and into the common termination of the Eustachian tubes, the respective conduits of the eye and ear for conducting their superfluous moisture to the nasal passages. An anterior transverse section of the head of the same eagle is shown in No. 1540, which exhibits the external nostrils, the anterior terminations of the middle turbinated cartilages, and of the lachrymal ducts, in which bristles are placed; together with the communications of the maxillary air-cells with the cancellous structure of the upper mandible. ('Cat. Gallery,' vol. iii.)

"The extraordinary powers of vision," says Mr. Yarrell, "which birds are known to exercise beyond any other class of animals are in no genus more conspicuous that in that of *Falco*. Their destination, elevating themselves as they occasionally do into the highest regions, and the power required of perceiving objects at very different distances and in various directions, as well as the rapidity of their flight, seem to render such a provision necessary. The eyes of birds are much larger in proportion than those of quadrupeds, and exhibit also two other peculiarities. The one is the marsupium, a delicate membrane arising at the bottom of the eye, and terminating at or near the edge of the crystalline lens: the other is a ring of thin bony plates enveloped by the sclerotic coat. Comparative anatomists do not seem to be agreed as to the means by which birds obtain their power of vision, whether by an alteration in the form or situation of the crystalline lens, or by both, either or both of which, the greater quantity of aqueous humour which birds are known to possess would seem to facilitate. The existence of muscle attached to the inner surface of the bony hoop of the sclerotica, and inserted by a tendinous ring into the internal surface of the cornea, as shown by Mr. Crampton ('Annals of Philosophy,' 1813), by which the convexity of the cornea may be altered, gives a still greater scope of action, since with two, or at the utmost three, varieties of powers the sphere of distinct vision may be indefinitely extended. Whether the five speices called the True Falcons possess, with their exclusive rapidity of flight, any power of vision beyond their generic companions would be difficult to ascertain; but it may, while on this subject, be worthy of remark that the irides of the gyrfalcon, peregrine, hobby, merlin, and kestrel are hazel-brown, or still darker, while those of all the hawks, buzzards, harriers, and kites are of various shades of yellow. I refer only to adult birds, and do not remember a single exception."



1, bony ring of a Golden Eagle; 2, crystalline lens of the same bird; *a*, the anterior surface, somewhat less convex than the posterior one. (Yarrell.)

Mr. Yarrell observes, that the number of bony plates forming this circle in the Golden Eagle is fifteen; in the White-Tailed Eagle there are but fourteen: and he adds, that the external convex form of the bony ring in the Golden Eagle will be found to extend through all the species of every genus of British birds, except the owls, in all of which it is concave.

In the Museum of the College of Surgeons are the following preparations illustrative of this part of the subject. No. 1741. The head of an eagle, with the eyes in situ. In the left eye the anterior part of the tunics and the humours have been removed to show the retina expanding from the oblique line by which the optic nerve terminates, and the vascular processes of the marsupium extending forwards from the centre of the optic fissure. In the right eye a lateral section of the coats has been removed, together with the humours and a great part of the retina, showing the uniformly dark-coloured choroid, the thin but dense texture of the sclerotica, and the zone of osseous plates which supports the projecting cornea. The marsupium is preserved in situ. It is of an unequal quadrilateral figure, broadest below, and extending upwards and inclined a little backwards, with a slight convexity towards the nasal side of the eyeball. The large size of the eyes is worthy of notice. No. 1742 exhibits a longitudinal section of the eye of an eagle, showing the oblique manner in which the optic nerve perforates the sclerotica and its extended termination, from which the retina expands in a plicated manner: only the folds at its origin are here preserved. The parts being minutely injected, the vascularity of the choroid is shown: also the breadth of the ciliary zone, the breadth and thickness of the bony imbricated hoop surrounding the base of the cornea, the thickness of the cornea itself, and the large size of the anterior chamber of the eye. No. 1743 is the eye of an eagle, with a portion of the coats removed from one side, showing the folds of the marsupial membrane, from which the colouring matter has been removed. In No. 1538, above alluded to, portions of the eye and eyelids with the nictitating membrane are preserved, showing the situation of the two puncta lachrymalia, through which bristles are passed along the ducts to the nose; and in No. 1539, at the back part of the preparation, the left eyeball is laid open, showing the marsupial membrane. The right eyeball is entire, and the abductor, attollens and deprimens oculi, together with the quadratus and pyramidalis muscles of the membrana nictitans, are well displayed. See also No. 1540, as referrible to the organs of vision. No. 1796 exhibits the eyeball, with portions of the horizontal eyelids, the vertical eyelid, or membrana nictitans, of an eagle. The quadratus nictitantis may be observed to have a more extensive origin than in the ostrich, and both muscles of the third eyelid are relatively larger. The cornea is cut away, and the nictitating membrane raised, to show the termination of the duct of the Harderian gland, in which a bristle is placed. Bristles are also placed through the two puncta lachrymalia. The round and slightly concave tarsal cartilage of the lower eyelid may be observed, the upper lid has no tarsal cartilage. In No. 1797 the three eyelids of an eagle are exhibited, and the tarsal cartilage, which is raised as in the act of closing the eyes, is shown.

Aristotle divided the *Falconidæ* into 'Αετοί, or Αἰετοί (Eagles), 'Ιέρακες (Hawks), and 'Ικτῖνοι (Kites), with many subdivisions. Mr. Vigors is of opinion that the division 'Ιέραξ (Hierax) of Aristotle comprises all the *Falconidæ* of Vigors which belong to the stirpes or sub-families of Hawks, Falcons, and Buzzards. Pliny separates the group into *Aquilæ* (Eagles) and *Accipitres*, a general term comprising, as used by him, the rest of the *Falconidæ*. The subdivisions of both Aristotle and Pliny do not differ much from the subdivisions of some of the modern zoologists.

Belon, beginning with the Vultures, proceeds from them to the Eagles; thence to the Gerfault, which he gives as the Morphnos, Morphna, Nittophonos, Plangos, Plancus, Plangus, and Clangus, of the Greeks, and *Anataria* of the Latins; next he places the Orfraye, which he makes the *Haliæetus* of the Greeks, the Aguista Piombina of the modern Italians, and gives *Aquila marina* as the Latin name. He then treats of the *Ossifragus* as the Phinis of the Greeks, *Aquila barbata* in Latin, recording it provisionally as a species of Vulture (Petit Vautour) and next describes the Buzzard (Buse ou Busard) as a kind of Bastard Eagle, and as the Gypaëtos, Percnopterus, or Oripelargus, of the Greeks. Then comes the Goiran, or Boudree, which he describes as living upon rats, mice, frogs, lizzards, &c., caterpillars, and sometimes slugs and serpents, asserting that it becomes very fat, and that it is taken frequently in winter for the sake of its flesh, which is good for food. This he supposes to be the *Hierax*, called Phrynolochos by the Greeks, and gives *Rubetarius Accipiter* as the Latin name. Jean le Blanc, or Oyseau Saint Martin, which he considers to be the Pygargus of the Greeks, follows, and is succeeded by another Oyseau Saint Martin, or Blanche-Queue. Belon then gives an account of the Birds of Prey employed in falconry. The Sacre and her Sacret, the Autour and her Tiercelet, the Fau-Perdrieux (Circus?), and the Falcons generally, with their Tiercelets. He then describes the Hobreau (Hobby?), the Esmerillon (Merlin?), the Espervier (Sparrowhawk?), the Lanier and Laneret, and the Cresserelle (Kestrel?). Next follow the Butcher-Birds, then come the Kites (Milan Royal, Milan Noir—Milvus), and (the Cuckoo intervening from a supposed similitude to the Birds of Prey) the Owls.

Passing by Gesner, Aldrovandus, and Jonston, we pause to notice Willughby's arrangement. He separates the carnivorous and rapacious birds, called Birds of Prey, into the Diurnal (those that prey in the day-time) and the Nocturnal (those that fly and prey by night). The following is his table of the Diurnal section:—

Diurnal	The Greater, and these either . . .	The more generous, called Eagles: the Golden Eagle, the Sea-Eagle, the Black Eagle, &c.		
		The more cowardly and sluggish, called Vultures.		
	The Lesser, called in Latin *Accipitres*	The more generous, that are wont to be reclaimed and manned for fowling, called Hawks, which our falconers distinguish into	Long-Winged, whose wings reach almost as far as the end of their train, as the Falcon, Lanner, &c.	
			Short-Winged, whose wings when closed fall much short of the end of their trains, as the Goshawk and Sparrowhawk.	
		The more cowardly and sluggish, or else indocile, and therefore by our falconers neglected, and permitted to live at large .	The Greater.—The Common Buzzard, Bald Buzzard, &c.	
			The Lesser	European: Butcher Birds or Shrikes.
				Exotic: Birds of Paradise.

Ray, in his 'Synopsis,' follows Willughby, and both Ray and Willughby place the Cuckoo after their Diurnal Birds of Prey and immediately before the Nocturnal.

Brisson's third order consists of birds with a short and crooked beak, and the first section contains the genera Epervier (Hawk), Aigle (Eagle), and Vautour (Vulture).

Linnæus makes his first order, *Accipitres*, consist of the genera *Vultur*, *Falco*, *Strix*, and *Lanius*. The genus *Falco* contains the elements of the different branches of the family of *Falconidæ*.

Without entering into the methods of Buffon, Schæffer, and Scopoli, we proceed to that of Latham, who made the *Accipitres* his first order of Terrestrial Birds, containing the genera Vulture, Falcon, and Owl.

Pennant makes the Rapacious Birds (his first section) consist of two genera only, namely, Falcon and Owl.

M. de Lacépède placed the Birds of Prey (his seventh order) at the head of his second division of birds. His genera are *Vultur*, *Gypaëtos* (Griffon), *Aquila*, *Astur*, *Nisus*, *Buteo*, *Circus*, *Milvus*, *Falco*, and *Strix* (Owl).

M. Duméril divided his first order, *Rapaces*, into three families: the first Nudicolles, or Ptilodères, consisting of the genera *Sarcoramphus* and *Vultur*; the second Plumicolles, or Cruphodères, containing the genera Griffon, Messager, Aigle, Buse, Autour, and Faucon; and the third the Nocturnes or Nycterins (Owls).

Blumenbach's first order, *Accipitres* (Birds of Prey, with strong hooked bills and large curved talons, a membranous stomach, and short cæca) consists of the genera *Vultur*, *Falco*, *Strix*, and *Lanius*.

Meyer's first order, *Rapaces*, is divided into two sub-orders: first, the *Scleropteræ*, or Diurnal Birds of Prey; second, the *Malacopteræ*, or Nocturnal Birds of Prey.

The third order of Illiger, *Raptatores*, is composed of the *Nocturni* (*Strix*), the *Accipitrini* (*Falco*, *Gypogeranus*, *Gypaëtus*), and the *Vulturini* (*Vultur*, *Cathartes*).

Cuvier divides his first order (the Birds of Prey) into Diurnal and Nocturnal. The first are subdivided into the Vultures and the Falcons (*Falco*, Linn.), which last are separated into the Noble Birds of Prey, or Falcons properly so called (*Falco* of Bechstein), comprising the genera Faucon (*Falco*) and the Gerfaults (Gyr-Falcons, *Hierofalco* of Cuvier); and the Ignoble Birds of Prey, consisting of the Eagles (*Aquila* of Brisson), which are subdivided into the Eagles properly so called (*Aquila* of Cuvier), the Aigles-Pêcheurs (Fishing Eagles, with comparatively long wings, *Haliæetus* of Savigny), the Balbusards (*Pandion* of Savigny), the Circaëtes (*Circaetus*, Vieillot, Jean le Blanc, &c.), the Caracaras (*Polyborus*, Vieillot, and *Ibycter*, Vieillot), and the Harpies, or Fishing Eagles, with short wings (*Harpyia* of Cuvier); the tribe *Cymindis* of Cuvier; the Aigles-Autours (*Morphnus* of Cuvier, Spizaëtos of Vieillot); the Autours (*Astur* of Bechstein, *Dædalion* of Savigny); the Milans (*Milvus* of Bechstein, *Elanus* of Savigny); the Bondrées (*Pernis* of Cuvier, Honey Buzzard); the Buses (*Buteo* of Bechstein); the Busards (*Circus* of Bechstein); and the Messager or Secrétaire (*Serpentarius* of Cuvier, *Gypogeranus* of Illiger).

Vieillot divides his first order, *Accipitres*, into the Diurnal and Nocturnal tribes, making the first tribe to consist of three families:—1st, Vautourins, among which he places the *Caracara*; 2nd, Gypaëtes; 3rd, Accipitrins, consisting of the genera Aigle, Pygargue, Balbuzard, Circaëte, Busard, Buse, Milan, Elanus, Ictinie, Faucon, Physète, Harpie, Spizaëte, Asturine, and Epervier.

Temminck's first order, *Rapaces*, comprises the genera Vautour, Catharte, Gypaëte, Messager, Faucon, and Chouette.

Mr. Vigors thus arranges the *Falconidæ*:—

	TYPICAL GROUPS.	
Beaks short, strongly toothed. Prey aërial.	Wings short.	Sub-Family, *Accipitrina*. Hawks.
	Wings long.	Sub-Family, *Falconina*. Falcons.
	ABERRANT GROUPS.	
Beaks long, or subloug, not toothed. Prey terrestrial	Beaks hooked (adunca) from the base. Wings long.	Sub-Family, *Buteonina*. Buzzards.
	Beaks hooked from the base. Tail forked. Wings very long.	Sub-Family, *Milvina*. Kites.
	Beaks hooked at the apex only * Long-Winged. * * Short-Winged.	Sub-Family, *Aquilina*. Eagles.

De Blainville divides the *Raptatores* into the Diurnal and the Nocturnal. The former he divides into the Anomalous (the Secretary, *Serpentarius*); and the Normal (*Falco*, Linn.).

M. Latreille separates his first order of terrestrial birds (*Rapaces*) into two tribes—the Diurnal and the Nocturnal. The first contains two families:—1st, the Vautourins (Vultures); 2nd, the Accipitrins. The latter consists of the genera Aigle, Pygargue, Balbuzard, Harpie, Aigle-Autour, Asturine, Messager, Autour, Epervier, Elane, Milan, Bondrée, Busard, Faucon, Gerfault.

Prince C. L. Bonaparte, in his 'Tabella Analitica,' divides his 'Ordine *Accipitres*' into the 'Famiglia *Vulturini*,' and the 'Famiglia *Rapaces*.' These last he separates into the *Diurni*, with eyes on the sides of the head, "Occhi nei Lati;" and the *Nocturni*, with eyes in the face, "Occhi sulla Faccia." His Diurnal rapacious birds consist of two genera, namely, *Gypaëtos* and *Falco*. The latter comprises the following sub-genera:—*Aquila*, *Haliaëtos*, *Pandion*, *Falco*, *Astur*, *Milvus*, *Elanus*, *Buteo*, *Circus*.

M. Lesson, in common with other zoologists, separates his first order, the Birds of Prey, *Accipitres* or *Rapaces*, into the Diurnal and Nocturnal. The first embraces three families:—1st, the Vultures; 2nd, the Falcons, or *Falconidæ*, which he subdivides into the Noble Birds of Prey, namely the genera *Falco*, *Hiero-Falco*, *Physeta*, and *Gampsonyx*; and the Ignoble Birds of Prey, namely the genera *Aquila*, *Haliæetus*, *Pandion*, *Circaëtus*, *Caracara*, *Harpya*, *Morphnus*, *Cymindis*, *Astur*, *Nisus*, *Milvus*, *Ictinia*, *Elanus*, *Nauclerus*, *Pernis*, *Buteo*, *Circus*. 3rd, the Messagers, or *Serpentarii*, consisting of one genus only, *Serpentarius*, the Secretary Falcon.

Mr. Swainson ('Fauna Boreali-Americana') remarks that in contemplating the Diurnal Birds of Prey, arranged by Linnæus under the genus *Falco*, we can be at no loss to discover the two typical forms in the Toothed-Billed Falcons and the Sparrowhawks. Their peculiarities, he adds, did not escape the notice oven of the earliest systematic writers; and the moderns, he observes, have only confirmed the justness of the distinction. But with regard to the remaining groups he states that much diversity of opinion still exists; not indeed as regards the leading divisions, for here likewise the ancients had long ago anticipated our distinctions between the Eagles, Kites, and Buzzards. It is not therefore to these groups, taken per se, that any doubts can attach on their respective peculiarities, but rather as to their relative rank with those that are considered typical. These doubts, in Mr. Swainson's opinion, can only be solved by analysis; and from an attentive consideration of the difficulties arising from the want of materials in our museums, and other causes, he has been induced to dissent from several modern writers upon this family. He admits that it has been sufficiently proved that the various forms of which it is composed exhibit, as a whole, a circular succession of affinities; but the true series of the secondary groups among themselves has not, he asserts, yet been made out: he adds however that the inability to state in what way the falcons or hawks form their own respective circles cannot militate against the belief that such is their true distribution. "It remains therefore," continues Mr. Swainson, "to be considered whether there is presumptive evidence to believe that the three remaining divisions, namely, the Buzzards, Kites, and Eagles, form one circular group independent of their affinity to the two former. The true Buzzards, of which the *Vulgaris* and the *Lagopus* may probably be types, are slender long-winged birds; the bill is small, short, and considerably curved: in this structure they agree with the true falcons, yet they are well known to be distinguished from them by wanting the toothed-bill, and by the shortness and graduated abbreviation of the exterior quill-feathers. Now, if nature had proceeded in a simple course from the buzzards to the falcons, we should have had birds uniting the distinctions of both variously modified. Both these groups being composed in their typical examples of slender long-winged birds with short bills, any species exhibiting the reverse of such characters, and intervening between the two forms, would certainly appear anomalous, on the supposition of a simple series of affinities being aimed at. Yet that such birds are to be found even among the few that we are subsequently to notice is unquestionable. Let us then take the *Buteo borealis*, which as being more allied to the falcons than to the kites may be considered an intervening form between the *Buteo vulgaris* and *Falco*. We here see a large-sized heavy bird with shortened wings not reaching to more than half the length of the tail, while the elongated bill, unlike either that of *Buteo* or *Falco*, obviously assimilates to that lengthened form which belongs to the eagles. Now upon the supposition that a bird so constructed is intended to fill up the interval between *Buteo* and *Falco*, and at the same time to unite the former with the eagles, the singularity of its structure is no longer surprising; but if we consider it with a simple reference to the passage between *Buteo* and *Falco*, we are almost tempted to suspect that in this instance a real saltus has been made." While upon this subject we may cite an acute observation made by Prince C. L. Bonaparte, that "the *Borealis* is almost as much an *Astur* of the first section as a *Buteo*;" a proof at least that its affinities to *Astur* and to the aberrant eagles adjoining that group have not escaped observation. Our idea that the buzzards are truly united to the eagles is still further strengthened by the *Buteo pterocles*, Temm. ***. In this species the wings, as in *Buteo*, are remarkably long; but the bill is so considerably lengthened, that were we to judge alone from this member we should have no scruple in placing the bird among the *Aquilæ*. On the other hand, it must be remembered that as every group, from the highest to the lowest denomination, when perfect, contains a representation of the other four, united to a form peculiar to itself, so we might naturally expect that one division of the buzzards would represent the true eagles. To ascertain therefore whether the resemblances above stated are those of analogy or of real affinity, recourse must be had to strict analysis. Now this in our present state of knowledge cannot be done, at least from the resources to be found in this country. We have thought it advisable to cite the above facts, drawn from the structure of the birds themselves, as likely to awaken the attention of ornithologists to a further investigation of the subject; they will at least show that our opinion on the unity of the three aberrant groups is not entirely without foundation. Mr. Swainson considers the relative value of the whole group equivalent to that of *Vultur* or *Strix* in its own order, and to the families composing the *Rasores*, *Grallatores*, and *Natatores*, and he contemplates the five principal divisions as genera, arranging the subordinate forms as sub-genera; but in considering the five forms of the *Falconidæ* as genera rather than sub-families, he guards himself against the supposition that he may mean to insinuate that the minor distinctions which have been dwelt upon by several able ornithologists who have investigated this family are either trivial or that they deserve not to be brought immediately before us. On the contrary, he recommends to others the plan adopted by himself, namely, the minute examination of every change of structure, and the assembling together in minor groups such species as agree in certain peculiarities. Further, he would proceed in certain cases even to impose a name upon such groups, but in a family already so crowded by generic names he considers it essential to preserve a distinction between groups of unequal value; and not to elevate sub-genera, or forms of transition, to a rank they do not hold. *Milvago*, *Polyborus*, *Daptrius*, and *Ibycter* are unquestionably, in his opinion, of the latter description, each confined but to one species;

and he says that he has another of the same natural group in his cabinet, equally deserving a patronymic name. By regarding these as genera, each as he thinks is made equivalent to the whole genus of typical falcons; whereas, by representing them as lesser variations, which he considers them in truth to be, the student immediately perceives that their station is subordinate.

The genera into which Mr. Swainson ('Natural History and Classification of Birds,' 1836) divides the *Falconidæ* are *Falco*, *Accipiter*, *Buteo*, *Cymindis*, and *Aquila;* and he gives the following table as the concentration of his remarks in reference to the sub-genera of *Falco*:—

Sub-genera of *Falco*.		Genera of the *Falconidæ*.
	1. Typical Group.	
Falco.	Pre-eminently typical; bill acutely toothed; wings pointed, rather long.	*Falco.*
	2. Sub-Typical Group.	
Harpagus.	Wings shorter, rounded; tarsi with entire transverse scales.	*Accipiter.*
	3. Aberrant Group.	
Lophotes.	Feet short; head crested.	*Aquila.*
Aviceda.	Feet small, very short; soles broad and flattened; outer toe and claw shortest.	*Cymindis.*
Gampsonyx.	Bill neither notched or (nor) festooned; head small; feet strong.	*Buteo.*

By throwing each of these columns into their respective circles, and then bringing them into juxtaposition (which he does in the work quoted), the same results, he remarks, will follow. Into the Accipitrine circle he admits *Ictinia* provisionally, *Accipiter* (type), *Astur* (Goshawks), *Haliæetus* (*H. Pondicerianus*), and no more. In the Aquiline circle he retains four 'types,' namely, *Pandion*, *Harpyia*, *Aquila*, and *Ibycter*. In the Cymindian or Milvine circle he places *Polyborus*, *Cymindis*, *Elanus*, *Nauclerus*, and *Circætus*, the last with a query, and in the cut of the circle it is not mentioned. In the Buteonine circle *Milvus*, *Circus*, and *Buteo*.

Mr. Vigors, who as we have seen first proposed the application of the Quinary System to the *Falconidæ*, and indeed to the birds in general, thus defines the family which is the subject of our inquiry, and thus follows out his arrangement:—

Falconidæ. (Leach.)

Head plumose. Beak strong, hooked, with a cere at the base. Nostrils lateral, more or less rounded, open and situated in the cere. External toes especially connected with the middle toes. Claws or nails strong, very sharp, very much incurved, and retractile.

1st Sub-Family, *Aquilina.*

Beak long, hooked at the apex only. Fourth quill the longest.

* Long-Winged Eagles.

Ibycter (Vieillot).—Beak convex above; lower mandible notched at the apex, and subacute; cere naked; cheeks, throat (gula), and crop (jugulum), featherless; claws acute.

Mr. Vigors remarks that the type of this genus is *Falco aquilinus* of Gmelin, Petit Aigle d'Amerique of Buffon, and that he believes it still stands single in the genus.—Beak cærulean; cere and feet yellow; orbits yellow; irides orange; body, above, cærulean; below, red going into white; neck purplish to rufous; claws black. Gmelin gives it as the Red-Throated Falcon of Latham. It is a native of South America.

Daptrius (Vieillot).—Beak convex above; lower mandible angular beneath, notched at the apex, obtuse; cere with scattered hairs; orbits, throat, and crop, featherless; claws acute.

"How far," writes Mr. Vigors, "the two preceding genera of M. Vieillot are sufficiently distinct from each other, or from the remainder of the Naked-Cheeked Eagles, it is not for me to hazard an opinion, without the opportunity of more accurate examination of the birds than is at present within our power, and a more accurate knowledge of them than a mere description affords us. It would appear however that one group at least, that of *Ibycter*, is sufficiently distinguished from the other *Falconidæ* with the naked cheeks, by the difference of its food and habits. The accounts which have reached Europe of its mild and gentle manners and vegetable food, have even induced some naturalists to refer it to the Gallinaceous Birds. I have strong doubts indeed whether the birds that compose this genus may not belong to quite a distinct station from the present, and be referrible to one of those groups which I have elsewhere observed to be wanting among the Birds of Prey, to perfect that chain of affinities which is to be found complete in all the other orders. It is impossible however at present to come to any decision on the subject. While our materials for classification are so scanty, the most that is in our power is to conjecture the place which more perfect information will enable us to assign any group hereafter. For the present we

Head and foot of Red-Throated Falcon (*Ibycter aquilinus*).

may leave the genus before us in that situation, between the *Vulturidæ* and the *Falconidæ*, which they have hitherto been generally supposed to fill."

D. ater, the Iribin Noir of Vieillot, and the Caracara Noir, *Falco aterrimus*, of Temminck. Black with bluish reflections; tail white at its base above, and rounded; beak and claws black; cere blackish-ash, space round the eyes naked and of a flesh-colour; feet yellow Length from 14 to 15 inches French.

It is a native of Brazil and Guyana.

Head and foot of *Daptrius ater*.

Polyborus (Vieillot).—Beak compressed above; lower mandible entire and obtuse; cere covered with hairs, large; cheeks and throat featherless; crop woolly.

P. Brasiliensis (*P. vulgaris*, Vieillot), the Brazilian Caracara Eagle. We select Mr. Bennett's description and general history of this species as the most complete. After giving the generic characters, and observing that the wings nearly equal the tail in length, that they are of a rounded form with the third and fourth quills longest; that the legs are rather long, naked, and reticulated, and the claws of moderate length and curvature, but with little acuteness or power of grasping, the last-named author thus proceeds:—"In the Brazilian Caracara the whole upper surface of the head is black, with the feathers slightly elongated backwards, and capable of being partially elevated in the shape of a pointed crest. The entire neck is of a light brownish-gray, which also forms the ground colour on the breast and shoulders, but with the addition on these parts of numerous transverse wavy bars of a deeper brown. Nearly all the rest of the plumage is of a tolerably uniform shade of blackish-brown, with the exception of the tail, which is at the base of a dirty white, with numerous narrow transverse undulated bands of a dusky hue, and, in its terminal third, black without any appearance of banding. The beak is horn-coloured at the tip and bluish at the base; the iris hazel; the cere and naked cheeks of a dull red; the legs yellow, and the claws black. Such at least are the colours of the living specimen in the Society's garden. Several changes however take place in the plumage of the bird as it advances in age, and these are well illustrated by an extensive series of specimens in the Museum in Bruton-street,"—now in the Gardens, Regent's Park. "So great in fact is the variation of colours in this species that scarcely any two descriptions of it correspond throughout, and the figures by which it has been illustrated differ from each other even more remarkably than the descriptions by which they are accompanied." ('Gardens and Menagerie of the Zoological Society.')

Head and foot of the Brazilian Caracara Eagle (*Polyborus Brasiliensis*).

The same author observes that Marcgrave was the first to introduce into Europe the name of Caracara, the vulgar appellation of the bird in Brazil, derived from its hoarse and peculiar cry. But although M. Cuvier regards Marcgrave's Caracara as identical with the species described by Mr. Bennett, the latter remarks that both the figure and description are so much at variance with it that he feels himself compelled to adopt in preference the opinion of Professor Lichtenstein, founded upon the original drawing, that they belong to a totally different bird. Mr. Bennett is consequently unable to trace the history of the true Caracara beyond the year 1784, when a figure and description were published at Vienna by the younger Jacquin, from his father's papers, under the name of *Falco Cheriway*. These Mr. Bennett has no hesitation in referring to the present species. The principal differences between them consist, he states, in the markings on the breast and neck, which in the figure are more longitudinal than transverse; and in the very awkward foreshortening of the beak, which completely distorts its natural form. The former appears, from the specimens in the Society's Museum, to be one of the distinctive marks of the young bird. Cuvier, in the last edition of the 'Règne Animal,' observes that the *Falco Cheriway* of Jacquin may be nothing but a variety of age. Mr. Bennett then notices the very complete description of the adult Caracara in D'Azara. According to this author, the full-grown bird measures 21½ inches in length and 50 in the expanse of the wings. Its colours agree with the description above given, excepting that the first six quill-feathers of the wings are white, marked with rays and spots of brown, and become blackish towards the point; the back is transversely rayed with brown and white, the latter predominating on its upper half, and vice versâ; the fore part of the neck and breast are traversed by dusky lines mixed with a larger proportion of white; the cere is of an orange hue; and the throat and sides of the head are almost white. This description, Mr. Bennett remarks, very nearly coincides with that of M. Cuvier, taken from specimens in the Paris Museum, and with the figure of one of these specimens given by M. Vieillot in his 'Galerie des Oiseaux;' and Mr. Bennett then refers to the figure given by M. Spix in his 'Birds of Brazil,' as the young of this species, which resembles M. Vieillot's in its form, except that the legs are longer and thicker, and the tips of the wings reach to the extremity of the tail. In colour it is rather of a darker brown, approaching more nearly to the Society's specimen alluded to by Mr. Bennett; the throat is light brown instead of white; and the transverse waves of the breast and shoulders are replaced by longitudinal brown dashes upon a light ground. The cere and naked cheeks are in both of a bright yellow; indeed Mr. Bennett states that he has nowhere met with them of the same hue with those of the Society's living specimen, except in the figure and description of Jacquin.

The Caracara is said to live either alone or in pairs. But D'Azara states that he has seen them join in companies of four or five to hunt down prey which a single Caracara would find a difficulty in mastering, such as red buzzards, herons, and other large birds; and it is believed that they will even destroy the American ostrich, young fawns, and lambs, when so associated. In its food it seems to be content with any animal substance. Carrion (for if a Caracara see a vulture devour a piece of flesh he is said to pursue him and compel him to disgorge it), toads, frogs, worms, snails, lizards, grubs, grasshoppers, winged-ants, snakes, and flies, birds—in short the general prey of buzzards, hawks, falcons, and insectivorous birds—all suit its appetite. Two of the specimens obtained by M. Spix were shot in the act of extracting insects from the hides of oxen. D'Azara will not allow that the Caracara preys on the smaller birds, because, he says, that it is unable to catch them; but Prince Maximilian found in the stomachs of those which he opened the remains of small birds and insects, especially grasshoppers, which abound in its haunts. It is by no means shy, and advances like the vultures to inhabited places, perching on trees and house-tops and not caring to conceal itself. It is seldom attacked, for it rarely molests domestic poultry, but it is stated that it will sometimes carry off the sportsman's game. The nest, according to D'Azara, is built on the tops of trees, especially those round which the climbing plants are most luxuriant, or in a bushy thicket. It is large, and composed of sticks and twining branches laid nearly flat, and lined, inartificially, thickly with hairs. The eggs, which are laid in August, September, or October, are two in number, pointed at one end, and dotted and blotched with crimson on a brownish-red ground.

This bird extends over a considerable part of South America; the island of Aruba, on the coast of Venezuela (Jacquin); Brazil and Paraguay (Cuvier); most abundant in the south and east of Brazil (Prince of Neuwied); Spix's specimens were from the northern provinces; less numerous on the Rio de la Plata than in Paraguay, where it is almost equal in number to all the other birds of prey put together (D'Azara); Straits of Magalhaens (Captain Phillip Parker King, R.N.).

Mr. Bennett's provisional species *Polyborus* (?) (*hypoleucus*) was founded on the Angola Vulture of Pennant, *Vultur Angolensis* of Gmelin, in an immature state of plumage.

Dr. Smith proposed the genus *Polyboroides* for the *Falco Gymnogenys* of Temminck in the South African Journal, in April, 1830, and M. Lesson, in the November of that year, separated the same form under the generic title *Gymnogenys*.

From *Ibycter* and *Polyborus* Mr. Vigors passes to the Fishing Eagles, and particularises as the first

Pandion (Savigny).—Beak rounded above; cere hispid; nostrils lunulated and membranaceous on the upper margin; tarsi naked; acrotarsia covered with rigid reticulated scales; toes free, the external toes versatile; claws equal, rounded underneath; second quill longest.

P. Haliæetus, the Bald Buzzard, Osprey, or Fishing Eagle; the Fishing-Hawk and Fish-Hawk of the Americans; Aquila Pescatrice of the Italians; *Haliætus* and *Morphnos* of Aldrovandus; *Balbusardus Anglorum* of Ray; and *Falco Haliætus* of Linnæus. This bird appears to be widely diffused. Temminck observes, that it is generally distributed through Europe, and that it abounds in Russia, Germany, and Switzerland. It is also found in Egypt. In the British Islands it seems to be comparatively rare. Willughby records one that was shot at Penzance with a mullet in its claws; and White mentions another that was shot at Frinsham Pond, near Selbourne, while it was sitting on the handle of a plough and devouring fish. "It used," says White, "to precipitate itself into the water and take its prey by surprise."

Bald Buzzard (*Pandion Haliaetus*).

It has been seen at Killarney in Ireland; and Montagu speaks of its frequent occurence in Devonshire. Selby says, "I have seen them upon Loch Lomond, where they are said to breed: but they are far from being numerous in Scotland." Montagu corroborates this; for he says, in his 'Ornithological Dictionary,' "It is said to make its nest generally on the ground by the side of water, composed of flags and rushes; but we once saw the nest of this bird on the top of a chimney of a ruin in an island on Loch Lomond in Scotland; it was large and flat, formed of sticks laid across, and resting on the sides of the chimney, lined with flags."

Prince C. L. Bonaparte states that it is found near Rome.

In America it is said to be found in the summer from Labrador to Florida; and it is even stated to have been seen in Cayenne: indeed Latham gives it the name of Cayenne Osprey. But it is in the more temperate climate of the new continent that the bird abounds; and there its coming is eagerly watched by the fishermen as the harbinger of the shoals of fish that approach the shores in the spring.

"Towards the close of March," writes Nuttall in his interesting 'Manual,' "or beginning of April, they arrive in the vicinity of Boston with the first shoal of alewives or herrings, but yet are seldom known to breed along the coasts of Massachusetts." The same author attributes their departure from New York and New Jersey, as early as the close of September, or at farthest the middle of October, when they migrate farther south, to the going of the fish on which they are accustomed to feed; for they principally live on fish, which they take by dashing from on high into the water with such violence, that, as Pennant observe, the Italians have applied to the bird the epithet 'piombina.'

But the Bald Buzzard is haunted by a persecutor that often snatches from it the hard-earned prey. Catesby and others describe its sufferings from the piracy of the White-Headed Sea-Eagle, *Haliæetus leucocephalus;* and Wilson gives the following vivid description of such a scene—a description which those only who have devoted themselves to watching the habits of animals can give:—"Elevated," says that admirable ornithologist, speaking of the White-Headed Eagle, as he saw him in America, "on the high dead limb of some gigantic tree that commands a wide view of the ocean, he seems calmly to contemplate the motions of the various feathered tribes that pursue their busy avocations below, the snow-white gulls slowly winnowing the air; the busy tringæ coursing along the sands; trains of ducks streaming over the surface; silent and watchful cranes, intent and wading; clamorous crows, and all the winged multitudes that subsist by the bounty of this vast liquid magazine of nature. High over all these hovers one whose action instantly arrests his attention. By his wide curvature of wing, and sudden suspension in the air, he knows him to be the fish-hawk, settling over some devoted victim of the deep. His eye kindles at the sight, and balancing himself with half-opened wings on the branch, he watches the result. Down, rapid as an arrow from heaven descends the distant object of his attention, the roar of its wings reaching the ear as it disappears in the deep, making the surges foam around. At this moment the eager looks of the eagle are all ardour; and levelling his neck for flight, he sees the fish-hawk once more emerge struggling with his prey, and mounting in the air with screams of exultation. These are the signals for our hero, who, launching into the air, instantly gives chace, and soon gains on the fish-hawk. Each exerts his utmost to mount above the other, displaying in these rencontres the most elegant and sublime aërial evolutions. The unincumbered eagle rapidly advances, and is just on the point of reaching his opponent, when with a sudden scream, probably of despair and honest execration, the latter drops his fish; the eagle, poising himself for a moment, as if to take a more certain aim, descends like a whirlwind, snatches it in his grasp ere it reaches the water, and bears his ill-gotten booty silently away to the woods."

The Bald Buzzard is a powerful bird, and the females, which are the largest, as indeed they are among most of the birds of prey, sometimes weigh 5 lbs. The plumage, which is very like that of the water-fowl, and adapted to resisting the fluid into which it plunges for its prey, is white below, with a few brown streaks and speckles on the throat. There is indeed a patch of brown on the upper part of the breast in young birds. The crown of the head is light-brown, edged with white; and there is a streak of dark-brown from the eye to the shoulders. The whole of the upper part of the body is brown. The feathers on the thighs are close, and the legs short, stout, and grayish: and in this part of its organisation we see a beautiful instance of adaptation to its habits. The close thigh-feathers resist the action of the water, while the talon of the outer toe is much larger than the inner one, and capable of being turned backwards; the under surfaces of all the toes are also very rough and covered with protuberances, which enable it to secure its slippery prey. The irides are of a lemon colour.

Head and foot of Bald Buzzard (*Pandion Haliæetus*).

The Bald Buzzard, or Osprey, lays from two to four eggs, a little larger than those of the common fowl, of a reddish or yellowish cream-colour, marked with blotches and dots of reddish-brown. During incubation the male often feeds the female. Nuttal, in his 'Manual,' gives the following account of their habits in the breeding season:—

"Unlike other rapacious birds, the ospreys may be almost considered gregarious, breeding so near each other, that, according to Mr. Gardiner, there were on the small island on which he resided, near to the eastern extremity of Long Island, New York, no less than 300 nests with young. Wilson observed twenty of their nests within half a mile. I have seen them nearly as thick about Rehoboth Bay, in Delaware. Here they live together at least as peaceably as rooks; and so harmless are they considered by other birds, that, according to

Wilson, the crow blackbirds, or grakles, are sometimes allowed refuge by the ospreys, and construct their nests in the very interstices of their eyry. It would appear sometimes, that, as with swallows, a general assistance is given in the constructing of a new nest; for, previous to this event, a flock have been seen to assemble in the same tree, squealing, as is their custom, when anything materially agitates them."

Mr. Vigors is of opinion that this group presents us with a decidedly characteristic difference from all the other species of the family, except those of *Elanus*, in the internal parts of the nails being rouuded instead of grooved. The culmen of the bill, he observes, is also broader than usual, and much rounded; the toes are entirely separated, and the tarsi are covered with strong, prominent, and thickly reticulated scales. The same author remarks that the Osprey (*Falco Haliæetus* of Linnæus) is the type of the genus to which the valuable researches of Dr. Horsfield iu Java have added a second species, *P. Ichthyætus*. In this species however, which agrees with *Pandion* in the more essential characters, Mr. Vigors finds a strong approximation to the following genus, *Haliæetus*. Its bill, he adds, is more compressed than that of *Pandion*, its acrotarsia are scutellated, and the 4th quill-feather, as iu *Haliæetus*, is the longest. It thus stands, in the opinion of Mr. Vigors, osculant between the two groups.

The last group of the Fishing Eagles, according to Mr. Vigors, is comprised in the next genus,

Haliæetus (Savigny).—Beak convex above; nostrils lunnlated, transverse; cere subhispid; tarsi semiplumed; acrotarsia scutellated. Toes free, tho external toe versatile; claws unequal.

Mr. Vigors notices the difference of this form from *Pandion* in the structure of the nails, and the more compressed culmen of the bill; in the tarsi also, which have the acrotarsia scutellated, and are feathered half way below the knee. Thero are several species; for instance, *Falco leucocephalus*, *F. albicilla*, *F. Pondicerianus*, *F. blagrus*, *F. vocifer*, &c. &c.

H. leucocephalus, the Sea-Eagle, Bald Eagle, White-Headed Eagle—the symbol of the United States of America.

Head and foot of the Sea-Eagle (*Haliæetus leucocephalus*).

Before we proceed to the descriptiou of our example, it may be necessary, with Mr. Bennett's assistance, to clear up the confusion which, as he observes, has existed in the synonymy of *Haliæetus albicilla*, the difference of the colours of tho plumage in the various stages of its growth having induced authors to record it under several distinct names. Three of these were almost universally admitted till about twenty-six years ago, when the result of F. Cuvier's observations on the individuals kept in the Jardin des Plantes led him to unite *Falco ossifragus*, *F. albicaudus*, and *F. albicilla* of Gmelin under one name: subsequent inquiry has confirmed this conolusion. In the earlier stages of life, the beak of *H. albicilla* is of a bluish horn-colour; its head and neck deep brown; the plumage above, brownish-black mixed with whitish or ash-coloured spots on the back and tail. In this state it is *Falco ossifragus* of systematists. About the third or fourth year the head and neck become ashy-brown; the beak gradually changes from bluish to pale-yellow, the white spots on the back vanish, aud the tail becomes uniformly grayish-white. It is now *Falco albicaudus* of Gmelin, Petit Pygargue of Buffon, and the Lesser White-Tailed Eagle of Latham. In its fifth year it is come to maturity, and the change is complete. The head and neck have little of the brown tinge left, the back is throughout of a dusky-brown intermingled with ashy-gray, and the tail is quite white. In this its perfect state it is *Falco albicilla*, the Grande Pygargue, tho White-Tailed or Cinereous Eagle. In all the stages of this the Great Sea-Eagle which inhabits nearly the whole of Europe and of Northern Asia, the cere and naked parts of the legs are yellow; the under part of tho body is of a lighter hue than the upper, and more thickly interspersed with pale ciuereous spots; the claws are completely black. ('Gardens and Menagerie of the Zool. Soc.')

Mr. Bennett, in the work last quoted, remarks, that in the earlier stages of its growth there is littlo to distinguish this species from the Great Sea-Eagle. M. Vieillot indeed, following the example of Daudin, has united the White-Headed Eagle to the list of synonyms of the Great Sea-Eagle. "That such a uuion," writes Mr. Bennett, "is fouuded upon insufficient data is proved by the gradual development in the bird under consideration of a character which, after a certain age, at once distinguishes it from the remainder of its tribe. This character consists in the pure whiteuess of its head and neck, from whence it has derived the popular but inappropriate title of tho Bald Eagle, by which it is most commonly known." The young are clothed at first with a thick whitish or cream-coloured cotton-liko down, aud they become gradually gray as the development of the true plumage goes on. In the third year the white may be traced upon the head, ueck, tail-coverts, and tail; and by the end of the fourth year these parts become completely white, or sometimes tinged slightly with cream-colour. The eye, which is at first hazel, changes to a brilliant straw-colour as the head whitens. (Wilson.) "This account of the metamorphoses in colour of the White-Headed Sea-Eagle," says Mr. Bennett, "derived from the personal observations of the accurato author of the 'American Ornithology,' has been in a great measure verified under our own inspection in the specimen now before us, which remained for several years in the possession of Mr. Brookes, before it was presented by him to the Society.

"During a considerable part of the time it was regarded as the Common Sea-Eagle; and it was not uutil its gradual change of plumage had at length rendered obvious its true character, that it was ascertained to be in reality a distinct species. The same error appears frequently to have existed with regard to it; aud M. Temminck observes that the only mark of distinction that can be traced iu it until it has assumed the adult colouring, consists in the somewhat greater length of its tail. He might however have added its smaller size, which is probably one-fourth less than that of the preceding bird, at the same age and under similar circumstances. From the observations which we have been enabled to make upon tho subject, we should be led to conclude that the period in which it attains its full growth and perfect colouring is, in this country at least and in captivity, two or three years longer than that stated by Wilson. Iu its immaturo state, that is to say about the third year, the upper parts of the head and body exhibit a mixture of brown and dirty white, the separate feathers having a ground of the latter colour, and being deeply tipped and broadly barred along the centre with the former. The quill-feathers and primary wing-coverts are black, with their shafts of a pale-brown; the secondary are considerably lighter; and the tail, which projects iu a trifling degree beyond the extremities of the wings, is brown ou tho outer quills and of a mixed white and brown on the inner. The under surface, as far backwards as the middle of the belly, is of a much lighter shade than the upper, being of a dull white, with numerous broad streaks of pale-brown. In the posterior part it is of a deep brown, the feathers beiug only slightly margined with whito. A similar hue prevails ou the upper parts of the legs, which are plumed somewhat below the knees. The beak is of a dusky brown; the cere and legs of a golden yellow; the iris somewhat lighter; and the talons deep blackish-browu. Tho latter are long, strougly curved, of considerable power, and extremely sharp at the poiuts. The full-grown bird measures upwards of 3 feet in length from beak to tail, and more than 7 feet iu the expanso of its wings. Its beak is changed to a bright-yellow; and its head, a greater or less proportion of the neck (accordiug as the bird is more or less advauced in age), aud the entiro tail, aro become perfectly white. An analogous change, as we have before seen, takes place in the plumage of the preceding species; but the head aud neck of that bird always retain more or less of a brownish tinge, seldom changing fully into gray, and never turuing completely white. These observations have been made upon numerous individuals, many of them placed for upwards of ten years under the eyes of various scientific observers: their accuracy may therefore be regarded as unquestionable. The remainder of the plumage in this state is of a deep brown, approaching to black, and strongly contrasted with the head and tail. The colour of the legs, feet, and talons remains nearly the same; but the iris generally continues to assume a lighter and a lighter hue. The eyes, it should be observed, are deeply sunk in the head, and instead of being placed in a line parallel with that of the cheeks, are directed forwards, so as to form with them a considerable angle."

We have already given an account of the robberies committed by the Bald Eagle on the osprey; but its acts of plunder are not confined to that bird, for it will rob the vultures, and even in hard times make them disgorge their carrion to satiate its appetite. According to Audubon it will strike down a swan and other aquatic birds, and now and then procure fish for itself by pursuing them in shallow creeks; it also devours young pigs, lambs, fawns, and putrid flesh of every description. Niagara is one of its favourite haunts, where it watches for the swollen carcasses that the cataract has precipitated down the falls. Wilson saw one seated on a dead horse, keeping a whole flock of vultures at a distance till it had satisfied itself; and on another occasion, when many thousands of tree-squirrels had been drowned in their migration across the Ohio, and had collected hosts of vultures, the sudden appearance of a Bald Eagle sent them all off, and the eagle kept sole possession for many days.

Benjamin Franklin thus speaks of this emblem of the United States of America:—"For my part, I wish the Bald Eagle had not been chosen as the representative of our country. He is a bird of bad moral character; he does not get his living honestly. You may have seen him perched on some dead tree, where, too lazy to fish for himself, he watches the labours of the fishing-hawk; and when that diligent bird has at length taken a fish, and is bearing it to his nest for the support of his mate and young ones, the Bald Eagle pursues him and takes it from him. With all this injustice, he is never in good case, but, like those among men who live by sharping and robbing, he is generally poor, and often very lousy. Besides, he is a rank coward: the little King-Bird, not bigger than a sparrow, attacks him boldly, and drives him out of the district. He is therefore by no means a proper emblem for the brave and honest Cincinnati of America, who have driven all the King-Birds from our country; though exactly fit for that order of knights which the French call Chevaliers d'Industrie."

With regard to its reproduction, M. Audubon says that incubation commences in the beginning of January. He shot a female on the 17th of that month, as she sat on her eggs, in which the chicks had made great progress. "The nest," says that author, "which in some instances is of great size, is usually placed on a very tall tree, destitute of branches to a considerable height, but by no means always a dead one. It is never seen on rocks. It is composed of sticks from three to five feet in length, large pieces of turf, rank weeds, and Spanish moss in abundance, whenever that substance happens to be near. When finished, it measures from five to six feet in diameter, and so great is the accumulation of materials, that it sometimes measures the same in depth, it being occupied for a great number of years in succession, and receiving some augmentation each season. When placed in a naked tree, between the forks of the branches, it is conspicuously seen at a great distance. The eggs, which are from two to four, more commonly two or three, are of a dull white colour, and equally rounded at both ends, some of them being occasionally granulated. Incubation lasts for more than three weeks, but I have not been able to ascertain its precise duration, as I have observed the female on different occasions sit for a few days in the nest before laying the first egg. Of this I assured myself by climbing to the nest every day in succession, during her temporary absence." ('Ornithological Biography,' vol. i.)

This bird is found in every part of the United States of America, seldom appearing, according to Audubon, in very mountainous districts, but preferring the low lands of the sea-shores, those of the larger lakes, and the borders of rivers. Mr. Bennett remarks, that the White-Headed Eagle is usually spoken of as inhabiting the northern parts both of the old and new continent; but that it appears to be only a rare and occasional visitant of the former. It is probable, he adds, that some of the varieties of the Common Sea-Eagle of this quarter of the globe have been frequently mistaken for it, and remarks, that throughout nearly the whole of North America, on the contrary, where the European species seems to be unknown, it is met with in great abundance. Sir John Richardson says that it is the earliest of the summer visiters to the Fur Countries, and the period of its arrival has given the name of Meekeeshew Espeeshim, or Eagle-Moon, to the month of March. "Temminck," says Sir John ('Fauna Boreali-Americana'), "assigns for its habitual residence the regions within the Arctic Circle; and Wilson observes, that it is found at all seasons in the countries it inhabits. Both these assertions however require, I apprehend, to be taken with considerable latitude. We did not, on the late expeditions, meet with it to the north of the Great Slave Lake (62° N. lat.), although it is common in the summer, in the country extending from thence to Lake Superior, and its breeding-places in the latter district are numerous. But in the month of October, when the rivers from which it draws its principal supply of food are frozen over, it entirely quits the Hudson's Bay lands; and if, after that period, it is to be seen in the northern regions, it can only be on the sea-coast, and for a limited time, while the sea continues unfrozen. . . . It is known to breed as far south as Virginia, but its nests do not appear to be so common within any part of the United States as they are in the Fur Countries." The bird is not mentioned in the 'Supplement' to Sir W. E. Parry's 'First Voyage,' nor in that to Sir John Ross's 'Last Voyage.'

This bird is the Meekeeshew (name for the species), Wapustiquan-Meekeeshew (White-Headed Eagle—mature bird), Appisk-Meekeeshew (Black-Headed Eagle—immature bird), and Meekeeseeseeah (yearling birds) of the Cree Indians.

Colonel Sykes notes among the birds of Dukhun (Deccan) *Haliæetus Ponticerianus*, *Falco Ponticerianus* of Latham, Brahmuny Kite of the Europeans in India. The colonel says that it is seen constantly passing up and down rivers at a considerable height, but prepared to fall at an instant on its prey. Usually it seizes while on the wing, but occasionally dips entirely under water, appearing to rise again with difficulty. It is quite a mistake, he adds, to suppose it feeds on carrion. On the examination of the stomach and craw of many specimens, the contents were found to be fish, and fish only, excepting on one occasion, when a crab was met with. ('Zool. Proc.,' 1832.)

Leaving the Fishing Eagles, Mr. Vigors proceeds to

Circætus (Vieillot).—Beak convex above; nostrils lunulate, transverse; cere subhispid; tarsi elongated, naked; acrotarsia reticulated; toes short, the external toe connected with the middle one at the base; claws short, subequal. This genus is founded upon the well-known Jean de Blanc of the European continent, *Falco brachydactylus* of Wolff, *F. Gallicus* of Gmelin, Aquilotto of the Italians. Here Mr. Vigors observes, we find the exterior toe united to the middle by a short membrane, which is the case indeed in the greater portion of the family, while in the two latter genera the toes are all divided to the origin.

C. brachydactylus is, according to Temminck, the *Falco brachydactylus* of Wolff; the *Aquila brachydactyla* of Meyer; *Falco Gallicus* of Gmelin; *F. leucopsis* of Bechstein; *Aquila leucamphoma*, 'Borkh. Deut. Orn.'; Le Jean le Blanc of Buffon and the French generally; Aigle Jean le Blanc of Temminck; Falco Terzo d'Aquila, 'Stor. deg Ucc.'; and Kurzzehiger-Adler of Meyer.

Head and foot of *Circætus brachydactylus*.

Old Male.—Head very large; below the eyes a space clothed with white down; summit of the head, cheeks, throat, breast, and belly, white, but variegated with a few spots of bright brown; back and coverts of the wings brown, but the origin of all the feathers of a pure white; tail square, gray-brown, barred with deeper brown, white below; tarsi long and grayish-blue, as are the toes; beak black; cere bluish; iris yellow. Length, two feet.

Female.—Less white than the male. The head, the neck, the breast, and the belly, are marked with numerous brown spots, which are very much approximated.

Young.—Upper parts darker, but the origin of the feathers pure white; throat, breast, and belly, of a red-brown, little or not at all spotted with white; bands on the tail nearly imperceptible; beak bluish; feet grayish-white.

It feeds on lizards and serpents, to which it gives the preference; rarely birds and domestic poultry. The nest is built on the highest trees, and the eggs are two or three in number, of a lustrous gray, and spotless.

It inhabits the great fir forests of the eastern parts of the north of Europe; not common in Germany and Switzerland; rare in France; never seen in Holland. (Temminck.) Prince C. L. Bonaparte notes it as rather rare near Rome. Colonel Sykes notes it among the birds of the Dukhun (Deccan).

Dr. Smith's *Circaëtus pectoralis*, which undergoes many changes of plumage before it arrives at maturity ('South African Museum and Catalogue'), is stated ('Zool. Proc.,' April, 1833) to be synonymous with *Circætus thoracinus* of Cuvier.

Mr. Vigors next proceeds to the True Eagles.

Aquila (of Authors).—Beak sub-angular above; nostrils rounded; cere sub-hispid; tarsi plumed to the toes.

Mr. Vigors observes that the predominant mark of distinction in this genus is the tarsi being feathered to the toes. The culmen of the bill appears also to differ from that of the other Eagles in being more angular. The species *Aquila heliaca* of Savigny, *Falco chrysaetos*, and *Falco nævius* of Linnæus, *Falco bellicosus* of Daudin, with some others lately made known to us, belong to the group which contains the most powerful birds of the family.

A. chrysaetos, the Golden Eagle; Adler of the Germans; Eryr Melyn of the Welsh.

Leg and foot of Golden Eagle (*Aquila chrysaetos*).

Old Birds.—Summit of the head and nape with acuminated feathers of a lively and golden-red; all the other parts of the body obscure brown, more or less blackish, according to the age of the individual; inside of the thighs and feathers of the tarsus clear brown; never any white feathers among the scapulars; tail deep gray, barred with tolerable regularity with blackish-brown, and terminated at the end by a large band of that colour; beak horn-colour; iris always brown; cere and feet yellow. In this state Temminck considers it to be the *Aquila fulva* of Meyer; *Falco niger* of Gmelin; *F. fulvus* and *F. Canadensis* of Gmelin; *F. chrysaetos* of Linnæus; L'Aigle Royal of Buffon; Le Grand Aigle of Gerard, 'Tab. Elem.'; L'Aigle Commun and L'Aigle Royal of Cuvier; Ring-Tail Eagle and Golden Eagle of Latham; and Aquila Reale di Color Leonato and Aquila Rapace, 'Stor. deg. Ucc.'

Young Birds of one and two years. (Ring-Tail Eagle.)—All the plumage of a ferruginous or clear reddish-brown, uniform on all parts of the body; lower tail-coverts whitish; inside of the thighs and feathers of the tarsus of a pure white; tail quite white from the base to three-fourths of its length, but afterwards brown to the end; internal barbs of the quills and of the caudal feathers pure white—this same colour occupies also the greatest part of all the feathers of the body from their base. In proportion as the young bird advances in age the colours of the plumage become brown, the white of the tail occupies less space, and traces of the transverse bars appear. In the third year the young bird puts on his adult plumage.

Golden Eagle (*Aquila chrysaetos*).

Varieties.—Partially or totally white. (*Falco albus* of Gmelin *F. cygneus* of Latham; L'Aigle Blanc of Brisson.)

The Golden Eagle preys on lambs, fawns, &c., and often on large birds. Extreme hunger will drive it to prey on carcasses.

It inhabits the great forests in plains, and in a less degree those in the mountains of the north of Europe; very common in Sweden, in Scotland, in the Tyrol, Franconia, and Suabia; more rare in Italy and Switzerland; rather common in France, in the forest of Fontainbleau, in the mountains of Auvergne, and on the Pyrenees; rare in Holland; less common in the Oriental countries than the preceding species, that is, *Aquila heliaca* of Savigny, *A. imperialis* of Temminck. (Temminck.) According to Wilson the Golden Eagle inhabits America, and occurs from the temperate to the arctic regions, particularly in the latter, where it breeds on precipitous rocks, always preferring a mountainous country. Sir John Richardson ('Fauna Boreali-Americana') mentions it with a query as breeding in the recesses of the subalpine country which skirts the Rocky Mountains, and as seldom seen farther to the eastward. "It is," he says, "held by the aborigines of America, as it is by almost every other people, to be an emblem of might and courage, and the young Indian warrior glories in his eagle plume as the most honourable ornament with which he can adorn himself. Its feathers are attached to the calumets, or smoking-pipes, used by the Indians in the celebration of their solemn festivals, which has obtained for it the name of the Calumet Eagle. Indeed so highly are these ornaments prized that a warrior will often exchange a valuable horse for the tail-feathers of a single eagle." It is the Kœoo of the Cree Indians. Sir John Richardson observes that the mature British Golden Eagle has a darkish brown tail and wings, blackish-brown back, clouded with brownish-black, and a paler and brighter brown head. He had not seen an American one in this state, but we do not think that any reason for a doubt. Many other authors mention the eagle and ring-tails in such terms as to leave the identity of the bird almost unquestionable; and though Sir John Richardson says that it is seldom seen farther to the eastward than the Rocky Mountains, M. Audubon relates that he saw a Golden Eagle on the coast of Labrador, besides others in various parts of the United States. It inhabits Russia, Iceland, and Germany, and is said to occur in northern Africa and Asia Minor. Mr. Yarrell, in his 'History of British Birds,' thus sums up its localities in our islands:—"The Golden Eagle, though occasionally seen and sometimes obtained in the southern counties of England, is more exclusively confined to Scotland and its western and northern islands. Some years ago a specimen was killed at Bexhill, in Sussex. It has also occurred, but very rarely, in Suffolk, Norfolk, Derbyshire, Durham, and Northumberland. Mr. Mudie, in his 'Feathered Tribes of the British Islands,' has named 'the higher glens of the rivers that rise on the south-east of the Grampians, the high cliff called Wallace's Craig on the northern side of Lochlee, and Craig Muskeldie on its south side,' as localities for the Golden Eagle. Mr. Selby and his party of naturalists observed this species in Sutherlandshire in the summer of 1834. Mr. Macgillivray, in his detailed descriptions of the rapacious birds of Great Britain, has recorded his own observations of this species in the Hebrides; and other observers have seen it in the Orkney and Shetland Islands, where it is said constantly to rear its young. In a direction west of London the Golden Eagle has been obtained or seen on the coasts of Devonshire and Cornwall. In Ireland a Ring-Tailed Eagle (the young of the Golden) was seen by a party of naturalists in Connamara in the autumn of 1835; and from William Thompson, Esq., vice-president of the Natural History Society of Belfast, to whom I am indebted for a catalogue and notes of the birds of Ireland, which will be constantly referred to throughout the work, I learn that specimens of the Golden Eagle are preserved in Belfast, which were obtained in the counties of Donegal and Antrim." The longevity of the eagle is almost proverbial. One that died in Vienna is said to have lived in confinement 104 years. Colonel Sykes notes the Golden Eagle among the birds of the Dukhun (Deccan). His specimen differed so slightly from the European bird as not to justify its separation. ('Zool. Proc.,' 1832.)

In the catalogue of birds collected on the Ganges between Calcutta and Benares, and in the Vindhyian Hills between the latter place and Gurrah Mundela, on the Nerhudda, by Major James Franklin, F.R.S., &c., we find recorded an eagle, *Aquila Vindhiana*, with a query whether it is the Cawnpoor Eagle of Latham ('Zool. Proc.,' 1831), and among the Dukhun birds, *Aquila bifasciata* of Hardwicke and Gray. ('Ind. Zool.') A whole rat was found in the stomach of one bird. A second was shot by Colonel Sykes at the dead carcass of a royal tiger, but it had not fed, for the stomach was empty. Dr. Smith stated ('Zool. Proc.,' 1833) that the eagle from the Cape presented to the Society by the Hon. J. T. Leslie Melville, and in the Society's menagerie, was not the young of *A. vulturina* (Daudin), but of *A. Choka* (Smith), *Falco rapax* (Temminck). Specimens of *A. bellicosa* and *A. rapax* are in the South African Museum, as well as of *A. vulturina*. The first is only found in wooded districts, preys upon small quadrupeds, and has been known to pounce upon small antelopes and carry them off entire to its nest. *A. rapax*, though it principally preys on living creatures, does not wholly reject carrion, being frequently one of the first birds that approaches a dead animal. ('Catalogue of South African Museum.') Mr. Keith Abbott ('Zool. Proc.,' 1834) notes among the Trebizond birds *A. pennata*, inhabiting Eastern Europe and the adjacent parts of Asia and Africa.

Hæmatornis (Vigors).—Beak rather strong, sufficiently elongated; upper mandible straight at the base, very much curved at the apex; nostrils oval, placed obliquely in the cere. Wings long, subrounded; the first quill rather short, the second and third longer, the fourth and fifth nearly equal and longest, the rest gradually decreasing. Feet rather weak, subelongated; tarsi rough, reticulated with scales; toes rather short, reticulated; claws strong. Tail sufficiently long, somewhat rounded. (Vigors.)

This group was observed to bear a near affinity to the genus *Pandion* in the shape of the bill, wings, and the rugose reticulated scales of the tarsi, but to differ from it in the comparative length and weakness of the legs and claws, as well as in having the nails grooved underneath, and not convex as in the latter group. To this genus belongs the *Falco Bacha* (Latham) of Africa, and the Manilla bird then lately described in the 'Proceedings' (page 96) under the name of *Buteo holospilus*. These, from the apparent weakness of their limbs, had hitherto generally been ranked among the buzzards; although from the description of the courageous habits of the Bacha Falcon, the only one well known of the group, doubts had been expressed of the propriety of ranking them with that tribe. Mr. Vigors suggested the sub-family of Eagles as a more appropriate station for them; where, united by many important characters to *Pandion*, they apparently led off by the length of their tarsi to the genus *Limnaëtus* ('Memoirs of Sir S. Raffles') and others of the long-legged Eagles. The three species of the group were exhibited, their general similarity in colour and markings pointed out, and their specific differences explained. These consist chiefly in size, *H. holospilus* being one-third smaller than *H. Bacha*; while *H. undulatus* (which is 2 feet 7 inches in length) considerably exceeds the latter. The first is spotted all over the body, the second only on the abdomen, while the third is marked by spots on the wing-coverts, and by ocelli bearing an undulated appearance upon the abdomen, the breast also being crossed by undulating fasciæ. A specimen of *H. undulatus* was afterwards (January 1832) exhibited from Mr. Hodgson's Nepaul collection. It agreed accurately with that which had been previously exhibited except in size, the present specimen being about one-third longer. From this difference in size it was conjectured to be a female. Colonel Sykes identified a specimen shot in the Dukhun (Deccan) with *Hæmatornis Bacha*. ('Zool. Proc.')

H. undulatus (male and female probably). Back and wings intense brown; head crested, the feathers white at the base, of a dark brown, nearly approaching to black at the end, the hind ones being margined with a light rufous band at the apex. The wing-coverts near the carpal joint deep brown, marked with small white spots; quill-feathers fuscous, darker at the apex, and marked with white towards the base of the interior web; the cere, base of the beak, and legs, yellow; claws black. (Vigors, in Gould's 'Century of Birds from the Himalaya Mountains.')

Hæmatornis undulatus.

** Short-Winged Eagles.

Harpyia (Cuvier). — Beak above convex; upper mandible slightly toothed; nostrils semilunar, transverse; tarsi elongated, very strong, feathered at the base; acrotarsia scutellated; claws long, very strong, acute.

Mr. Vigors, in placing *Harpyia* next to *Aquila*, observes that the former equals the latter in size and powers of body. Its tarsi, he remarks, are strong, thick, partly plumed, with scutellated acrotarsia. The nares are elongated, apparently semilunar, and placed transversely on the cere. The upper mandible, he adds, seems to have a notch somewhat analogous to that of the True Falcons.

Falco imperialis (Shaw). This powerful bird is the Grande Harpie d'Amerique of the French; Aquila Corouada of the Spanish; *Falco destructor* of Daudin; Aigle Destructeur of Sounini; Grand Aigle de la Guiane of Mauduyt; *Harpyia destructor* of Cuvier. Mr. Vigors states with truth that much confusion has arisen as to the synonyms of this bird, and even as to the characters of the genus. Mr. Bennett has, in our opinion, well cleared this confusion away, and we therefore select his synonymy.

"M. Temminck," says the last-mentioned zoologist ('Gardens and Menagerie of the Zoological Society'), "the latest writer on this magnificent bird, positively denies its identity with the *Vultur harpyia* of Linnæus, and the Crowned Eagle (*V. coronatus*) of Jacquin, on the singular ground that those names indicate a smaller bird with longer and more slender legs. Now Linnæus, who borrowed his original description of the Harpy from Hernandez, asserts, on the authority of that writer, that it is equal in size to a common ram; and Jacquin states his bird to have measured full two feet and a half in height in its natural sitting posture, and almost two inches in the diameter of its legs. It is impossible to read the descriptions of Hernandez and Jacquin, making in the case of the former some little allowance for exaggeration, without feeling a conviction that they both refer to the bird now under consideration. That of the latter author in particular is admirably characteristic. Linnæus originally founded his species on the indication given by Hernandez; in the tenth edition of his 'Systema' he suggested a comparison between it and a bird seen by a friend, probably a pupil, in the Royal Menagerie at Madrid, which there is every reason to believe from the description given to have been just. It was only in the twelfth edition of his immortal work that he introduced a slight confusion by adding to the citation from Hernandez to the account furnished by his friend, and to some particulars extracted from Jacquin's then unpublished description of his supposed species, a synonym from Marcgrave, which can alone justify M. Temminck's criticism. We restore without hesitation both these synonyms of Linnæus and Jacquin, excluding only from the twelfth edition of the 'Systema Naturæ' the references to Marcgrave and his copyists. With the *Vultur harpyia* of Linnæus and the

V. coronatus of Jacquin are necessarily included among the synonyms of the Harpy Eagle, the *Falco harpyia* and the *F. Jacquini* of Gmelin, by whom the trivial name assigned by Jacquin to his bird was changed on account of its introduction into a genus in which that appellation was pre-occupied. In the year 1778, Mr. Dillon observed in the menagerie of Buen Retiro at Madrid, a species of eagle which he imagined to be 'an undescript kind not taken notice of by Linnæus.' This bird, which he figures in his 'Travels through Spain' under the name of the Crested Falcon, is evidently of the same species with the Harpy, although the representation is rudely executed, and in some respects, as for example the length of the beak, grossly caricatured. We might almost be tempted to suspect that the specimen seen by him was identical with that described by Linnæus from the same menagerie twenty years before, were it not that the latter bird is expressly called Mexican, while that of Mr. Dillon is stated to have come from the Caracas. For this reason Dr. Latham introduced it into his 'Synopsis' under the name of the Caraca Falcon.

"Gmelin, quoting from Latham, soon after latinised its former name into *Falco cristatus*, and this may therefore be added to the synonyms of our bird, of which Mr. Dillon's was the first published figure. The next original describer of the Harpy Eagle was Mauduyt, who also regarded his specimens as nondescript, and gave them the name of Grand Aigle de la Guiane, from the country whence they were obtained. To these birds, which formed part of the collection of the Paris Museum, Daudin, in his 'Ornithology,' published in 1800, applied the scientific appellation of *Falco destructor;* and the names given by these two writers have been generally adopted on the continent of Europe as the only ones certainly applicable to the species. M. Sonnini seems doubtful whether or not to regard the two specimens described by him as distinct species, and names the one Aigle Destructeur, and the other Grand Aigle de la Guiane; but there seems no sufficient reason for their separation. Dr. Shaw's *Falco imperialis* is founded on this indication of Sonnini. In all probability the Crested Eagle of Stedman's 'Expedition to Surinam,' spoken of as a very strong and fierce bird, belongs to the same species. Figures of the Harpy are likewise given by M. Cuvier in his 'Règne Animal;' by M. Vieillot, in the second edition of the 'Nouveau Dictionnaire des Sciences;' and by M. Temminck, in his 'Planches Coloriées.' Those of the two last-named works are strikingly characteristic. That of the 'Dictionnaire' exhibits the crest-feathers equally and stiffly elevated round the back part of the head, a state in which we have never seen them in our bird, and which on account of their laxity, and the lower position of the middle ones, we doubt their power to assume. It is right however to remark that the crest is stated by Linnæus and other authors to possess this power of elevation round the head in form of a crown, an ornament alluded to in the Spanish name of the bird, Aquila Coronada, and in the trivial appellation, *coronatus*, affixed to the species by Jacquin. We believe that we have now restored to this bird all the original synonyms which unquestionably belong to it. The original descriptions of Hernandez, Linnæus, Jacquin, Mauduyt, Daudin, and Sonnini, and the figures of Dillon, Shaw, Cuvier, Vieillot, and Temminck, are such as leave no doubt upon our minds of the accuracy of the references to those authors. We have purposely abstained from mentioning others which have been occasionally quoted, but which either do not appear to us to be satisfactorily determined, or are evidently founded on mistake. Of the former class the Owyra-Ouassou of Lery, or Royal Bird of Prey of Brazil, may serve as an example; of the latter, the Calquin and Tharu of Molina."

Adult Bird.—Head with thick downy plumage, of a light slaty-gray colour. Crest arising from the back part, of numerous broad feathers increasing in length towards the middle line of the head, and thus assuming a rounded form, of a dull black, with the exception of a slight margin of gray on the tips of the longer feathers, and a more extensive tinge of the same colour on those of the sides. This crest is slightly raised above the level of the feathers of the back of the neck when the bird is quiet, but is capable of being elevated at right angles with them upon any sudden excitement. In this state, to an observer placed in front of the bird, the middle feathers of the crest are rarely visible, on account of their being inserted much lower down than the lateral ones; while the latter, converging on either side, form, as it were, two lax ear-like processes. Below the crest, the whole of the back and wings, together with a broad collar round the fore part of the neck, black, each of the feathers of the back terminating in a narrow transverse somewhat lighter streak. Under surface, from the breast backwards, pure white; plumage of the legs white with blackish transverse bars. Tail with four transverse black bands, of about equal breadth with the four alternating whitish or ash-coloured spaces; the tip light ash. (Bennett).

Immature Bird.—Upper parts mottled with brown, gray, and whitish; cheeks, occiput, throat, and under parts, light gray, with a few black feathers in front of the neck, and some large irregular black spots on each side of the lower surface of the tail-feathers on a light ash-coloured ground. (*Falco imperialis*, Shaw; Vieillot, young female ?). Back and wings grayish fawn-colour, irregularly marbled and spotted with black; collar ashy-fawn, more or less spotted with black; bars crossing the legs fewer and more irregular; all the lower parts whitish-fawn sprinkled with darker spots; upper surface of tail ash-coloured, with small blackish spots; patches of black mark the places of the future bands, which gradually increase at each change; under surface whitish, dotted with fawn. (Temminck.)

Bird farther advanced.—Collar, crest, back, and wing-coverts, almost uniformly gray; quill-feathers of the wings black; under surface of body dirty white; each of the tail-feathers marked beneath by four large black patches crossing its shaft and occupying about half its width. (Bennett.)

Upper mandible very thick at the base, straight for some distance, and suddenly curving downwards with a strong arch towards the sharp point; lower mandible straight, short, and blunt; nostrils transverse and oval; wings when closed not reaching beyond the middle of the tail, which is rounded at the extremity; legs feathered on the upper part of their anterior surface only, the rest naked and reticulated; talons extremely strong, internal and posterior ones very long. Mr. Bennett observes that in some of these characters, as for instance the nakedness of the legs, the Harpy approaches the Sea-Eagles; but it differs from them in many essential points, and in none more remarkably than in the shortness of its wings, and the robustness of its legs and talons; the former character rendering it, like the short-winged hawks, more adapted for preying near the surface of the ground on gallinaceous birds and quadrupeds, and the latter enabling it to carry off a prey of much greater magnitude.

Harpy Eagle (*Harpyia destructor*).

The Harpy is stated to be a solitary bird, frequenting the thickest forests, where it feeds upon the sloths; it also preys on fawns and other young quadrupeds. Sonnini observed it sitting motionless and uttering no cry, on a high tree on the banks of the Orapu. Hernandez does not seem inclined to detract from the powers of the bird, for he says that it will attack the most fierce beasts, and even man himself; and he further states that it may be trained like a hawk to pursue game. Linnæus gives the bird credit for strength sufficient to split a man's skull with a single blow (unico ictu). These accounts of its prowess must be taken with some grains of allowance, but that the bird is very powerful is without doubt. Jacquin's specimen was found dead in the ship that was conveying it to Europe, and its death was with some probability attributed to the sailors, whose monkeys the eagle had destroyed. When these animals gambolled too near its cage they were seized by its talons and devoured with almost all their bones, but not their skin, which the bird invariably stripped off. One Harpy which was obtained by Mr. Hesketh, consul at Maranham, near the mouth of the river Amazonas, and brought to England by Colonel Sabine, is said to have destroyed and eaten a King of the Vultures (*Sarcoramphus Papa*) while on its passage to England. After its arrival a cat was put into its cage, and the eagle, with one blow of its immense foot, broke its back.

It inhabits Mexico (Hernandez, Linnæus, and others); the neighbourhood of the river Magdalena, in New Granada (Jacquin); Caracas (Madrid specimen); Guyana (Sonnini).

Morphnus (Cuvier.)—Beak convex above; nostrils elliptical; tarsi elevated, rather slender; acrotarsia scutellated; toes rather short; claws acute.

Mr. Vigors observes, that this genus differs from *Herpyia* in its more slender, lengthened, and scutellated tarsi, and the comparative weakness of its toes. It is separated into two sections, as the tarsi are plumed or otherwise; among the former M. Cuvier arranges *Falco occipitalis*, *F. ornatus*, and *F. albescens* of Daudin, and *F. maculosa* of Vieillot; among the latter, *F. Guianensis* of Daudin, and *F. Urubitinga* of Gmelin. *Spizaëtus* of Vieillot corresponds with this group.

a. Tarsi naked.

M. Urubitinga, *Falco Urubitinga* of Gmelin, *Aquila Brasiliensis* of Brisson, Brasilian Eagle of Latham, Urubitinga of Marcgrave, Willughby, Ray, and others. The following is Willughby's:—This bird is like an eagle, of the bigness of a goose of six months old. It has a thick hooked black beak; a yellowish skin (cere) about the nostrils; great sparkling aquiline eyes; a great head; yellow legs and feet; four toes in each foot, disposed after the usual manner; crooked, long, black talons; large wings; a broad tail. It is all over covered with dusky and blackish feathers; yet the wings are waved with ash colour. The tail is nine inches long, white for six, the end for three inches being black; howbeit in the very tip there is again a little white.

Head and foot of Brasilian Eagle (*Morphnus Urubitinga*).

Young of the Year.—Blackish-yellow below; the centre of each feather marked with blackish-brown tear-like spots; throat and cheeks with brown striæ on a whitish ground. Locality, Brazil and Guyana, where it is said to seek its prey on inundated places.

b. Tarsi feathered.

M. occipitalis, *Falco occipitalis* of Daudin, L'Aigle Autour Noir Huppé d'Afrique, and Huppart. It is the size of a crow; black, with a long crest or tuft dependant from the occiput; tarsi, edge of the wing, and bands on the tail, whitish. It is a native of Africa.

Cymindis (Cuvier).—Beak convex above; nostrils nearly closed, rimiform; tarsi short, semipalmated.

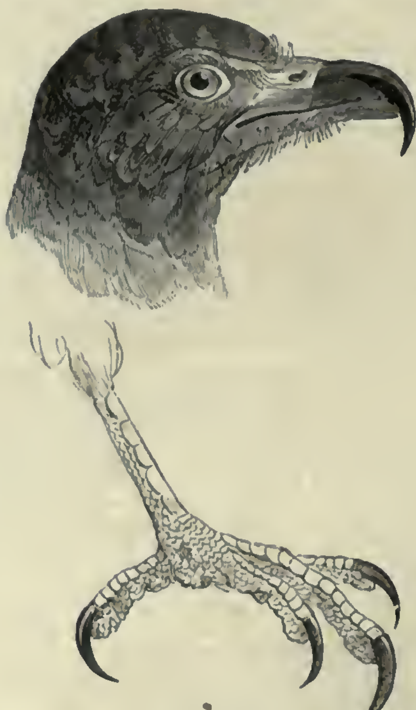
Distinguished by their short, half-plumed, and reticulated tarsi, and more particularly by their nostrils being nearly closed, and bearing the appearance of a narrow slit or channel.

a. Acrotarsia scutellated.

C. hamatus, *Falco hamatus* of Illiger.

Head and foot of Huppart (*Morphnus occipitalis*).

Adult.—Upper mandible extremely hooked; cere and feet yellow; all the plumage uniform lead colour. Length 15 inches 8 lines French.



Head and foot of *Cymindis hamatus*.

Young of the Year.—Plumage sombre brown, each feather bordered and blotched with red; summit of the head and cheeks marked with yellowish elongated spots; a yellowish band below the eyes; front of the neck whitish. It is a native of Brazil.

b. Acrotarsia reticulated.

C. Cayennensis, *Falco Cayennensis* of Gmelin, Petit Autour de Cayenne.

Summit of the head ash-coloured; back (manteau) brown, barred with deeper brown; belly white; tail gray, barred with white beneath; feet ash-coloured. It is a native of Cayenne.

Head and foot of *Cymindis Cayennensis.*

Asturina (Vieillot).—Beak couvex above; nostrils lunulate; tarsi short, somewhat slender; claws long, very acute.

A. cinerea. Bluish ash-colour; whitish bands on the under part of the body; tail traversed by two black stripes, white at the point; beak blue below; cere blue; feet yellow. It is a native of Guyana.

Head and foot of *Asturina cinerea.*

Mr. Vigors observes, that it is among these Short-Winged Eagles that the greatest difficulty prevails in deciding on their immediate affinities. Being for the most part extra-European, and not within the reach of general examination, their manners also being but little noted, and the characters on which we depend for formiug our decision respecting their affinities being for the most part passed over in the descriptions given of them, it is only by conjecture that we can assign them a place in the general arrangement. Of this nature, he remarks, is the genus last described. The same difficulty, he adds, extends to several other described species of the *Falconidæ*, which appear to him to belong to the group of Short-Winged Eagles, although they have been assigned a different locality by the authors who have described them. Among these is the *Falco Bacha* of Daudin, which has been generally rauked with the Buzzards. Its short wings and lengthened bill however seem, accordiug to Mr. Vigors, to bring it among the present group of the Eagles; and its habits, as described to him by Dr. Horsfield, who had an opportunity of closely observiug them in the Island of Java, where the birds are by no means uncommon, do not in any respect correspond with the Buzzard tribe. Mr. Vigors would place it, together with *F. albidus* of Cuvier, near those species of the genus *Cymindis* which are distinguished by the reticulated acrotarsia, if uot in that genus itself. He has indeed some doubts whether most of the Short-Winged *Falconidæ* at present placed among the Buzzards, such as *F. buson* and *F. tachiro* of Daudin, *F. pœcilonotus* of Cuvier, &c., may not be more properly removed to a situation between the Short-Winged Eagles and the Hawks, with both of which tbey seem to have a considerable affinity. There is, continues Mr. Vigors, another group which also appears allied to the present, distinguished by a rather feeble and elongated bill, short wiugs, and slender lengthened tarsi, feathered to the toes. It includes *F. limnæctus* of Horsfield ('Zool. Res.,' No. 6), *F. niveus* of Temminck (Pl. Col. 127), and *F. atricapillus* of Cuvier (Pl. Col. 79). These appear to be strongly allied, in the opinion of Mr. Vigors, if not to appertain, to the before-mentioned genus *Morphnus*. *F. tyrannus* of Prince Maximilian (Pl. Col. 73) bears also, Mr. Vigors thinks, a strong similitude to the same group, though partially differing in external characters.

2nd Sub-Family *Accipitrina* (Hawks).

Beak short, hooked from the base; wings short, fourth quill longest.

Head and foot of *Dædalion cachinnans.*

"The short wings of the last groups," writes Mr. Vigors, "lead us to the present division of Hawks, all of which, a considerably extensive tribe, are characterised by their wings exteuding no further than two-thirds of the extent of their tail. The fourth quill-feather is the longest, the first, second, and third gradually exceeding each other in length. In this division we may observe that the upper mandible, though not furnished with distinct teeth like the True Falcons, has the festoon or prominence that generally supplies its place more strong and angular than is usual among these tribes. In some of the *Accipitres* this is particularly distinguishable. The sub-family we have just quitted includes all the birds of the present family in which the beak is straight at the base, and hooked only at the apex. We now enter upon the first of those groups where the bill is curved from the base, a character that extends through the remainder of the *Falconidæ*. It may be observed, that this character, which thus separates the family into two departments, was equally noticed as a mark of distinction between the species known to the ancients. Pliny, apparently referring to it as a line of demarcation between them, divides the group into his two departments of *Aquilæ* and *Accipitres*. It is from adopting the same views respecting the family, that M. Brisson instituted his two leading divisions, to which he assigned corresponding denominations."

Dædalion (Savigny).—Beak short; tarsi moderate; acrotarsia reticulated. Type, *Falco cachinnans* of Linnæus, and *F. melanops* of Latham.

Mr. Vigors adopts the name which was conferred by M. Savigny on the whole of the sub-family, for the present division of it.

D. melanops. Adult male—white, flamed with black on the neck and breast; back, wings, and tail, deep black, the last with a white stripe, and terminated with white; there are dots of the same colour on the coverts of the wings; cere and tarsi reddish. It is a native of Guyana. We have illustrated the form by *Dædalion cachinnans*.

Astur (Bechstein).—Beak short; nostrils suboval; tarsi moderate; acrotarsia scutellated.

Mr. Vigors observes that *Astur* is a title which has been applied to the whole group, but which may be confined to those whose tarsi, moderate in length, have their acrotarsia scutellated or covered with broad and even scales. He considers our European species, *Falco palumbarius* of Linnæus, as the type; to which may be added *F. Novæ Hollandiæ* of Latham, and a considerable number of corresponding species from every quarter of the globe.

A. palumbarius. This is the Autour and Atour of the French; Astore (Zinan.) and Girifalco (Bonaparte), Sparviere da Columbe, and Sparviere Terzuolo, of the Italians; Grosser Gepfeilter-Falck and Hunerhabicht of the Germans; Goshawk of the English, and Hebog Marthin of the Welsh.

A full-grown female measures from 23 to 24 inches in length; the males one-fourth, and sometimes one-third less; but when adult, the plumage is nearly similar. The beak is horn-colour or bluish-black; the cere and irides yellow; the top of the head, the whole of the back, upper surface of the wings, and tail-feathers, dark grayish-brown; in females the colour inclines to clove-brown; the upper surface of the tail-feathers barred with darker brown; a band passing over the lore, eyes, cheeks, and ear-coverts; the nape of the neck, throat, breast, belly, and thighs, nearly white, with spots, transverse bars, and undulating lines of dull black; under tail-coverts white; lore, cheeks, and ear-coverts, grayish-brown, forming an elongated dark patch on the side of the head; the legs and toes yellow; the claws black.

Young birds have the beak, cere, and eyes, nearly similar to those of the old birds; the top of the head, nape, and ear-coverts, ferruginous white, each feather darker in the middle; back, wings, and upper tail-coverts, brown, margined with buff; upper surface of the tail-feathers with five bands of dark brown and four bands of lighter brown, the ends of all the feathers white; wing-primaries dark brown, barred with two shades of brown on the inner webs: the chin, throat, breast, and belly, grayish-white, each feather with a central elongated patch of dark brown; thighs and under tail-coverts with a dark brown longitudinal streak instead of a brown patch; under surface of the wings grayish-white, with transverse dusky bars; under surface of the tail-feathers grayish-white, with five darker grayish-brown transverse bars, the tips of all the feathers white; legs and toes yellow-brown; the claws black; those of the inner toe considerably larger than those of the outer. (Yarrell.)

This bird flies low, and pursues its prey in a line after it, or in the manner called 'raking,' by falconers. If the game takes refuge it will sit patiently on a tree or stone till it moves, or till some other prey is accessible. Food—hares, rabbits, pigeons, pheasants, grouse, and partridges. The female was generally flown by falconers at fur, and the male at feather; but the female was also trained to take the larger winged game, the male being principally flown at partridges. Turbervile says, "You shal not neede to shew any other game to a goshawke for her first entring than a partridge, because in learning to flee the partridge they prove most excellent; and the first yeare you shall doe best to flee them to the field, and not to the covert, for so will they learne to hold out (and not to turne tayle) in the middest of their flight; and when they be mewed hawkes, you may make them doe what you will; and understand you, that you shall not neede to take such pain, nor to use such art in making of a goshawke which is taken a brancher as with a Nyasse, for she will alwayes know of her selfe what to doe." ('The Book of Falconrie.') Nest, on a high tree in the outskirts of the forest; rarely found in the interior, except in those parts which are open and free from timber. Eggs three or four, frequently hatched in the middle of May. (Hewitson, ex relatione Hoy.) Mr. Yarrell says that the eggs are rare, and that the few which he has seen were uniform in size and colour, 2 3/10ths inches in length by 1 11/16th inch in breadth, of a pale bluish-white, without any spots or streaks.

It is found in Denmark, Norway, Sweden, Siberia, Russia, and Chinese Tartary. (Müller, Linnæus, Pennant.) Very common in France, Germany, Russia, and Switzerland; more rare in Holland. (Temminck.) Rare in the south of England. Mr. Yarrell says, "The few that are used for hawking are obtained from the Continent. Colonel Thornton, who kept them constantly in Yorkshire, procured some of his specimens from Scotland. Dr. Moore, in his 'Catalogue of the Birds of Devonshire,' says that it is found occasionally on Dartmoor, but I can find no record of its appearance farther west in England, nor any notice of it in Ireland. A fine adult male was trapped by a gamekeeper in Suffolk in March, 1833; and Mr. Doubleday of Epping has sent me word that he received a young bird from Norfolk in the spring of the same year. Mr. Selby mentions that he had never seen a recent specimen south of the Tweed, but states that it is known to breed in the forest of Rothiemurcus, and on the wooded banks of the Dee. Mr. Low says that this species is pretty frequent in Orkney; but as he speaks of it in connection with sea-beaten rocks without shelter or woods, is there not reason to suspect that Mr. Low was mistaken, and that the birds he saw were Peregrine Falcons?—the more so, as several visitors to these northern islands have observed peregrines, but no goshawks." ('British Birds.') Prince C. L. Bonaparte has noted the goshawk as not common in the neighbourhood of Rome, and as rare in that of Philadelphia. Sir John Richardson ('Fauna Boreali-Americana') describes one shot in company with the female at the nest on the plains of the Saskatchewan, and states that another specimen was killed in the woody country three or four degrees of latitude farther north than the preceding. He records another killed near Jasper's House, on the Rocky Mountains, and a fourth killed at York Factory, supposed to be a young bird of the season (the specimen noticed by Mr. Sabine in 'Franklin's Journey').

Goshawk (*Astur palumbarius*).

The Falcon-Gentil is supposed to be the female and young of this species, which is the Ash-Coloured or Black-Capped Hawk of Wilson.

Colonel Sykes describes an *Astur* (*A. hyder*) among his birds of the Dukhun (Deccan), and there are specimens of *A. musicus* and *A. melanoleucus* in the South African Museum.

Accipiter (of Ray, Brisson, and authors).—Beak short; nostrils suboval; tarsi elongated, smooth; acrotarsia scutellated, the suture scarcely to be discerned. Type, the Common Sparrowhawk *Accipiter fringillarius* of Ray: to which, says Mr. Vigors, may be added many corresponding species which do not seem to have any limits to their geographical distribution.

A. fringillarius, the Sparrowhawk, is L'Epervier of the French; Falco Palombino and Sparviere da Fringuelli of the Italians; Die Sperber of the Germans; Sparfhoek of the 'Fauna Suecica;' *Falco Nisus* of Linnæus; Gwepia of the Welsh.

Adult Male.—About 12 inches in length; beak blue, lightest at the base; cere greenish-yellow; the irides yellow; top of the head, nape of the neck, back, wings, and wing-coverts, rich dark-brown—in very old males with a tinge of bluish-gray; tail-feathers grayish-brown, with three conspicuous transverse bands of dark brown; chin, cheeks, throat, breast, belly, thighs, and under tail-coverts, rufous, with numerous transverse bars of darker rufous brown; legs and toes long, slender, and yellow; the claws curved, sharp, and black.

Female.—Generally 3 inches longer than the male; beak bluish horn-colour; cere yellowish, the irides yellow; top of the head, upper part of the neck, back, wings, and tail-coverts, brown—the base of many of the feathers white, which, extending beyond the edge of the feather immediately above it, causes a white spot or mark; primaries and tail-feathers light brown, barred transversely with darker brown; under surface of the neck, body, wing-coverts, and thighs, grayish-white, barred transversely with brown; under surface of the wing and tail-feathers of the same colour, but the light and dark bars much broader; the first six wing-primaries emarginated; the fourth and fifth quill-feathers equal and the longest, the first quill-feather the shortest; legs and toes yellow; claws long, curved, sharp, and black.

Young Male.—Resembles the female; but the brown feathers of the back and the wing-coverts are edged with reddish-brown; feathers of the tail reddish-brown, particularly toward the base, with three conspicuous dark-brown transverse bands. In other particulars like the female: both have a collar formed by a mixture of white and brown, which extends from the sides of the neck to the nape. (Yarrell.)

The Sparrowhawk haunts wooded districts. It is the great enemy of small quadrupeds and birds, and is often very destructive to young chicks in poultry-yards in the breeding season. Used in falconry it is the best of all hawks for landrails. (Sebright.) "The Sparrowhawk generally takes possession of some old or deserted nest in a tree, most frequently that of the crow, in which the female deposits four or five eggs, each about 1 inch 7 lines long by 1 inch 4 lines broad, of a pale bluish-white, blotched and spotted with dark brown. The young are covered with a delicate and pure white down, and are abundantly supplied with food. Mr. Selby mentions having found a nest of five young sparrowhawks, which contained besides, a lapwing, two blackbirds, one thrush, and two green-linnets, recently killed, and partly divested of their feathers." (Yarrell.)

It is spread throughout Europe, Japan (Temminck), Smyrna (Mr. Strickland), Denmark, Sweden, Norway, Russia, and thence southward over the European continent to Spain and Italy. Common in most of the counties of England, and has been observed in the west and north of Ireland; occurs also in Scotland and its northern islands. (Yarrell.) Very common, migratory, near Rome. (Bonaparte.)

Head and foot of Sparrowhawk (*Accipiter fringillarius*).

The form is widely spread. Colonel Sykes records *Accipiter Dukhunensis* (resembling *A. fringillarius*, but differing in certain points), and *A. Dussumieri* among the birds of the Dukhun (Deccan). In the South African Museum will be found *Accipiter polyzonus*, *A. polyzonoides*, *A. niger*, *A. Gabar*, *A. Tachiro*, *A. minulus*, and *A. rufiventris*.

Mr. Vigors remarks that there are some species which seem to be allied to this sub-family and to be intermediate between it and the succeeding sub-family of Falcons, which, from some peculiarities of character, cannot well be appended to any established genus. They possess, he observes, a shortness of wing which would incline us to refer them to some of the present groups; but their upper mandible, strongly and doubly dentated, presents a character that will not admit of their being included in any of the foregoing genera, in which the mandibles are entire, or where the place of the tooth is supplied by a rounded prominence. These species Mr. Vigors would have wished to arrange in one genus; but they are found to differ in essential points which bring them respectively within the pale of the two conterminous sub-families now under consideration; and he feels obliged, for the sake of perspicuity, to adopt the following genus of which the type is *Falco bidentatus* of Latham.

Harpagus, Vigors (*Bidens* of Spix).—Beak short; upper mandible strongly bidentated, lower with a double notch; tarsi moderate; acrotarsia scutellated; third and fourth quills longest, equal.

Mr. Vigors observes that the essential characteristic of this group is the double tooth on both the upper and lower mandible. The wings, which correspond with those of the other Hawks, in being one-third shorter than the tail, have the third and fourth quill-feathers, which are the longest, of equal length. The tarsi are of moderate length and strength, and have the acrotarsia scutellated as in the latter groups of the present sub-family. The nostrils are of a semicircular form and the cere is naked.

H. bidentatus. Length, a foot and some lines (French). Slate-colour above; throat white; breast and belly red, undulated with yellowish; lower coverts of the tail white; tail nearly equal, brownish, barred with whitish. It is a native of Brazil and Guyana.

Head and foot of *Harpagus bidentatus*.

Mr. Vigors remarks that *Falco Diodon* of Temminck is to be referred to this genus.

Gampsonyx (Vigors).—Beak short, mandibles entire; nostrils rounded; wings short, second quill longest, third generally equal to the second, and internal web of the first and second strongly notched near the apex; tail moderate, equal; feet moderate; tarsi reticulated, acrotarsia feathered below the knee to the middle. (Vigors.)

"The genus is founded on a small and beautiful Hawk," writes Mr. Vigors in 'The Zoological Journal,' vol. ii., "which has been kindly submitted to my inspection by Mr. Swainson, one of the fruits of that gentleman's extensive researches in Brazil. This bird decidedly belongs to the Accipitrine sub-family of the *Falconidæ*; but it is placed at that remote extremity of it, where the species, gradually approaching the Falcons, partially assume some of their leading characters. It possesses the bill of the Hawks, and also the shortness of wing which so strongly characterises them; but the structure of the wing itself is the same as in *Falco*, the second quill-feather being the longest, and the first and second of these feathers being marked on the inner web by an abrupt emargination near the apex; while the tarsi also display the character of the same group in having the acrotarsia reticulated. The bird thus exhibits a striking modification of form, at once partaking of the chief of the respective characters of both the Hawks and Falcons; with the former of which it may in addition be observed that it agrees in its general form, and with some of the latter, particularly the beautiful group of *Ierax cærulescens*, in its colours, and in the general distribution of them. To the latter group indeed it has a striking resemblance, and might perhaps be referred unconditionally to it, could we pass over the important character of the untoothed bill."

G. Swainsonii. Above cineraceous-black, white beneath; front, cheeks, sides of the abdomen, and femoral feathers, orange; a black spot on each side of the breast. Beak black. Feathers of the back and scapulars ashy-black, spotted with ferruginous. Lower side and nuchal collar white, sparingly variegated with orange. Primaries blackish, internally margined with white at the apex; secondaries sparingly sprinkled with ferruginous, beneath white. Tail-feathers ashy-black, internally (the middle excepted) margined with white, beneath white. Feet yellow; claws black. Length of the body 9¾ inches. (Vigors.)

It is a native of Brazil. Mr. Vigors says that the following manuscript note was appended to this bird in Mr. Swainson's handwriting:—"The only individual of this species I ever met with was shot on the table-land, about ten leagues in the interior of Bahia, in a direction west-south-west from the bay of St. Salvador. It was perched on the trunk of a withered tree, apparently watching some small birds. The tarsi are bright and the irides hazel."

3rd Sub-Family, *Falconinæ* (Falcons).

Beak short, hooked from the base. Wings long. Second quill longest.

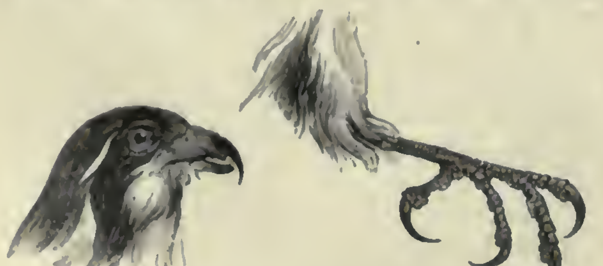
Mr. Vigors observes that this, closely allied to *Harpagus* by the double tooth on its upper mandible, is another group for which he proposes the name of

Ierax (Vigors).—Beak short; upper mandible strongly bidentated, lower simply notched; tarsi moderate; acrotarsia scutellated. Wings short; second quill longest, slightly notched near the apex.

Bengal Falcon (*Hierax cærulescens*).

"Whoever," writes Mr. Vigors, "has seen that beautiful species, the smallest of its race, *Falco cærulescens* of Linnæus, now rendered familiar to us by the accurate and splendid illustrations of Dr. Horsfield, will at once acknowledge its separation from every other established genus of the family. Its upper mandible is strongly and sharply bidentated as in *Harpagus*, but the under mandible is simply notched as in the true Falcons. Its wings, shorter than the tail, differ also from those of *Harpagus* in having the second quill-feather the longest, thus again establishing the affinity of the genus to the Falcons. The tarsi are moderate, and the acrotarsia scutellated as in the latter group of Hawks. From its thus possessing characters in common with both sub-families it is difficult to say to which we should refer it; but I prefer placing it in its present situation on account of the length of the second quill feather, a peculiarity which distinguishes the true Falcons, and gives a striking character to their flight. Placed however at the extremity of the division, it preserves its affinity with those that went before."

H. cærulescens is, according to Dr. Horsfield, the Allap or Allap-allap of the Javanese; *Falco cærulescens* of Linnæus; *F. Bengalensis* of Brisson; *Falco parvus Indicus*, 'Ger. Orn.'; Little Black and Orange



Head and foot of Bengal Falcon (*Hierax cærulescens*).

Indian Hawk of Edwards; and the Bengal Falcon of Latham. Entire length 6¼ inches. Upper parts bluish-black and glossy. Throat, breast, axillæ, sides of the neck, forehead, and a line continued from the environs of the bill over the eye and along the neck, white, with a ferruginous tail. Lower part of the breast, abdomen, vent, and thighs, ferruginous. Hypochondria, thighs posteriorly, and a broad patch extending from the eye along the side of the head, black; the plumes which cover the thighs behind are terminated by long silky filaments or radii which are straggling and pendulous, and by their laxity and irregularity afford a peculiar character to the bird. (Horsfield.) The natives told Dr. Horsfield that this small but robust bird was uncommonly bold in the pursuit of little birds. Several individuals were brought to him from the range of the southern hills, which are covered with forests, during his abode at Surakarta. He obtained one in the eastern districts. In the other parts of the Island of Java he did not observe it. Bengal is also given as its locality.

Mr. Vigors ('Zool. Proc.,' 1831) describes another species, *Ierax erythrogenys*, the size of *I. cærulescens*, from the neighbourhood of Manilla.

Falco.—Beak short; upper mandible strongly toothed; lower notched; acrotarsia reticulated; second quill longest; first and second deeply notched internally near the apex.

This genus, which includes, as Mr. Vigors observes, the greater portion of the present sub-family, comprises the typical species. "The upper mandible of this group," writes that zoologist, "is armed with a strong angular tooth; the lower is notched near the extremity. The nares are rounded. The wings are for the most part as long as the tail, the second quill-feathers being invariably the longest. The first and second quill-feathers are also distinguished by an abrupt emargination on the inner web near the extremity. In some species, as in *F. peregrinus*, the emargination of the second quill-feather is not so abrupt as in others. But in all the species of the true Falcons that have come under my examination, this emargination of the first quill-feather at least is strongly apparent. The tarsi are moderate in length and strength, and have the acrotarsia reticulated. Our European species—*F. peregrinus*, Linn.; *F. subbuteo*, Linn.; *F. Æsalon*, Linn.; *F. rufipes*, Bechstein—are readily distinguished as belonging to this typical genus. Some species belonging to the group have the wings somewhat shorter than the tail, which in conjunction with *Ierax* thus evince a gradual series of affinity between the short and long-winged tribes. Among these we may distinguish *F. tinnunculus*, Linn.; *F. rupicolus*, Daud.; with some corresponding species."

F. peregrinus, the Peregrine Falcon, is Le Faucon Pelerin of the French; Sparviere Pellegrino and Falco Reale of the Italians; Wander Falke of the Germans; Apestæ-Kæoo (Little Eagle) of the Cree Indians; Hebog Tramor and Commin of the Welsh.

Peregrine Falcon (*Falco peregrinus*).

Adult.—Length from 15 to 18 inches, depending on the sex and age of the bird. Beak blue, approaching to black at the point; cere and eyelids yellow, irides dark hazel-brown; top of the head, back of the neck, and a spot below the eye, nearly black; back and upper surface bluish-slate or ash colour, becoming lighter at every succeeding moult, the males usually the most so; feathers of back, wing-coverts, and tail, barred with a darker tint; primaries brownish black, inner webs barred and spotted with rufous white; front of neck white, with dark longitudinal lines; breast rufous white, with dark-brown transverse bars; flanks, under tail-coverts, and under surface of the tail-feathers, barred transversely with dark-brown and grayish-white; legs and toes yellow, claws black.

Young.—Head and upper surface of body and wing-coverts brownish-ash, the edge of each feather rufous; the dark longitudinal streaks on the white under-side of the body more conspicuous, but, gradually shortening and spreading laterally, they ultimately change their direction, and become transverse. This change is first observed on the belly and flanks. (Yarrell.)

Temminck considers the Lanier (Lanner) of Buffon the perfect state of the male Peregrine. He also adds *Falco Barbarus* of Latham as one of its synonyms.

The food of the Peregrine consists of land and water-fowl, rabbits, young hares, &c. It was highly prized in falconry. Tubervile, in his chapter 'Of the Haggart Falcon, and why she is called the Peregrine or Haggart,' gives the following reasons for the name:—"First, because a man cannot find, nor ever yet did any man, Christian or heathen, find their eyrie in any region; so as it may wel be thought that for that occasion they have atchieved aud gotten that name and terme of Peregrine or Haggart Falcons, as if a man would call them pilgrims or forainers. The second cause is, because these falcons do rangle and wander more then any other sort of falcons are wont to doe, seeking out more strange and uncouth countries, which indeed may give them that title of Haggart and Peregrine Hawks for theyr excellency, because they doe seeke so many strange and forraine coasts, and doe rangle so farre abroad. The third and last cause, I doe thinke, may be their beauty and excellency, because this word (Peregrino), or Peregrine, doth many times import an honourable and choice matter had in great regard. . . . Wherefore I conclude that these Haggart Falcons are not of Italie, but transported and brought thither from forraine places, as, namely, from Alexandrio, Ciprus, and Candie. And yet this is for certaine, that in Italio there are taken of these Haggart Falcons, as in the dominion of the renowned Duke of Ferrara and in the countrie near Ravenna, being brought thither by force of weather and wind. And by that means there are none of those Haggarts found Eyesses, but they are al either soare Hawks or mewed Haggarts."

"In the language of falconry," writes Yarrell, "the female Peregrine is exclusively called the Falcon, and on account of her greater size, power, and courage, is usually flown at herons and ducks; the male Peregrine, being smaller, sometimes one-third less than the female, is called the Tercel, Tiercel, and Tiercelet, and is more frequently flown at partridges, and sometimes at magpies. Young Peregrines of the year, on account of the red tinge of their plumage, aro called, tho female a Red Falcon and the male a Red Tiercel, to distinguish them from older birds, which are called Haggarts or Intermewed Hawks. Tho Lanner of Pennant is a young female Peregrine, at which age it bears some resemblance to the true Lanner, *Falco lanarius* of authors—a true Falcon also, but much more rare than the Peregrine, and which probably has never been killed in this country. Mr. Gould says he was unable to find a specimen in any collection here, either public or private, at the time he was desirous of figuring this species in his 'Birds of Europe.' The true Lanner is only found in the south and south-eastern parts of Europe. Tho king of France, Louis XVI., had Lanners sent annually from Malta; but they were brought from tho eastern countries. It exceeds the Peregrine Falcon in size, being intermediate between that and the Gyr-Falcon; was much esteemed for flying at the kite, with which the Peregrine is hardly able to contend." The name of Lanner is confined to the female; the male is called a Lanneret, on account of his smaller size. ('British Birds.') It makes its nest on high rocks. In Britain Mr. Yarrell states that the Peregrine builds on various parts of the coast, more frequently in Scotland than in England. The eggs are from two to four in number, about 2 inches long by 1 inch and 8 lines in breadth, mottled all over with pale reddish brown. Mr. Selby notices their eyrio at St. Abb's Head. It was from this locality that the late Mr. Baird of Newhyth usually obtained his cast of Hawks, for each of which he gave the persons who undertook the peril of climbing the rock one guinea. Other localities for tho nest in Britain are the cliffs between Freshwater Gate and the light-house near the Needles; Devonshire and Cornwall, where it is called Cliff-Hawk; Holyhead and the Great Orme's Head (Yarrell); rocky coast of Caernarvonshire (Pennant); rocky situations inland and marine in Ireland (Thompson quoted by Yarrell); Vale of Moffat in Dumfriesshire; the Bass Rock and the Isle of May in the Forth (Sir Wm. Jardine). It is also found in all the mountainous countries of Europe, particularly on rocks; very rare in champaign countries; never found in marshy districts; abundant in Germany and France; sufficiently common in England and Holland; rare in Switzerland (Temminck); Shetland Isles, where it breeds; Denmark, Sweden, Norway, Lapland, and Greenland (Yarrell); Uralian and Siberian mountains (Pennant). Sir John Richardson, who describes an old male from Melville Peninsula, 68° N. lat., says ('Fauna Boreali-Americana')—"The Peregrino being a raro bird in the wooded districts of the Fur Countries where tho trading posts aro established, I did not procure a specimen on the late expeditions; but I have frequently seen it whilst on the march across the Barren Grounds. Of the two specimens figured by Edwards, one was from Hudson's Bay and the other was caught off the entrance of Hudson's Straits. Sir W. E. Parry likewise brought home several male and female specimens from Melville Peninsula, some of which are preserved in the British Museum. It is a summer visitor of the northern parts of America, and frequents the coasts of Hudson's Bay and the Arctic Sea, with the Barren Grounds, but is very seldom seen in the interior. It preys habitually on the long-tailed ducks (*Anas glacialis*), which breed in great numbers in the arctic regions, arriving in June and departing in September. Sir W. E. Parry observed it, in his second voyage, following flocks of the snow-hunting on the coast of Greenland, near Cape Farewell. It frequents the shores of New Jersey and Pennsylvania in the winter, and is celebrated there for the havoc it makes among the water-fowl. Mr. Ord states that the ducks which are struck by it aro lacerated from the neck to the rump; it gives the blow in passing, and returns to pick up its bird." Port Famine, Straits of Magalhaens (Captain King); Australia (Vigors and Horsfield); Cape of Good Hope (Dr. A. Smith). Prince C. L. Bonaparte notes it as rare and as seen only in winter near Rome, and as rare and casual near Philadelphia. Dr. Smith ('South African Museum,' No. 94) says that the bird so numbered, though it does not exhibit exactly the plumage of the Peregrine Hawk of Europo, yet approaches it so closely that it might be considered as attempting too great a refinement to class it as a different species.

Mr. Vigors observes that Cuvier has separated the *Falco Islandicus* of Latham from the rest of the true Falcons, under the generic title of *Hierofalco*, which he characterises as possessing no tooth on the uppor mandible, but a rounded prominence in the centre, and in which he observes that the wings considerably fall short of the tail in length. In this opinion Mr. Vigors does not acquiesce. He cites examples of the Jerfalcon in its different stages of growth, and in none did he perceive any material difference between its bill and that of the true Falcons. He adds that he feels much hesitation in advancing the above opinion, not merely on account of the known accuracy of Cuvier, but on account of some facts that had then lately come to his knowledge. He mentions a specimen in the British Museum, in which the mandible accords exactly with Cuvier's description—"Il n'a qu'un feston commo celui des ignobles." In several specimens from the arctic regions however in the same collection, he found the tooth. After referring to the figures quoted by Cuvier, and their discrepancies, he inquires whether it may not be possible that there are two species. He cannot think that tho character itself is variable, or that Cuvier would have adopted one which must have been known to him as such, even from the plates. "In no specimen of a true falcon," says Mr. Vigors, "have I seen the slightest alteration of the tooth, except by accident."

Our limits will not permit us to do more than hint at the other species of *Falco*. *F. chicquera*, Himalaya Mountains (Gould), Deccan (Sykes), South Africa (Smith), seems to be the nearest in typical points to tho Peregrine Falcon. The following species of *Falco*, besides *F. peregrinus* and *F. chicquera*, are in tho catalogue of the South African Museum:—*F. biarmicus*, *F. rupicolus*, *F. rupicoloides*, *F. subbuteo*, and *F. Swainsonii*.

F. tinnunculus, the Kestrel, inhabits Asia and Africa, as well as Europe, and is very abundant in the Dukhun (Deccan). (Sykes; Abbott.)

4th Sub-Family, *Buteonina* (Buzzards).

Beak moderate, hooked from the base. Tail equal.

The sub-family of the Buzzards agrees, in the opinion of Mr. Vigors, with the last in the length of the wings, and the bill being bent from the base; and differs from it by a weaker and somewhat more elongated bill, by the third or fourth quill-feather being longest, and more particularly by the absence of a tooth on the upper mandible. A gradation seems however, as Mr. Vigors observes, to soften down these differences, and there is an approximation to the tooth of the Falcons in the first genus of the sub-family.

Ictinia (Vieillot).—Beak short; upper mandible subdentated, lower notched; tarsi short and weak; acrotarsia scutellated; wings long, third quill longest.

Mr. Vigors states that this genus is founded upon the Milan Cresserele of M. Vieillot, and has a strong and short bill, the upper mandible of which is somewhat angularly festooned, and the under distinctly notched. The nares aro rounded as in the Falcons; the tarsi aro rather short, and feathered below tho knees, and the acrotarsia scutellated. The wings are of considerable length, extending far beyond the tail; a character which induced M. Vieillot and others to place the bird near the Kites. Its strong affinity however to the last sub-family, of which it possesses so many of the characteristics, inclines Mr. Vigors to assign it its present situation. In manners, he adds, it seems also to approach the Falcons; and he remarks that if we consider the Mississippi Kite of Wilson to belong to the present group of Vieillot, of which Mr. Vigors has little doubt, we must attribute to the bird before us, judging from the interesting description in the 'American Ornithology,' much of those spirited and generous qualities which we admire in the typical groups of tho family.

I. plumbea (*Falco plumbeus* of Latham). Back and wings slate-blue; head and belly whitish, spotted with brown. Iris fine red.

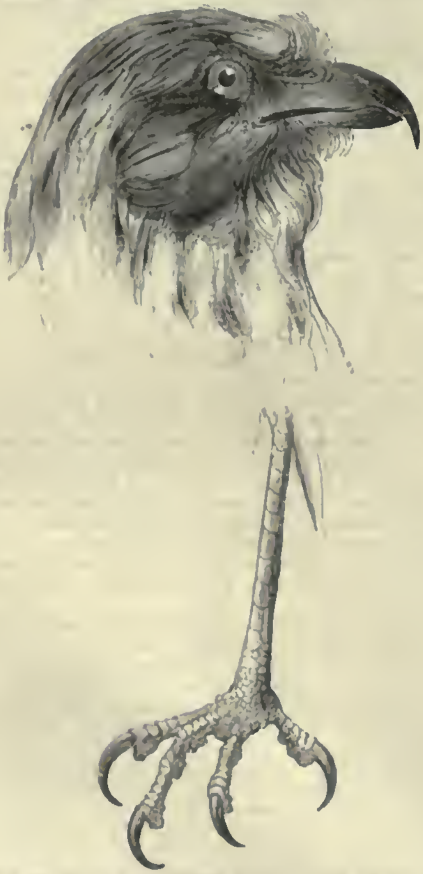
It is said to fly to a great height, where it remains a long time poised or stationary, and cleaves the air with rapidity in order to seize the great insects which are its prey, independently of reptiles and birds. It is a native of America.

Head and foot of *Ictinia plumbea.*

Circus (of Authors).—Beak moderate; nostrils sub-oval; tarsi elongated; acrotarsia scutellated; toes generally short; third quill longest; sides of the head furnished with a circle of feathers very like the capital disc of the Owls.

"This genus," says Mr. Vigors, "exhibits still a slight approximation to the last groups in the structure of the upper mandible, which has a rounded protuberance towards the middle, similar to that of the Hawks. They are distinguished from the rest of the buzzards by their elevated and slender tarsi, which are covered with feathers for some space below the knee, and of which the acrotarsia are scutellated. The nares are sub-oval and transverse on the cere, and the third quill-feathers are the longest." It includes, according to Mr. Vigors, the European species *F. æruginosus* of Aldrovandus, and *F. pygargus* of Linnæus, to which he says may be added *F. acoli* and *F. melanoleucos* of Daudin, together with some newly-described species.

C. æruginosus. This is the Harpaye, Busard Harpaye, and Busard de Marais of the French; Falco Castagnolo and Falco con la Testa



Head and foot of White-Headed Harpy (*Circus æruginosus*).

Bianca (young birds), Falco Albanella con il Collare (old), of the Italians; Schwartz-Brauner Fisch-Geyer mit dem gelben Kopf, Brauner Rohr-Geyer, Brandweihe, Wasserweihe, and Sumpfweihe, of the Germans; Moor-Buzzard, Marsh-Harrier, Duck-Hawk, Harpy, and White-Headed Harpy, of the English; and Bod y Gwerni of the Welsh.

Adult Male (third moult).—Beak bluish-black, with a slight festoon on the cutting edge; cere and irides yellow; top of the head, cheeks, and nape of the neck, yellowish-white, tinged with rufous, and streaked with dark brown; back, wing-coverts, and tertials, dark reddish-brown, with lighter margins; primaries brownish-black; secondaries and tail-feathers ash-gray.

After the third Moult.—Wing-coverts and tertials become, in addition, partially or entirely ash-gray; wing-primaries slate-gray; chin and throat nearly white; breast rufous, streaked longitudinally with dark brown; belly, thighs, and under tail-coverts, reddish-brown, each feather streaked with dark brown; legs long, slender, and yellow; toes yellow; claws sharp and black.

Second Year.—Head, neck, chin, and throat, dull yellow, with an occasional patch of the same colour on the carpus, or anterior point of the wing. (Bewick's Figure.)

Young of the Year.—All the plumage chocolate-brown; feathers tipped with lighter reddish-brown; irides darker than in the adult; legs and feet as in old birds; length from 21 to 23 inches, depending on the sex. (Yarrell.)

The Moor-Buzzard, when in pursuit of game, flies low, and will, so to speak, beat a moor or other piece of ground with the regularity almost of a well-trained pointer. Young rabbits, small quadrupeds, birds, especially water-birds, reptiles, and even fish are its prey. Sometimes it will sit on the look-out on a stone or low bush. It builds its nest generally on the ground, in a tuft of rushes or coarse grass or furze, and composed of rushes or rank grass, and small sticks. Latham says that it will sometimes build its nest in the fork of a large tree, but that the instance is rare. Eggs, three or four, oval, rather pointed at one end, 2 inches and 1 line in length, by 1 inch 6 lines in breadth. (Yarrell.)

It is found in Denmark, Norway, Sweden, south of Russia, Germany, France, Holland, Spain, Italy, and Turkey; in all countries where there are marshes; very abundant in Holland; rare in the south, migratory in the autumn (Temminck); common in the marshes near Rome, but only young birds, and migratory (Bonaparte); Trebizond (Abbott); Ganges, between Calcutta and Benares, &c. (James Franklin); Europe, India, Africa (Gould); Smyrna (Strickland).

The Moor-Buzzard may be seen in most parts of England and Wales favourable to its habits. It occurs in Scotland and the Hebrides, and Mr. Thompson notes it as existing in several counties of Ireland from Cork to Antrim.

Mr. Vigors observes that the sub-family of Buzzards is that which of all the *Falconidæ* approaches nearest to the family of the Owls (*Strigidæ*). In their dull and slothful habits, their heavy flight, and indeed their whole appearance, these contiguous groups evince, he remarks, a general resemblance, indicating a corresponding inferiority in the qualities which distinguish the birds of prey. The soft and loose texture of the plumage of both presents a similar affinity, and he adds that *Circus*, in particular, furnishes us with a still further and more intimate point of resemblance. The feathers that cover the cheeks and ears form, as he says, a sort of rounded collar that rises on each side of the face; thus exhibiting a conformity to the disc or circular erection of the face-feathers so conspicuous in the Owls.

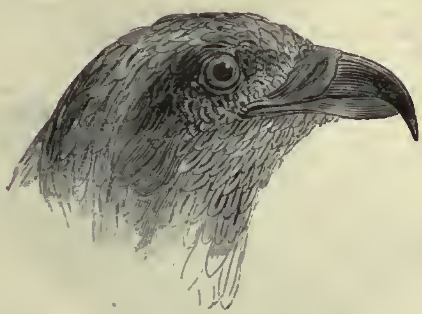
Speaking of *C. cyaneus*, the Hen-Harrier, Mr. Gould, in noticing the Trebizond collection of birds presented to the Zoological Society by Mr. Keith Abbott, says that European, African, Indian, Chinese, and North American specimens present no specific difference. *C. cineraceus* he notes as European, Indian, and African. ('Zool. Proc.,' 1834.) In the South African Museum will be found *C. ranivorus* (with habits very much resembling those of our Moor-Buzzard), *C. Maurus*, *C. Swainsonii*, and *C. Vaillantii*. In the British Museum there is a very good series of the Moor-Buzzard, illustrating the different changes of plumage.

Pernis (Cuvier).—Beak moderate; lore covered with serrated feathers; tarsi moderate, semi-plumed; acrotarsia reticulated; third quill longest.

Mr. Vigors observes that *Pernis* is distinguished by the singular character of the lorum that surrounds the eye, being covered with feathers, instead of being naked as in the other *Falconidæ*, or furnished only with hairs. In other respects also, he states, the genus differs from that of *Buteo* which follows. Its acrotarsia are reticulated, and, like *Circus*, it has the third quill the longest. The nares are similar to those of *Buteo*. *Falco apivorous* of Linnæus, the Honey-Buzzard, and a corresponding species from Java, *P. ptilorhynchus* of Temminck, form, he adds, the typical species of the genus.

P. apivorus, the Honey-Buzzard. It is La Bondrée and Buse Bondrée of the French; Wespen-Busard of the Germans; Frosch-Geyer of Kramer; Stag-Hok of the 'Fauna Suecica;' Muse-Haeg and Muse Baage of Brunnich; and Bod y Mel of the Welsh.

Old Male.—Space between the eye and the beak covered with small serried feathers. Top of the head very pure ashy-blue; upper parts of the body brown, more or less ashy; secondaries barred alternately with blackish-blue and gray-blue; tail with three bands of blackish-brown, at unequal distances; throat yellowish-white, with brown spots; neck and belly marked with triangular brown spots on a whitish ground; cere deep ash; interior of beak, iris, and feet, yellow. Length about two feet.



Head and foot of Honey-Buzzard (*Pernis apivorus*).

Female and Young.—Ashy-blue on the forehead only; front of the neck marked with great spots of bright brown; breast and belly yellowish-red with deeper spots; under surface of the body often whitish, with reddish-brown spots.

Young of the Year.—Cere yellow; iris bright brown; head spotted with white and brown; under part of the body reddish-white, with great brown spots; feathers of the upper parts bordered with reddish. (Temminck.)

The Honey-Buzzard feeds on field-mice, moles, mice, hamsters, birds, reptiles, wasps, and other insects. (Temminck.) "Examinations," says Mr. Yarrell in his 'British Birds,' "have usually proved the food to have been the larvæ of bees and wasps, to obtain which the receptacles containing them are scratched out and broken up in the manner described by Sir William Jardine. In one instance, in the case of a honey-buzzard kept in confinement, I was told that it killed and ate rats, as well as birds of considerable size, with great ease and good appetite." The same author records that the stomach of a specimen killed in the north of Ireland and examined by Mr. Thompson of Belfast, contained a few of the larvæ and some fragments of perfect coleopterous insects; several whitish-coloured hairy cater pillars; the pupæ of a species of butterfly, and also of the six-spot hornet-moth. Willughby says, "In the stomach and guts of that we dissected we found a huge number of green caterpillars of that sort called *Geometræ*, many also of the common green caterpillars and others." White's specimen had in its stomach limbs of frogs, and many gray snails without shells. Willughby says that it runs very swiftly like a hen. Vieillot states that it seldom flies, except from one tree to another, or from bush to bush, and then always low, and that it runs on the ground with great rapidity like the common fowls. Nest on a lofty tree in a wood or forest. White mentions one on a tall slender beech near the middle of Selborne Hanger. Willughby says, "It builds its nest of small twigs, laying upon them wool, and upon the wool its eggs. We saw one that made use of an old kite's nest to breed in, and that fed its young with the nymphæ of wasps; for in the nest we found the combs of wasps' nests, and in the stomachs of the young the limbs and fragments of wasp-maggots. There were in the nest only two young ones, covered with white down spotted with black. Their feet were of a pale yellow, their bills between the nostrils and the head white; their craws large, in which were lizards, frogs, &c. In the crop of one of them we found two lizards entire, with their heads lying towards the bird's mouth, as if they sought to creep out." The same author says that the eggs are cinereous, marked with darker spots. The egg mentioned by White was smaller and not so round as those of the common Buzzard, dotted at each end with small red spots, and surrounded in the middle with a broad blood-red zone. Pennant mentions two blotched over with two shades of red, somewhat darker than those of the Kestrel. "The eggs of the Honey-Buzzard," writes Mr. Yarrell, "are rare; I have only seen three or four specimens, one of which answered to the description given by White, the colouring-matter being confined to a broad band round the middle. One specimen in my collection resembles those mentioned by Pennant, being mottled nearly all over with two shades of orange-brown: long diameter 2 inches 1 line; transverse diameter 1 inch 9 lines."

This bird is found in oriental countries; it is very rare and accidental in Holland; more abundant in France in the Vosges and in the south, a bird of passage (Temminck). Denmark, Norway, Sweden, Russia, Germany, France, Italy, and the south of Europe generally (Yarrell and authors by him quoted). Skins received from India (Gould). In Britain the bird has been obtained in Suffolk, Norfolk, and along the eastern coast as far north as Northumberland, and in several western counties, including Dorsetshire, Devonshire, and Worcestershire. Rare in Cumberland, according to Dr. Heysham, who had only met with one specimen, and was told that it bred in the woods at Lowther. Mr. Thompson mentions one killed in the north of Ireland, and Mr. Macgillivray two as having occurred in Scotland. Buffon and others, Belon among the rest, say that it gets very fat in winter and is then good eating.

Buteo (of Authors).—Beak moderate, rather weak; nostrils somewhat rounded; tarsi short; acrotarsia scutellated; fourth quill longest.

Mr. Vigors remarks that the true Buzzards are known by their comparatively feeble bill, their short tarsi, and scutellated acrotarsia. Their nares are round and their fourth quill-feather the longest. Their tarsi are either plumed to the toes or half way covered with feathers. Of those whose tarsi are completely feathered, *F. lagopus* of Linnæus is the type, according to Mr. Vigors, and *F. desertorum* of Daudin appears to appertain to it; of those birds whose tarsi are but half plumed he gives *Buteo vulgaris*, the Common Buzzard, as an example, and remarks that the genus is very numerous in species, and that the form is very generally to be observed over the globe.

B. vulgaris, *Falco Buteo* of Linnæus; *Buteo* of Gesner; *Falco variegatus* of Gmelin; *F. glaucopis* of Merrem; La Buse of the French; Falco Bottaone and Pojana of the Italians; Mause-Falk and Wald-Geyer of the Germans; Quidfogel of the 'Fauna Suecica;' Oerne Falk of Brunnich; and Bod Teircaill of the Welsh. "The whole length of the Common Buzzard is from 20 to 22 inches, depending on the sex—the females, as in the *Falconidæ* generally, being the largest. From the habit of seeking food late in the evening, observed in this species, and also in the Rough-Legged Buzzard, and in the softer and more downy texture of the feathers, as compared with the plumage of the true Falcons, the Buzzards are considered as indicating an approach to the Owls. The beak is bluish-black, darkest in colour towards the point; the cere yellow; the irides generally yellow; but, as the Common Buzzard and indeed all the Buzzards are subject to considerable variation in the colour of their plumage, the irides are observed to vary also, presenting some reference to the prevailing

Common Buzzard (*Buteo vulgaris*).

tone of the colour of the feathers. The upper part of the head, occiput, and cheeks, pale-brown, streaked longitudinally with darker brown; the whole of the back, wing-coverts, upper tail-coverts, and upper surface of the tail-feathers, dark clove-brown, the latter barred with lighter brown, the feathers of the former-named parts having lighter-coloured edges; the wing-primaries brownish-black; the chin and throat almost white; front of the neck, breast, under wing-coverts, belly, and thighs, grayish-white, barred transversely with dark wood-brown; legs and toes yellow; the claws black." (Yarrell.)

The following are varieties:—*Falco albidus*, Gmel.; *F. versicolor*, Gmel.; Weisslicher Busard, Borkh. 'Deut. Orn.' (Temminck.)

The flight of the Buzzard is slow, and it generally remains perched on some tree in the wooded districts patiently waiting for its prey, namely, small quadrupeds, birds, and reptiles, and even earth-worms and insects. It may be seen sometimes soaring in circles, but not often, and does not pursue its game, but pounces at it when on the ground. Its nature is slothful and cowardly, but its philoprogenitiveness appears to be great. The Cock Buzzard will hatch and bring up the young if the hen is killed (Ray), and among other instances Mr. Yarrell records one of a female buzzard kept in the garden of the Chequers Inn, at Uxbridge, which showing an inclination a few years back to make a nest and sit, was supplied with materials and two hen's eggs, which she hatched and afterwards reared the chicks. Since that time she has hatched and brought up a brood of chickens every year. Once they put down chicks just hatched to her to save her the labour of sitting, but she killed them all. Her family, says Mr. Yarrell, in June 1831, consisted of nine; the original number were ten, but one had been lost. When flesh was given her she was very assiduous in tearing and offering it as food for her nurslings, and appeared uneasy if, after taking small portions from her, they turned away to pick up grain. ('British Birds,' where there is an elegant vignette of the bird and her foster family.) Indeed the young remain with the old birds some little time after they quit the nest, contrary to the usage of other birds of prey, which generally drive away their young as soon as they can fly. In Scotland, where the bird is said to be bolder, on rocks or on the edges of steep scars or beds of torrents. (Macgillivray.) In England the Buzzard builds (or sometimes takes to a nest) in the fork of a tree in a wood. The eggs are generally three, sometimes four, short oval, 2 inches 3 lines in length by 1 inch 10 lines in breadth, of a solid white, slightly spotted with pale-brown. (Yarrell.)

The Buzzard is common in all the wooded countries of Europe. Very abundant in Holland. (Temminck.) It is well-known, says Mr. Yarrell, over the wooded parts of the continent of Europe, south of Russia, and inhabits Spain and Italy, passing over the Mediterranean to North Africa: but Trebizond, Smyrna, and Madeira, appear to be its limits to the southward. Prince Bonaparte notes it as very common near Rome. In several parts of Ireland it is common (Thompson); not very plentiful in Scotland, nor does it appear in the lists of the birds of Orkney and Shetland, by the Rev. Mr. Low and Mr. Dunn, though it occurs in Denmark, Norway, Sweden, and Russia. Mr. Gould, in noticing the Trebizond birds presented to the Zool. Soc. by Mr. Keith Abbott, among which it was, observes that it was not previously observed in Asia, although there is a nearly allied species in the Himalaya Mountains, and that it had not then been noticed in Africa. ('Zool. Proc.,' 1834.) In England, though lately more rare, it is still far from uncommon.

Sir John Richardson ('Fauna Boreali-Americana') states that the Common Buzzard arrives in the Fur Countries in the middle of April, very soon afterwards begins to build its nest, and, having reared its young, departs about the end of September. It haunts the low alluvial points of land which stretch out under the high banks of a river, and may be observed for a long time motionless on the bough of a tree watching for some small quadruped, bird, or reptile to pass within its reach. As soon as it espies its prey, it glides silently into the air, and sweeping easily but rapidly down seizes it in its claws. When disturbed, it makes a short circuit, and soon settles on another perch. One of Sir John's specimens had two middle-sized toads in its crop. It builds its nest, he says, on a tree, of short sticks, lining it with deer's hair. The eggs are from three to five in number, and he remarks that it was seen by the expedition as far north as the 57th parallel, and that it most probably has a still higher range. He gives a description of two; one a male, shot on the 17th June at the nest, which contained three eggs, on the plains of the Saskatchewan; and another, a female, killed at the nest also, near Carlton, May 22.

Buteo Bacha is recorded by Major James Franklin among the collection formed by him on the banks of the Ganges and in the mountain chain of Upper Hindustan. In the South African Museum the *B. Jackal* and *B. Tachardus* are preserved. The former obtains its name from uttering a cry somewhat similar to that of the small quadrupeds called Jackals at the Cape. It abounds throughout South Africa. In the same collection will be found *Butaëtes Lessonii.*

5th Sub-Family, *Milvina* (Kites).

Beak moderate, rather hooked from the base. Tail forked. The length of the wings and the forked tail, instruments of action to which the birds are indebted for their peculiar power and gracefulness of flight, are the characters which more particularly separate the Kites from the rest of the *Raptores*.

Elanus (Savigny).—Beak moderate, weak, compressed; tarsi short, semiplumed; acrotarsia reticulated; claws, with the exception of the middle one, rounded internally; second quill longest; first and second quills strongly notched internally.

E. melanopterus, the Black-Winged Swallow-Hawk. This is the *Falco melanopterus* of Daudin; *E. cæsius* of Savigny; and Le Blac of Le Vaillant. Size of a Sparrow-Hawk. Plumage soft and silky; tail a little forked. Above ash-coloured, quills blackish, beak and shoulders black. Below white. Tail principally white. Feet yellow.

Black-Winged Swallow-Hawk (*Elanus melanopterus*).

The bird is said to live principally upon insects, which it captures on the wing. It is common in Africa from Egypt to the Cape. There is a specimen in the South African Museum. Savigny speaks of it as being in great abundance in Syria, Egypt, and Barbary. Cranch (Tuckey's Expedition) saw great numbers at the mouth of the Congo, and some were sent home from thence. Lesson says that it occurs in Australia. It is noticed among the birds collected by Major James Franklin on the banks of the Ganges, and in the mountain-chain of Upper Hindustan.

Nauclerus (Vigors).—Beak rather short, weak, compressed; nostrils sub-oval, placed in the cere, which is furnished with bristles in an oblique direction; wings long, second or third quill longest; tail long, very much forked; feet short, weak; tarsi reticulated; acrotarsia feathered below the knee to the middle; claws not cylindrical; body slender, elegant.

Mr. Vigors observes that *Nauclerus* is distinguished from the true *Milvus* by the greater development of the character of the forked tail; by the relative proportion of the wing-feathers, the fourth being the longest in *Milvus;* and by the reticulation of the acrotarsia, those of *Milvus* being covered with even scales or scutellated. He divides the genus into two sections.

1st. With the second quill longest.

N. Riocourii may be given as an example.

2nd. With the third quill longest.

N. furcatus (*Falco furcatus*, Linn.), the Swallow-Tailed Hawk.

Whole length 20 inches; beak bluish-black, cere lighter blue, irides dark; head, neck, breast, belly, under surface of the wings, sides of the body, thighs, and under tail-coverts, pure white; back, wing-primaries, secondaries, upper tail-coverts, and tail-feathers, black, with a purplish metallic lustre; tertials black on the outer webs, but patched with pure white on the inner; tail very deeply forked; legs and toes greenish-blue; claws faded orange. (Yarrell.)

We select Mr. Audubon's account of the habits and locality of this graceful bird:—"A solitary individual of this species has once or twice been seen in Pennsylvania. Farther to the eastward the Swallow-Tailed Hawk has never, I believe, been observed. Travelling southward along the Atlantic coast, we find it in Virginia, although in very small numbers. Beyond that state it becomes more abundant. Near the falls of the Ohio a pair had a nest, and reared four young ones in 1820. In the lower parts of Kentucky it begins to become more numerous; but in the states farther to the south, and particularly in parts near the sea, it is abundant. In the large prairies of the Attacapas and Oppellousas it is extremely common. In the states of Louisiana and Mississippi where these birds are abundant, they arrive in large companies in the beginning of April, and are heard uttering a sharp plaintive note. At this period I generally remarked that they came from the westward, and have counted upwards of a hundred in the space of an hour, passing over me in a direct easterly course. At that season and in the beginning of September, when they all retire from the United States, they are easily approached when they have alighted, being then apparently fatigued, and busily engaged in preparing themselves for continuing their journey, by dressing and oiling their feathers. At all other times however it is extremely difficult to get near them, as they are generally on wing through the day, and at night rest on the higher pines and cypresses, bordering the river bluffs, the lakes, or the swamps of that district of country. They always feed on the wing. In calm and warm weather they soar to an immense height, pursuing the large insects called Musquito-Hawks, and performing the most singular evolutions that can be conceived, using their tail with an elegance of motion peculiar to themselves. Their principal food however is large grass-hoppers, grass-caterpillars, small snakes, lizards, and frogs. They sweep close over the fields, sometimes seeming to alight for a moment to secure a snake, and holding it fast by the neck, carry it off and devour it in the air. When searching for grasshoppers and caterpillars, it is not difficult to approach them under cover of a fence or tree. When one is then killed and falls to the ground, the whole flock come over the dead bird, as if intent upon carrying it off. An excellent opportunity is thus afforded of shooting as many as may be wanted, and I have killed several of these hawks in this manner, firing as fast as I could load my gun. The Swallow-Tailed Hawk pairs immediately after its arrival in the southern states; and as its courtships take place on the wing, its motions are then more beautiful than ever. The nest is usually placed on the top branches of the tallest oak or pine tree, situated on the margin of a stream or pond. It resembles that of a carrion crow externally, being formed of dry sticks, intermixed with Spanish moss, and is lined with coarse grasses and a few feathers. The eggs are from four to six, of a greenish-white colour, with a few irregular blotches of dark brown at the larger end. The male and female sit alternately, the one feeding the other. The young are at first covered with buff-coloured down. Their next covering exhibits the pure white and black of the old birds, but without any of the glossy purplish tints of the latter. The tail, which at first is but slightly forked, becomes more so in a few weeks, and at the approach of autumn exhibits little difference from that of the adult birds. The plumage is completed the first spring. Only one brood is raised in the season. The species leaves the United States in the beginning of September, moving off in flocks, which are formed immediately after the breeding season is over."

The Swallow-Tailed Hawk (*Nauclerus furcatus*).

This species, according to Mr. Nuttall, will, like the Honey-Buzzard, prey upon locusts and wasps and their larvæ, and make a regular attack on their nests. M. Vieillot states that it visits Peru and Buenos Ayres. Mr. Yarrell gives it a place among the British birds on the authority of two specimens, one killed at Balachoalist in Argyleshire in 1772, and another taken alive in Shaw-Gill, near Hawes in Wensleydale, Yorkshire, in 1805. Apparently to avoid the violence of a tremendous thunder-storm and the clamorous persecution of a flock of rooks which attacked it at the same instant, on the 6th of September, it took shelter in a thicket, where it was seized before it could extricate itself. The person who caught it kept it a month; but a door being accidentally left open, it made its escape. It first alighted on a tree at no great distance, from which it soon ascended in a spiral flight to a great elevation, and then went steadily off in a southerly direction as far as the eye could trace it. ('Linn. Trans.,' vol. xiv.)

Milvus (of authors).—Beak moderate, weak, subangular above; nostrils oblique, elliptical; tarsi short; acrotarsia scutellated; wings very long, fourth quill longest; tail forked.

M. ictinus, Falco Milvus of Linnæus; *M. vulgaris* of Fleming and Gould.

This is the Milan Royal of the French from Belon to Buffon; Pojana, Milvio, Nicchio, and Nibbio, of the Italians; Rother-Milan of the Germans; Glenta of Brunnich; Glada of the 'Fauna Suecica;' Kite, Fork-Tailed Kite, Glead, or Glede (Pennant says from the Saxon 'Glida'), of the English; and Barcud of the Welsh. In some of the counties of England it is called the Puttock, a name also sometimes bestowed provincially upon the Common Buzzard. In Essex it is called the Crotched-Tailed Puddock.

Length about 26 inches; beak horn-colour; cere and irides yellow; feathers of the head and neck grayish-white, streaked along the shaft with ash-brown; feathers of the back and wing-coverts dark brown in the centre, broadly edged with rufous; inner web of some of the tertials edged with white; primaries nearly black; upper tail-coverts rufous; tail-feathers reddish-brown, the outer webs of one uniform colour, the inner webs barred with dark brown; the outer tail-feather on each side the darkest in colour; tail deeply forked; chin and throat grayish-white, streaked with dusky; breast, belly, and thighs, rufous-brown, each feather with a central longitudinal streak of dark brown; under surface of the wings near the body rufous, with dark brown feathers edged with red-brown towards the outer part of the wing; under tail-coverts plain rufous-white; under surface of the tail-feathers grayish-white, with the dark bars of the upper surface showing through; tarsi and toes yellow; claws black. (Yarrell.) The females are larger than the males.

Kite (*Milvus ictinus*).

The Kite sails gracefully in the air, now describing circles, and anon with outspread tail remaining stationary. It pounces on its prey, consisting of moles, mice, leverets, rabbits, unfledged birds, and the young of the Gallinaceous tribe especially. It was, when more plentiful than it is at present, a great scourge to the poultry-yard. It will eat frogs and snakes; and in the 'Magazine of Natural History' an observer bears witness to its taking fish from a broad river near which he resided. The nest, made of sticks and lined with soft materials, is usually built on the fork of a tree in a thick wood. The eggs are two, sometimes three, short oval, 2 inches 2 lines in length by 1 inch 9 lines in breadth. They are of a dirty white, with a few reddish-brown spots at the large end. The female lays early in the season, and she often makes a vigorous defence when her nest is attacked.

The Kite is found in France, Italy, Switzerland, and Germany; less abundant in Russia; more rare in Holland; migratory in autumn. (Temminck.) Very common near Rome, especially near the herds of cattle. (Bonaparte.) It also occurs in Siberia, and the country about Lake Baikal; and has been observed in Egypt, and several parts of Africa north of the equator. In Ireland it does not seem to be known. In Britain, especially in the southern counties, it is become rare, though at one time it was evidently abundant. Clusius states that when he was in London an amazing number of Kites flocked there for the offals which were thrown into the streets. They were so tame that they took their prey in the midst of crowds, and it was forbidden to kill them. In falconry it was used both as pursuer and pursued, and is very docile. Louis XVI. flew at the Kite with powerful falcons; and Sir John Sebright tells us that "Fork-Tailed Kites were much flown some years ago by the Earl of Orford in the neighbourhood of Alconbury Hill. A great owl, to the leg of which the falconers usually tie a fox's brush, not only to impede its flight, but to make it, as they fancy, more attractive, is thrown up to draw down the Kite."

Colonel Sykes notes *Milvus govinda* as occurring both in South Africa and India. In the catalogue of the South African Museum is the following account of *Milvus parasiticus*, the Cape Kite, there preserved:—"This bird is the Kuicken Deif, or Chicken-Stealer of the Dutch colonists, and only appears in South Africa during the summer season. It resorts to inhabited places, and as its name implies, is very destructive to young chickens. Everywhere it is bold; but it is especially so in districts into which fire-arms have not as yet been introduced, where it will pounce down and seize pieces of flesh from the hands of children, or even grown persons. It feeds in part upon carrion, and many individuals are often seen congregated together upon dead carcases."

General Geographical Distribution of the *Falconidæ*.—Wherever birds and small quadrupeds are to be found, there is the bird of prey, whose office it is to keep their number within their proper bounds. Thus as Mr. Vigors writes ('Zool. Journ.,' vol. i. p. 329—'On the Groups of the Falconidæ'), there seem to be no limits affixed to the geographical distribution of the true Falcons. This indeed appears generally the case in the larger groups of this family. The Naked-Cheeked *Falconidæ* alone seem to be confined to the southern parts of the New World, and to Australia, if we are to refer *F. Novæ Zælandiæ* of Dr. Latham to the genus *Polyborus*, according to M. Temminck's opinion. But the remaining groups appear to be dispersed in every division of the globe.

The *Falconidæ* described and figured in Mr. Swainson's 'Birds of Western Africa,' before alluded to, belong to the two most typical or perfect divisions of the family, namely, the Noble Falcons (*Falconidæ*), and the Hawks (*Accipitrinæ*).

Some of the best illustrations of the *Falconidæ* will be found in Audubon, Bewick, Gould, Le Vaillant, Temminck, Savigny, Swainson, Vieillot, and Yarrell. Some of Frisch's figures are good. There are many fine and expensive works (the 'Planches Enluminées,' for example), which contain figures of these noble birds, but they are sadly deficient in character, and look like what they were mostly taken from—ill-stuffed specimens. There is more to be learnt from the wood-cuts of the heads by Swainson in 'Fauna Boreali-Americana' and the 'Classification of Birds,' than from the most gorgeously coloured ill-shaped engraving. The magnificent works of Audubon and Gould are full of the character of the respective species: Swainson particularly excels in this, whether he portrays the bird in his beautiful drawings, or gives an epitome of its leading points in the small compass of a wood-cut. The figures in Yarrell's 'British Birds' are excellent, and charming examples of the perfection to which wood engraving can be carried.

The following is an arrangement of the species of *Falconidæ* specimens of which are to be seen in the British Museum:—

Family FALCONIDÆ.
Sub-Family I. *Aquilinæ*.
I. *Aquila*.
a. *Aquila*.
1. *A. chrysaëtos*, the Golden Eagle.
2. *A. Mogilnik*, the Imperial Eagle.
3. *A. nævia*, the Rough-Footed Eagle.
4. *A. nævioides*, the Tawny Eagle.
5. *A. Bonellii*, Bonelli's Eagle.
b. *Uroaëtus*.
6. *A. audax*, the Bold Eagle.
c. *Pteroaëtus*.
7. *A. vulturina*, the Vulturine Eagle.
d. *Hieraëtus*.
8. *A. pennata*, the Booted Eagle.
e. *Heteropus*.
9. *A. Malayensis*, Reinwardt's Eagle.
II. *Spizaëtus*.
a. *Spizaëtus*.
1. *S. ornatus*, the Crested Goshawk.
2. *S. bellicosus*, the Martial Eagle.
3. *S. coronatus*, the Crowned Eagle.
b. *Spizastur*.
4. *S. melanoleucus*, the Black and White Eagle.
c. *Lophaëtus*.
5. *S. occipitalis*, the Occipital Eagle.
d. *Pterura*.
6. *S. Tyrannus*, the Tyrant Eagle.
e. *Lymnaëtus*.
7. *S. cirrhatus*, the Crested Indian Eagle.
8. *S. Borneonensis*, the Crested Borneau Eagle.
III. *Herpetotheres*.
1. *H. cachinnans*, the Laughing Falcon.
IV. *Circaëtus*.
a. *Circaëtus*.
1. *C. Gallicus*, the Jean-le-Blanc Eagle.
2. *C. thoracicus*, the Black-Breasted Eagle.
3. *C. fasciolatus*, the Banded Falcon.
b. *Spilornis*.
4. *C. Bacha*, the Bacha Eagle.
5. *C. Cheela*, the Cheela Eagle.
6. *C. Holospilus*, the Spotted Bacha.
c. *Harpyhaliaëtus*.
7. *C. coronatus*, the Crowned Eagle.
V. *Thrasaëtus*.
1. *T. Harpyia*, the Crested Eagle.
VI. *Morphnus*.
1. *M. Guianensis*, the Guyana Goshawk.
2. *M. Urubitinga*, the Brazilian Eagle.
3. *M. meridionalis*, the Rufous-Headed Falcon.
VII. *Pandion*.
a. *Pandion*.
1. *P. Haliaëtus*, the Osprey.
2. *P. leucocephalus*, the White-Headed Osprey.
b. *Polioaëtus*.
3. *P. Ichthyaëtus*, the Marine Eagle.
4. *P. humilis*, the Small Marine Eagle.
VIII. *Cuncuma*.
a. *Cuncuma*.
1. *C. Macei*, Mace's Eagle.
2. *C. leucogaster*, the White-Bellied Eagle.
3. *C. vocifer*, the Piscivorous Eagle.
b. *Geranoaëtus*.
4. *C. melanoleucus*, the Black and White Eagle.
IX. *Haliaëtus*.
1. *H. albicilla*, the Cinereous Eagle.
2. *H. leucocephalus*, the Bald Eagle.
X. *Helotarsus*.
1. *H. ecaudatus*, the Short-Tailed Eagle.
XI. *Haliastur*.
1. *H. Indus*, the Pondicherry Eagle.
2. *H. leucosternus*, the White-Headed Rufous Eagle.
3. *H. Sphenurus*, the Whistling Hawk.
Sub-Family II. *Polyborinæ*.
I. *Ibycter*.
1. *I. Americanus*, the Red-Throated Falcon.
2. *I. ater*, the Black Caracara.
II. *Milvago*.
a. *Milvago*.
1. *M. chimachima*, the Chimachima Falcon.
2. *M. chimango*, the Chimango Caracara.
b. *Phalcobaënus*.
3. *M. megalopterus*, the Long-Winged Caracara.
c. *Aëtotriorchis*.
4. *M. australis*, the Southern Caracara.
III. *Polyborus*.
1. *P. Brasiliensis*, the Brazilian Kite.
Sub-Family III. *Buteoninæ*.
I. *Buteo*.
a. *Buteo*.
1. *B. vulgaris*, the Common Buzzard.
2. *B. Tachardus*, the African Buzzard.
3. *B. rufinus*, the Long-Legged Buzzard.
4. *B. Jackal*, the Jackal Falcon.
5. *B. augur*, the North African Buzzard.
6. *B. plumipes*, the Half-Booted Buzzard.
b. *Pœcilopterius*.
7. *B. borealis*, the American Buzzard.
8. *B. lineatus*, the Barred-Breasted Buzzard.
9. *B. Pennsylvanicus*, the Broad-Winged Falcon.
c. *Tachytriorchus*.
10. *B. erythronotus*, the Red-Backed Buzzard.
11. *B. pterocles*, the Banded-Sided Hawk.
12. *B. albonotatus*, the White-Spotted Buzzard.
13. *B. leucops*, the White-Faced Buzzard.
d. *Buteogallus*.
14. *B. æquinoctialis*, the Equinoctial Eagle.
15. *B. nigricollis*, the Pamena Eagle.
e. *Leucopterius*.
16. *B. melanops*, the Streaked Falcon.
17. *B. albicollis*, the White-Necked Falcon.
18. *B. scotopterus*, the Brazilian Buzzard.
19. *B. polionotus*, the Gray-Backed Buzzard.
II. *Archibuteo*.
1. *A. Lagopus*, the Rough-Legged Falcon.
2. *A. Sancti Johannis*, the St. John's Eagle.

3. *A. ferrugineus*, the Cacique Buzzard.
4. *A. strophiatus*, the White-Breasted Buzzard.

Sub-Family IV. *Milvinæ.*

I. *Baza.*

a. *Aviceda.*

1. *B. cuculoïdes*, the African Baza.

b. *Baza.*

2. *B. lophotes*, the Cohy Falcon.
3. *B. subcristata*, the Small-Crested Baza.
4. *B. magnirostris*, the Large-Billed Baza.

II. *Pernis.*

1. *P. apivorus*, the Honey-Buzzard.
2. *P. cristata*, the Crested Honey-Buzzard.

III. *Milvus.*

a. *Milvus.*

1. *M. regalis*, the Kite.

b. *Hydroictinia.*

2. *M. Govinda*, the Govinda Kite.
3. *M. niger*, the Black Kite.
4. *M. affinis*, the Australian Kite.
5. *M. Ægyptius*, the Arabian Kite.

IV. *Elanoïdes.*

a. *Elanoïdes.*

1. *E. furcatus*, the Swallow-Tailed Falcon.

b. *Chelidopteryx.*

2. *E. Riocouri*, the Riocouris Falcon.

V. *Elanus.*

1. *E. melanopterus*, the Black-Winged Falcon.
2. *E. axillaris*, the Axillary Falcon.
3. *E. scriptus*, the Letter-Winged Falcon.
4. *E. leucurus*, the White-Tailed Hawk.

VI. *Gampsonyx.*

1. *G. Swainsoni*, Falcon-like Hawk.

VII. *Rostrhamus.*

1. *R. sociabilis*, the Hook-Billed Falcon.

VIII. *Cymindis.*

a. *Cymindis.*

1. *C. Cayanensis*, the Cayenne Falcon.

b. *Regerhinus.*

2. *C. uncinatus*, the Crook-Billed Falcon.

IX. *Ictinia.*

a. *Ictinia.*

1. *I. Mississippensis*, the Mississippi Kite.

b. *Pœcilopteryx.*

2. *I. plumbea*, the Spotted-Tailed Hobby.

Sub-Family V. *Falconinæ.*

I. *Falco.*

a. *Hierofalco.*

1. *F. Gyrfalco*, the Jerfalcon.
2. *F. subniger*, the Black Falcon.
3. *F. peregrinator*, the Sultan Falcon.
4. *F. peregrinus*, the Peregrine Falcon.
5. (?) *F. melanogenys*, the Black-Cheeked Falcon.
6. (?) *F. anatum*, the Duck Falcon.
7. *F. peregrinoïdes*, the Salakoo Falcon.

b. *Gennaia.*

8. *F. cervialis*, the Double-Bearded Falcon.
9. *F. lanarius*, the Lanner Falcon.
10. *F. Jugger*, the Jugger Falcon.

II. *Hypotriorchis.*

a. *Hypotriorchis.*

1. *H. subbuteo*, the Hobby Falcon.
2. *H. severus*, the Severe Falcon.
3. *H. rufigularis*, the Red-Necked Falcon.
4. *H. frontatus*, the Paramatta Falcon.

b. *Æsalon.*

5. *H. concolor*, the Uniform Falcon.
6. *H. Æsalon*, the Merlin.
7. *H. columbarius*, the Pigeon-Hawk.
8. *H. Chicquera*, the Chicquera Falcon.
9. *H. femoralis*, the Red-Thighed Hawk.

III. *Ieracidea.*

1. *I. berigora*, the Cream-Bellied Falcon.
2. *I. Novæ Zealandiæ*, the New Zealand Falcon.

IV. *Tinnunculus.*

a. *Tinnunculus.*

1. *T. alaudarius*, the Kestril Falcon.
2. *T. rupicolus*, the Rufous-Backed Kestril.
3. *T. rupicoloïdes*, the Rock-Falcon.
4. *T. punctatus*, the Spotted Falcon.

b. *Tichornis.*

5. *T. cenchris*, the Lesser Kestril.
6. *T. cenchroïdes*, the Nankin Hawk.

c. *Erythropus.*

7. *T. vespertinus*, the Ingrian Falcon.

d. *Pœcilornis.*

8. *T. sparverius*, the Little Falcon.
9. (?) *T. cinnamomeus*, the Cinnamon Falcon.

V. *Harpagus.*

1. *H. diodon*, the Two-Toothed Falcon.
2. *H. bidentatus*, the Notched Falcon.

VI. *Ierax.*

1. *I. cærulescens*, the Bengal Falcon.
2. *I. Eutolmus*, the White-Naped Falcon.
3. *I. sericeus*, the Silky-Falcon.

Sub-Family VI. *Accipitrinæ.*

I. *Astur.*

a. *Astur.*

1. *A. palumbarius*, the Goshawk.
2. *A. melanoleucus*, the Pied Goshawk.
3. *A. radiatus*, the Radiated Falcon.

b. *Spizageranus.*

4. *A. unicinctus*, the One-Banded Hawk.

c. *Leucospiza.*

5. *A. Novæ Hollandiæ*, the New Holland White Eagle.

d. *Lophospiza.*

6. *A. trivirgatus*, the Three-Streaked Hawk.

e. *Asturina.*

7. *A. nitidus*, the Plumbeous Falcon.
8. *A. poliogaster*, the Gray-Bellied Falcon.
9. *A. leucorrhous*, the Spotted Falcon.
10. *A. magnirostris*, the Great-Billed Falcon.

II. *Poliornis.*

1. *P. Teesa*, the Teesa Hawk.
2. *P. Liventer*, the Pale Hawk.
3. *P. Indicus*, the Gray-Cheeked Hawk.
4. *P. pyrrhogenys*, the Dark-Cheeked Hawk.

III. *Geranospiza.*

1. *G. gracilis*, the Slender Hawk.

IV. *Micrastur.*

1. *M. brachypterus*, the Pied Sparrow-Hawk.
2. *M. xanthothorax*, the Yellow-Necked Hawk.
3. *M. concentricus*, the Concentrical Sparrow-Hawk.

V. *Accipiter.*

a. *Accipiter.*

1. *A. nisus*, the Sparrow-Hawk.
2. *A. erythronemia*, the Red-Thighed Sparrow-Hawk.
3. *A. tachiro*, the Speckled Sparrow-Hawk.
4. *A. rufiventris*, the Red-Bellied Hawk.
5. *A. fuscus*, the American Brown Hawk.
6. *A. pileatus*, the Hooded Falcon.
7. *A. Madagascariensis*, the Madagascar Hawk.

b. *Hieraspiza.*

8. *A. tinus*, the Tiny Falcon.
9. *A. minullus*, the Dwarf-Falcon.
10. *A. virgatus*, the Streaked Hawk.

c. *Urospiza.*

11. *A. cirrhocephalus*, the New Holland Sparrow-Hawk.
12. *A. approximans*, the Australian Goshawk.

VI. *Micronisus.*

a. *Tachyspiza.*

1. *M. Soloensis*, the Soolo Falcon.

b. *Scelospiza.*

2. *M. Francesii*, Franco's Sparrow-Hawk.

c. *Micronisus.*

3. *M. badius*, Brown's Hawk.
4. *M. sphenurus*, the Short-Toed Sparrow-Hawk.
5. *M. Gabar*, the Red-Legged Falcon.
6. *M. monogrammicus*, the Single-Streaked Hawk.

VII. *Melierax.*

1. *M. musicus*, the Chanting Falcon.

Sub-Family VII. *Circinæ.*

I. *Serpentarius.*

1. *S. secretarius*, the Secretary.

II. *Polyboroïdes.*

1. *P. radiatus*, the Madagascar Falcon.

III. *Circus.*

a. *Strigiceps.*

1. *C. cyaneus*, the Hen-Harrier.
2. *C. melanoleucus*, the Black and White Indian Falcon.
3. *C. acoli*, the Long-Legged Falcon.
4. *C. cinereus*, Quoy's Buzzard.
5. *C. ater*, the Black Hen-Harrier.

b. *Glaucopteryx.*

6. *C. cinerescens*, the Ash-Coloured Falcon.
7. *C. Swainsoni*, the Pale-Chested Harrier.

c. *Spilocercus.*

8. *C. Jardinii*, Jardine's Hen-Harrier.

d. *Spizacircus.*

9. *C. macropterus*, the Salvador Falcon.

e. *Pygargus.*

10. *C. æruginosus*, the Moor-Buzzard.
11. *C. assimilis*, the Allied Moor-Buzzard.
12. *C. ranivorus*, the Ranivorous Falcon.

We subjoin a list of the British species of *Falconidæ* from Mr. Yarrell's 'British Birds':—

Aquila nævia, the Spotted Eagle.
A. chrysaëtos, the Golden Eagle.
Haliæetus albicilla, the White-Tailed Eagle and Cinereous Eagle.
Pandion Haliæetus, the Osprey, or Fishing-Hawk.
Falco Gyrfalco, the Gyr-Falcon.
F. peregrinus, the Peregrine Falcon.
F. subbuteo, the Hobby.
F. rufipes, the Red-Footed Falcon.
F. Æsalon, the Merlin.
F. tinnunculus, the Kestrel or Windhover.
Astur palumbarius, the Goshawk.
Accipiter nisus, the Sparrow-Hawk.
Milvus vulgaris, the Kite, the Fork-Tailed Kite and Glead.
Nauclerus furcatus, the Swallow-Tailed Kite.
Buteo vulgaris, the Common Buzzard.
B. lagopus, the Rough-Legged Buzzard.
Pernis apivorus, the Honey-Buzzard.
Circus æruginosus, the Marsh-Harrier.
C. cyaneus, the Hen-Harrier.
C. Montagui, Montagu's Harrier.

A very fine collection of the *Falconidæ*, unequalled in the number of species, is at present to be seen in the Gardens of the Zoological Society, Regent's Park, London.

FALCONRY, or HAWKING, the art of training and flying hawks to take other birds. Julius Firmicus, who lived in the middle of the 4th century, is the first Latin writer who speaks of falconers, and the art of teaching one species of birds to fly at and catch another. The art however had been in all probability practised in the east from remote ages, whence it certainly came to Europe.

From the Heptarchy to the time of Charles II. falconry was the principal amusement of our ancestors in England. A person of rank scarcely stirred out without a hawk upon his hand, which, in old illuminations and upon ancient seals, is the criterion of nobility. Harold, afterwards king of England, is thus represented in the Bayeux Tapestry, when visiting the court of William, duke of Normandy.

Florence of Worcester (4to edit. 1592, p. 310) states that King Alfred had his falconers among the persons whom he encouraged for their skill in different professions; and a metrical treatise on the art of falconry, still extant, is ascribed to King Edward the Confessor.

In Domesday Book the practice of falconry is illustrated by numerous entries. In several places we find a sum, no less than ten pounds, made the optional payment instead of finding a hawk ('Domesday Book,' tom. i. fol. 134, b. 172, 230); and once, at Worcester (tom. i. 172) a Norway hawk is specified. Aeries, or places destined for the breeding or training of hawks, are entered in the Survey, in Buckinghamshire, Gloucestershire, Worcestershire, Herefordshire, Shropshire, and, more frequently than in other counties, in Cheshire; as well as among the lands between the Ribble and the Mersey. ('Domesday Book,' tom. i. fol. 144, 152, 163 b, 172, 180, 252 b, 256 b, 257, 264, 265, 265 b, 266 b, 267, 267 b, 268 b, 269, 270.)

Nor were hawks less prized at subsequent periods. According to Madox ('Hist. Excheq.' i. 273), in the 14th Hen. II., Walter Cnot, one of the king's tenants, rendered his rent at the exchequer in three hawks and three girfalcons. King John had also his hawks ('Pat.' 4, 'Joh.' m. 2); and upon the Patent Roll of the 34th Hen. III. a copy occurs of the letter which the king sent in that year to the king of Norway for hawks. Bray, in the 'History of Surrey' (vol. iii. p. 82), relates a curious anecdote of Henry III.'s anger with one Roger Belet, who, by reason of something he had done or omitted about a sparhawk, was disseised of all his lands and 40*s*. rent in Bagshot. In the 34th Edw. III. it was made felony to steal a hawk; to take its eggs, even in a person's own ground, was punishable with imprisonment for a year and a day, besides a fine at the king's pleasure. In Queen Elizabeth's reign the imprisonment was reduced to three months; but the offender was to find security for his good behaviour for seven years, or lie in prison till he did. (Pennant, 'Brit. Zool.' 8vo, Lond. 1812, vol. i. p. 212.)

Edward III., according to Froissart ('Chron.' i. c. 210), had with him in his army, when he invaded France, thirty falconers on horseback, who had charge of his hawks; and every day he either hunted or went to the river for the purpose of hawking, as his fancy inclined him. Queen Elizabeth is represented enjoying this sport in a woodcut in Turbervile's 'Falconry,' published in 1575; and it was the favourite amusement with King James I.

By an entry upon the 'Originalia Rolls' of the 35th Edw. III. ('Origin.' vol. ii. p. 267), it appears that a falcon gentil cost 20*s*.; a tersil gentil, 10*s*.; a tersil lestour, 6*s*. 8*d*.; and a lanner, 6*s*. 8*d*.: these were the prices which the sheriff was to give for hawks for the king's use. In an account-book of the 20th Hen. VIII. a goshawk and two falcons are prized at 3*l*., and five falcons and a tersil at 8*l*. Bert, in his 'Address to the Reader,' prefixed to his 'Treatise of Hawkes and Hawking,' published in 1619, says he "had for a goshawke and a tarsell a hundred marks."

Falconry was attempted to be revived by George, earl of Orford, who died in 1791; and in Yorkshire Colonel Thornton had a hawking establishment at a rather later period. Sir John Sebright and a few other gentlemen also practised it in Norfolk at the beginning of the present century. As a rural diversion however, principally in consequence of the inclosures, it has gone into disuse.

A list of the hawks which were most used by sportsmen in the time of Charles I. is given in Walton's 'Complete Angler;' and an explanation of the words of art in hawking will be found in Latham's 'Falconry,' 4to, Lond. 1633.

The earliest printed treatise on hawking in English is the 'Book of St. Albans,' fol. 1481, ascribed to Juliana Barnes or Berners, abbess of Sopwell. There are numerous other and curious treatises upon falconry both in French and English, some of them of very rare occurrence. 'Le Miroir de Phebus, avec l'Art de Fauconerie,' published at Paris in 8vo. without date, was the first work upon the subject printed in the French language.

For further information upon falconry and its practice the reader may refer to Spelman's 'Glossary,' v. 'Acceptor,' edit. fol., Lond. 1626, p. 7; Warton's 'Observ. on Spenser's Fairy Queen,' vol. ii. pp. 171-173; Strutt's 'Sports and Pastimes of the People of England,' 4to., Lond. 1810, pp. 21-33; and Haslewood's 'Literary Researches into the History of the Book of St. Albans,' 4to., Lond. 1810, pp. 21-48.

FALCOPERN. [FALCONIDÆ.]

FALCUNCULUS. [LANIADÆ.]

FALLOPIAN TUBES, so called from Fallopius the anatomist, who first accurately described them. They are tortuous and slender membraneous canals, about three inches in length, which proceed on each side from the two upper corners of the flattened triangular or pear-shaped body of the uterus. They communicate with its cavity by minute openings capable of admitting a large bristle. As they diverge outwards from their origin they enlarge, and, curving backwards, terminate obliquely in open fringed extremities directed towards the ovaries, which lie below and somewhat behind them. They are included, as are likewise the ovaries, in the duplicature of the peritoneal lining of the abdomen, called the broad ligaments of the uterus, by which that body is itself invested and attached laterally to the cavity of the pelvis. A production of this membrane sheathes them to their loose trumpet-shaped extremities, and turning over the edge is continued for some distance up the interior surface, finally blending with the mucous lining which accompanies them in their exit from the uterus. This is the only instance in the body of the continuity of a serous and mucous membrane, and probably has some concern in the spreading of inflammation from the interior of the uterus to the peritoneum, which constitutes one of the forms of puerperal fever.

Before the period of conception these tubes are observed in the lower animals to become more full of blood, and to have a writhing peristaltic motion like that which impels the aliment along the intestinal canal. Certain prominences are also observed at this time on the surface of the ovaries, produced by the maturation and swelling of the Graafian vesicles, which are the ova or germs of the future progeny. The Fallopian tubes then become attached by their open fimbriated mouths over these prominences; and receiving the vesicles as they burst through the peritoneal covering of the ovaries, convey them by the peristaltic motion we have mentioned into the uterus.

These germs are sometimes fecundated before they reach their destination, when what is called extra-uterine conception occurs. In these cases the germ never reaches the uterus at all, but remains in the intermediate canal, and becomes attached to its surface; in this position it may attain its full size, expanding the tube as it grows, till at length it gives way, and the fœtus escapes into the general cavity of the abdomen. Such cases are not necessarily fatal; the fœtus, dead of course, sometimes becomes inclosed after a certain period in a membranous cyst, gradually extended around it from the parietes of the abdomen; and may remain for many years without exciting much irritation. In other instances abscesses form and break in succession, discharging the bones and other unabsorbed parts of the fœtus, and the case eventually does well. But such results are rare; and nothing but the Cæsarean operation affords much prospect of saving life.

FALLOW-CHAT. [SAXICOLA.]

FALLOW-DEER. [CERVIDÆ.]

FAMILIES OF PLANTS. The word Family in Botany is mostly applied to a group of Plants of the same value as a Natural Order. In this sense it has been mostly employed throughout the pages of this work. At the same time, in the arrangements of some writers, a Family is made a group of less value than an Order; whilst in the writings of others the term is loosely applied to distinguish any group of plants of higher value than a single species. It is thus sometimes employed synonymously with Genus. The names of natural orders, being mostly those of a genus, which serves as a type for the rest of the group, are easily Englished by adding the word Family. Thus the Order *Gentianaceæ* is called in English the Gentian Family, and so on. By this means the word Family is sometimes restricted to the species of a genus. Another word used synonymously with Natural Order by Dr. Lindley is Tribe. In his Natural System, all the orders having typical genera with English names have been called Tribes, with the English names attached. Thus, *Cinchonaceæ*, the Coffee tribe; *Pistiaceæ*, the Duck-Weed tribe; *Euphorbiaceæ*, the Euphorbium tribe. At the same time, Tribe is frequently used to express a group of less value than an

Order, as in the larger orders, *Umbelliferæ*, *Leguminosæ*, *Compositæ*, *Cruciferæ*, &c. More recently, Dr. Lindley has endeavoured to give a single English word to express each natural tribe or order: thus, *Magnoliaceæ* are called Magnoliads; *Scrophulariaceæ*, Figworts; *Galiaceæ*, Stellates. We have added these names after each order in the 'English Cyclopædia.'

The following plan will give an idea of the relative value of terms used in the subdivisions of Plants :—

Class.
Sub-Class.
Group.
Alliance.
Order, or Family.
Sub-Order, or Sub-Family.
Tribe.
Sub-Tribe.
Division.
Sub-Division.
Genus.
Sub-Genus, or Section.
Species.
Variety.

The divisions, groups, and alliances between the sub-class and order are adopted by Lindley in his Natural System, and frequently occur in this work. It is only a few orders, such as *Compositæ*, that require the subordinate divisions above, and only the larger genera require to be divided into sub-genera.

FARINA. [STARCH.]

FASCICLE, in Botany, is, strictly speaking, that kind of inflorescence in which the flowers are arranged in a flat-headed raceme or corymb, and begin to expand in the centre sooner than at the circumference. The term is however constantly applied to any collection of flowers or leaves in clusters at the end or on the sides of a branch: thus, the leaves of the larch are called fasciculate.

FASCIOLA, a name given to various forms of Trematode Worms. [ENTOZOA.]

FASSAITE. [PYROXENE.]

FAT. This substance varies in properties according to the animals producing it. In all cases however it is composed of three different kinds, which differ as to their melting point: these are termed Olein, or Elain, Stearin, and Margarin. It is not however to be considered that the substances to which these names are given are in all cases absolutely identical; they vary as to smell, taste, solubility in alcohol, &c.; but all fats agree in being insoluble in water, and in not containing any azote, which is a common constituent of most other animal matter. Olein, Stearin, and Margarin are composed of acids called oleic, stearic, and margaric acids, combined with a base called Glycerine. Glycerine is the oxide of a compound radicle called Lipyle. [ADIPOSE TISSUE.]

Human Fat varies a little according to the part of the body producing it: that from the region of the kidneys, after it has been melted, is yellowish and inodorous; it begins to concrete at 76° Fahr., and is solid at 64°; it dissolves in forty times its weight of alcohol of 0·821 when boiling, and on cooling stearin is deposited, which, after pressure in bibulous paper at 78°, is colourless, fusible at 122°, and may be cooled to 106° before it begins to congeal; its temperature, on account of the evolution of latent heat, then rises to 120°: 21·5 parts of this stearin are soluble in 100 parts of boiling anhydrous alcohol, the greater part of which separates in acicular crystals on cooling.

The Olein of human fat is a colourless oily sweetish fluid, and remains so at 40°; at 60° its specific gravity is 0·913; 123 parts of this Olein are soluble in 100 parts of boiling alcohol; on cooling to 170° the solution becomes turbid.

Ox Fat.—When this has been fused it begins to solidify at 98°, and the temperature then rises, for a reason already mentioned, to 102°. Forty parts of boiling alcohol, of specific gravity 0·821, dissolve one part of it; and it contains about three-fourths of its weight of stearin, which is solid, hard, colourless, not greasy, and of a granular crystalline texture; it fuses at about 112°, and may then be cooled to 102°, when, on congealing, it rises to 112°. It burns like white wax. Of this stearin about 15·5 parts are dissolved by 100 parts of anhydrous alcohol.

The Olein of ox fat is colourless, nearly inodorous, and its specific gravity is 0·913: boiling alcohol dissolves nearly one-fourth more than its weight.

Sheep's Fat (or Mutton Suet) greatly resembles that of the ox; it is however whiter, and by exposure to the air acquires a peculiar odour. After fusion it congeals at a temperature varying between 98° and 102°; it dissolves in 44 parts of alcohol of specific gravity 0·821. The Stearin is white, translucent, and after fusion but imperfectly crystalline; about 16 parts are dissolved by 100 parts of boiling anhydrous alcohol. The Olein of mutton suet is colourless; its specific gravity is 0·913; and 80 parts of it are dissolved by 100 parts of anhydrous alcohol at 168°.

Hog's Fat, or Hog's Lard, is a soft colourless solid, which fuses between 78° and 86°; its specific gravity at 60° is 0·938. By powerful and long-continued pressure at 42°, between folds of blotting-paper, it is stated to yield ·62 its weight of colourless olein, of specific gravity 0·915; of this, 100 of boiling alcohol dissolve 123 parts. The Stearin of hog's lard is inodorous, solid, and granular, which, after fusion, remains liquid down to 100°, and then, on congealing, the temperature rises to 109°. It becomes acid by exposure to the air.

Goat's Fat contains a peculiar fat, termed Hircin by Chevreul, and to the presence of this its peculiar odour is owing, and which remains to a great degree with the olein when this is separated from the stearin: by particular management this fat yields hircic acid.

The Fat of Birds.—Goose Fat is colourless, and of a peculiar taste and smell; after fusion it congeals at 80° into a soft solid of the consistence of butter. When subjected in bibulous paper to pressure at 30°, 100 parts are separable into 68 of olein and 32 of stearin, fusible at 112°. The Fat of Ducks fuses at 76°, and yields 72 olein and 28 stearin, fusible at 120°. Turkey's Fat is separable into 74 olein and 26 stearin, fusible at 112°. [OILS; ADIPOSE TISSUE.]

FATHER-LASHER. [COTTUS.]

FAUJASITE, a Mineral, consisting of a hydrous silicate of alumina, with lime and soda. It occurs crystallised in the form of an octohedron with a square base. Its colour is white, sometimes brown. Fracture vitreous or uneven. Fragile. Lustre brilliant. It is so hard as to scratch glass. It is found with *Augite* at Kaisarstuhls in Breisgau. Analysis, by Damour :—

Silica	49·36	
Alumina	16·77	
Lime	5·00	
Soda	4·34	
Water	22·49	
		97·96

FAULT. [COAL-FORMATION; GEOLOGY.]

FAUNA, a term employed by naturalists to express the whole of the members of the animal kingdom living in a particular district or at a particular time. Thus all the animals living in Great Britain constitute the British Fauna. Those inhabiting the land form the Terrestrial Fauna; those found in the seas constitute the Marine Fauna. It is often applied collectively to all the animals of the world, the extinct species constituting the Fossil Fauna, and the living species the Recent Fauna of the world. The word is derived from the Fauni, who were supposed to be the patrons of wild animals.

The word Flora is also applied in the same way, to comprehend the whole of the plants of a district, and admits of the same applications as the term Fauna. It is derived from Flora, the goddess of flowers. [FLORA.]

FAUVETTE. [SYLVIADÆ.]

FAVASTRÆA. [MADREPHYLLIÆA.]

FAVOSI'TES, a genus of Fossil *Zoophyta*, common in the Silurian strata of Norway and Wales. (Murchison, 'Sil. System.')

FAVULA'RIA, a generic title of certain Fossil Plants allied to *Sigillaria*, as *F. tessellata*, from the Coal-Formation. (Sternberg.) [COAL-PLANTS.]

FEATHER-ALUM, a hydrous sulphate of alumina, not mixed with any other sulphate. It occurs more frequently than the true Alums, which are double salts.

FEATHER-GRASS. [STIPA.]

FEATHER-ORE, a Mineral, consisting of sulphuret of antimony and lead. It occurs in fine capillary crystallisations like a cobweb. Its colour is dark lead-gray. It is found in the Eastern Harz. Its composition is—

Antimony	31	
Lead	47	
Sulphur	20	
		98

FEATHERS. [BIRDS.]

FECULA, or FÆCULA. [STARCH.]

FECUNDATION. [REPRODUCTION.]

FEDIA. [VALERIANELLA.]

FEELING. [NERVOUS SYSTEM; TOUCH.]

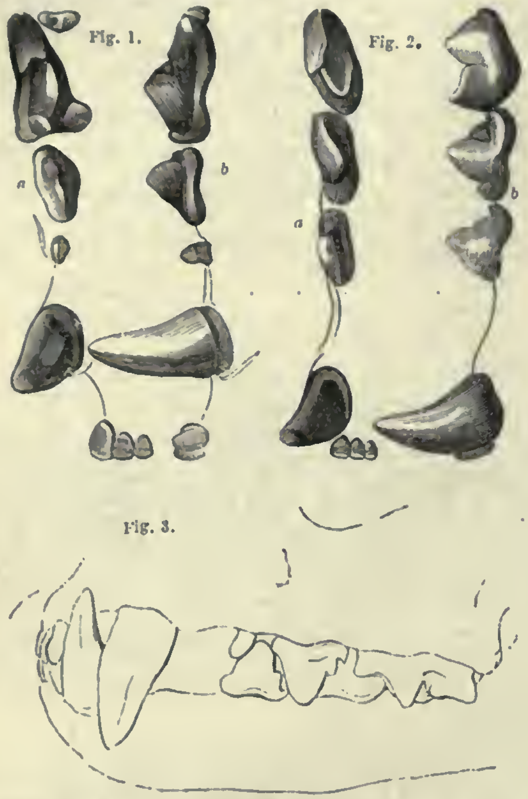
FE'LIDÆ, or FELINA, a Family of the Cat kind, of the order *Carnivora*, in which the organs of destruction reach their highest development. They are, among the quadrupeds, what the *Falconidæ* are among the Birds. Sometimes this family is made to include the Dogs, Hyænas, Wolves, and smaller *Carnivora*. We shall confine ourselves here to the members of the tribe *Felina* of Dr. J. E. Gray, comprising the Cats, Lions, Tigers, Leopards, and Lynxes.

The principal instruments of the destructive energy of these animals are the teeth and claws.

The dental formula then in these animals is the following :—

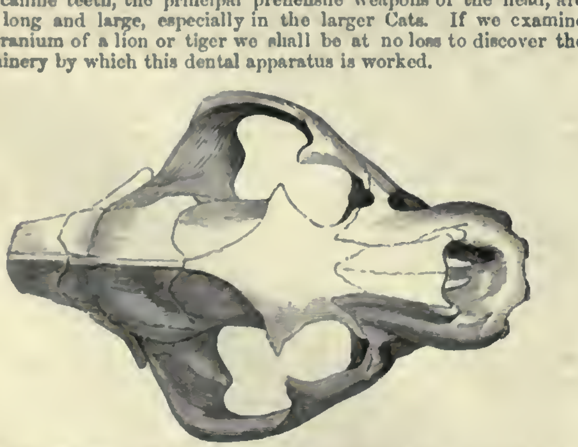
$$\text{Incisors, } \frac{6}{6}; \text{ canines, } \frac{1-1}{1-1}; \text{ molars, } \frac{4-4}{3-3} = 30.$$

The formation of these teeth is beautifully shown in four preparations in the museum of the Royal College of Surgeons in London. No. 329 is the anterior part of the right ramus of the lower jaw of a young lion, exhibiting the teeth, together with the gums in which they are imbedded, and the border of soft parts, or lip, with which they are surrounded. No. 330 is the anterior part of the upper jaw of a young lion injected, in which the body of the second or permanent laniary (canine tooth, or cuspidatus) is pretty completely formed, and the fang forming. The laniary is cut down in the direction of its axis to expose the cavity containing the pulp on which it was forming. There is one of the molars in the act of being shed, and the adnlt or permanent tooth is pushing into the gum. No. 331 is the counterpart, or oposite section of the same laniary; and No. 332 is the laniary of the jaw of the opposite side af the same lion, showing the whole of the pulp on which it was forming. ('Catalogue, Physiological Series, Gallery,' vol. i.)



Teeth of the Cat Family. 1, upper jaw; *a*, internal view; *b*, external view: 2, lower jaw; *a*, internal view; *b*, external view: 3, teeth when the jaws are shut seen in profile. From F. Cuvier.

The articulation of the condyles of the lower jaw in which this formidable apparatus is set is so contrived as to cause its operation in the most efficient manner. These processes are situated in the same straight horizontal line; they are cylindrical, and firmly locked in the transversely elongated glenoid cavities, the margins of which are so extended both before and behind the condyle that rotatory motion is impossible. The crowns of the molar or rather lacerating teeth are compressed, and covered with enamel, as indeed are those of all the others: the molars terminate in pointed processes, and the lower teeth shut within the upper. Thus, when called into action, the teeth and jaws operate like the antagonist blades of a pair of scissors upon the substance submitted to their cutting edges. The canine teeth, the principal prehensile weapons of the head, are very long and large, especially in the larger Cats. If we examine the cranium of a lion or tiger we shall be at no loss to discover the machinery by which this dental apparatus is worked.



Skull of Lion seen from above, showing the extent of the zygomatic arches and temporal fossæ.

The Crista Occipitalis, which is most strongly marked in the cats, is a sharp and prominent bony ridge rising from the upper and hind portion of the skull. Its chief use is for the attachment of the temporal muscle, and the size of the temporal fossa, and the strength and extent of the zygomatic arch depend upon the magnitude of that muscle. In no animals is this fossa larger than in the *Carnivora*. It not only occupies the whole of the sides and upper part of the skull, but is still further increased by the prominent bony crests proceeding from the frontal, parietal, and occipital bones. The temporal muscles would indeed almost completely cover the cranium in many of these animals, were it not for their separation by the parietal ridge.

Skull of Lion seen in profile, showing the prominent bony crests.

The zygomatic suture is so oblique that the temporal bone forms the whole superior margin, and the os malæ the inferior edge of the zygoma.

In consequence of the construction which we have endeavoured to explain, the lower jaw is capable of motion only upwards and downwards, and entirely incapable of that motion in a horizontal direction, which is necessary to mastication, properly so called. Accordingly the Cats cut and lacerate their food coarsely, and transmit it in large portions to the stomach, there to be acted on by the gastric juice.

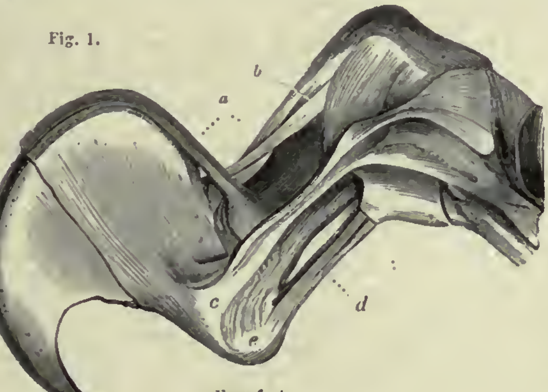
The muscles of the neck and fore quarter of the Cats are especially powerful to give full effect to this part of the organisation, and to enable the animal to drag or carry away its prey.

We must next turn our attention to the other organs of prehension, the claws.

The five toes of the anterior and four toes of the posterior extremities of the Cats are armed with very strong, hooked, sub-compressed sharp claws. These extremities, the anterior ones especially, thus become powerful instruments for seizing and rending the prey. The muscles that are to wield these weapons are of great strength; those of the fore arm especially, which in the lion and tiger offer the same arrangement for flexion, extension, pronation, and supination, as is observed in man, are highly developed, and the blow alone which the animal can deal with this limb is frequently fatal. It is asserted that the Bengal Tiger has been known to fracture the skull of a man with one stroke of its heavy paw. The claws, by a beautiful conformation, are always preserved without effort from coming in contact with external bodies, so as to keep them sharp and ready for action. There are some interesting specimens in the Museum of the Royal College of Surgeons in London, which will illustrate this provision. No. 287 of the 'Physiological Series' is a toe from the right fore foot of a lion, with the last phalanx retracted on the ulnar (which from the prone state of the foot is the outer) side of the second phalanx. This state of retraction is constantly maintained, except when overcome by an extending force, by means of elastic ligaments, two of which have bristles placed beneath them in the preparation. The principal one arises from the outer side and distal extremity of the second phalanx, and is inserted into the superior angle of the last phalanx; a second arises from the outer side and proximal end of the second phalanx, and passes obliquely to be inserted at the inner side of the base of the last phalanx; a third, which arises from the inner side and proximal extremity of the second phalanx, is inserted at the same point as the preceding. The tendon of the flexor profundus perforans, which is the antagonist of the ligaments, has been divided. No. 287 A is a toe from the left fore foot of a young lioness, with the last phalanx drawn out, as in the action of the flexor profundus. The same ligaments are shown as in the preceding preparation, together with the insertion of the flexor and extensor tendons. In order to produce the full effect of drawing out the claw, a corresponding action of the extensor muscle is necessary to support and fix the second phalanx; by its ultimate insertion in the terminal phalanx, it serves also to restrain and regulate the actions of the flexor muscle. A bristle is placed beneath that part of the extensor tendon which passes under one of the elastic ligaments to be inserted into the base of the last phalanx immediately above the articulation. In both preparations lateral processes of tendon may be observed going to the under part of the base of the phalanx, which are partly inserted there, and partly lost in the integument: they are given off from the extensor tendon as it passes over the proximate phalanx, and are joined by ligamentous fibres from the sides of the same phalanx.

No. 288 is a toe from the right hind foot of a lion, with the last phalanx drawn out, and the elastic ligaments put on the stretch. As the phalanges of the hind foot are retracted in a different direction to those of the fore foot, that is, directly upon and not by the side of the second phalanx, the elastic ligaments are differently disposed, as may be seen by comparing this with the preceding preparation. The outer ligament is of a flattened triangular form; it arises from the whole outer side of the middle phalanx, is strongest at the anterior margin, and is inserted at the superior angle of the last phalanx: the inner ligament is of a rounded form, arises from the inner side and distal end of the second phalanx, and is also inserted at the superior angle of the last phalanx, which is necessarily drawn back in the diagonal of the elastic forces. No. 288 A is the innermost toe or pollex of the right fore foot of a young lioness, exhibiting a disposition of the elastic ligaments and mode of retraction similar to the toes of the hind foot; but here the inner ligament is of the flattened triangular form, and the outer one rounded. The latter passes between a division in the extensor tendon, one part of which is inserted in the base of the last phalanx just above the articulation; the other part into the outer side of the base of the phalanx, and into the integument. ('Catalogue, Physiological Series, Gallery,' vol. i.) "It seems scarcely necessary," adds the able author of the foregoing description, "to allude to the final intention of these beautiful structures, which are, with some slight modifications, common to the genus *Felis*. The claws being thus retracted within folds of the integument, are preserved constantly sharp, and ready for their destined functions, not being blunted and worn away in the ordinary progressive motions of the animal; while at the same time, as soft parts only are brought in contact with the ground, this circumstance contributes to the noiseless tread of the feline tribe." ('Gallery.')

Fig. 1.



Fore foot.

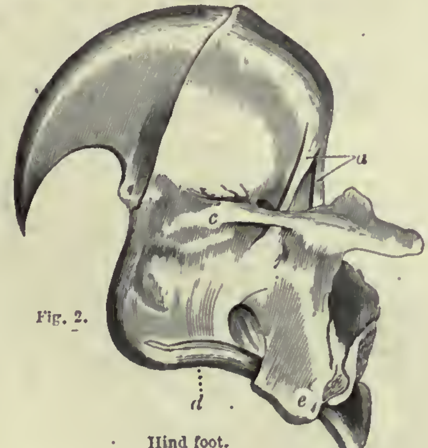


Fig. 2.

Hind foot.

Structure of the apparatus for retracting and extending the claws of the Cats, as exemplified in the fore foot and hind foot of the lion.

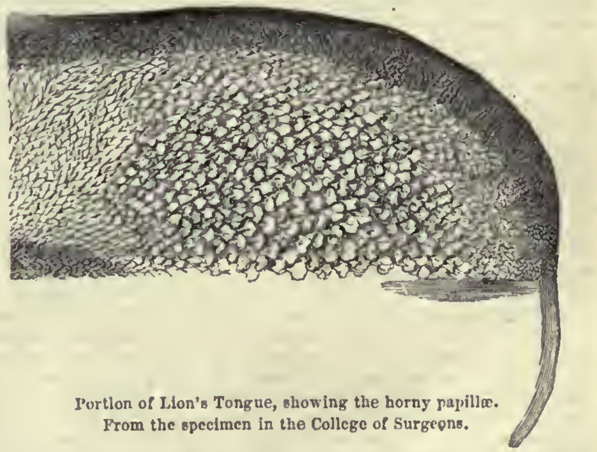
The elastic ligaments which retain the last phalanx and claw in a state of retraction are not the same in the fore and hind foot.

In *fig* 1, which is a toe from the left fore foot of a young lion, represented in a state of extensions, *a* points to the two elastic ligaments; *b*, the tendon of the extensor muscle; *c*, a process of inelastic tendon; *d*, the tendon of the flexor muscle, which passes over the upper extremity of the last phalanx at *e*, as over a pulley, and thus assists the powerful action of that muscle.

In *fig* 2, a toe from the hind foot, the two elastic ligaments (*a*) converge to be inserted into the upper angle of the last phalanx, and draw it backwards directly upon, instead of by the side, of the penultimate phalanx; *c* is a process of lateral inelastic tendon; and *d* the tendon of the flexor profundus, which is strongly strapped down by an annular ligament, *e*.

The claw is supported on the last phalanx, which is of a very peculiar form. Its two portions are united to each other at nearly right angles. The base of the claw is received into a groove in the body of the bone, to prevent its being pushed backwards in the violent action of the paws. The two parts of the bone form a species of hook or crotchet. The superior end of the phalanx in this state of repose is placed almost vertically; while the other extremity lies nearly parallel to the second. The articulation is at the upper end of the vertical portion, and the flexor tendons, passing over the upper part of the bone, are strongly fixed to the other portion. The action of the flexor profundus causes the whole bone to move through 90 degrees round the end of the second phalanx. (Dr. Traill.)

Having laid before the reader the mechanism of the parts more immediately concerned in the capture of the prey and the separation of its flesh, we must notice another organ which in the Cats is used for other purposes than those of mere taste and deglutition. The roughness of a domestic cat's tongue is familiar to every one, as well as the action of lions and tigers in licking the bones of their prey in order to detach any remnants of flesh that may be adhering thereto. This is effected by numerous horny papillæ, which are differently arranged in different species, some having them in straight rows, others in alternate lines; but in all the points are directed backwards. In the Museum of the Royal College of Surgeons are preparations well illustrating the structure of the tongue in these animals. No. 1509 exhibits the tongue and larynx of a young lion injected. The tongue is of considerable length, in consequence of the distance at which the larynx and os hyoides are placed behind the bony palate. The soft palate is of a proportional extent. All that part of the tongue which corresponds to the soft palate is smooth; as it advances forwards it is covered with large soft papillæ directed backwards; then there are four large fossulate papillæ, anterior to which the simple conical papillæ continue increasing in size to near the tip of the tongue: the strong cuticular spines with which they are armed have been removed, showing the vascular secreting surface beneath. With the larynx there are preserved the thyroid glands and part of the wide trachea. No. 1510 is a portion of the cuticular covering of the smaller posterior conical papillæ, from the preceding tongue. No. 1511 shows a portion of the cuticular covering of the anterior papillæ of the same tongue. At the fore part of the base of each of the larger spines may be observed a group of small gustatory papillæ. No. 1512 is the extremity of the tongue of a lion, with the cuticular covering of the papillæ removed from one side; and No. 1513 is the anterior part of the tongue of a lion, with the cuticular and spiny covering of the papillæ preserved. ('Catalogue, Physiological Series, Gallery,' vol. iii.)



Portion of Lion's Tongue, showing the horny papillæ. From the specimen in the College of Surgeons.

Professor Owen remarks, that in the Cats generally the connection of the os hyoides with the cranium is not by a long elastic ligament, as in the lion, but by an uninterrupted series of bones, and that this latter structure exists in the Cheetah (*Felis jubata*).

This leads us to the other digestive organs. In the *Felidæ* the salivary glands are small, as might be expected where it can hardly be said that mastication is exercised. The stomach of the lion is divided, by a slight contraction in its middle, into two portions. Its coats, particularly the muscular coat, are very strong, as in most of the *Carnivora*. Blumenbach observes, that in most carnivorous quadrupeds, particularly those of a rapacious nature, the stomach bears a considerable resemblance on the whole to that of the human subject. Mr. Lawrence, in his notes, remarks, that the food of carnivorous animals, approaching in its constituent elements more nearly to those of the animal than that of the herbivorous tribes, is more easily reduced into the state which is required for the nourishment of the body in the former than in the latter case. In the *Carnivora*, the stomach, which is of a cylindrical form, has no cul-de-sacs; the œsophagus opens at its anterior extremity, and the intestine commences from the posterior, so that everything favours a quick passage of the food, which receives no mastication, and is retained a very short time in the stomach. The intestine has no valves, is small in diameter, but muscular, and the whole canal, when compared with the body, is extremely short, being as 3 or 5 to 1. It is worth noticing, that in the Domestic Cat they are as 5 to 1, but in the Wild Cat they are only as 3 to 1. Some of the *Carnivora* have no cæcum, and in those that have this appendage it is constantly small and uniform in its cavity. In the Museum of the College of Surgeons are four preparations, Numbers 693 to 696 (Gallery), both inclusive, showing the structure of the intestines of a lion. No. 724 shows the termination of the ileum of a lion, with the cæcum or caput coli injected. The cæcum is simple, resembling that of the Suricate (*Ryzæna tetradactyla* of Illiger), with its apex similarly occupied by a cluster of glands; the terminal orifice of the ileum is also of a circular form, but it is situated on a valvular prominence in the large intestine. No. 730 is the injected colon of a lion. The longitudinal muscular fibres are very strong, and are disposed around the whole circumference of the intestine, which consequently is not drawn up into sacculi. The lining membrane is smooth, and is thrown into zig-zag rugæ. No. 736 is a portion of the rectum of a lioness, showing the strong round fasciculi of longitudinal fibres forming the outer stratum of the muscular coat, part of which has been turned down to show the inner circular fibres. The intestinal glands of the ileum in the lion are shown by No. 757. No. 806 shows the liver of the Domestic Cat, and its subdivision, as in all carnivorous quadrupeds, into a great number of lobes. The second lobe from the left side, or cystic lobe, is deeply cleft for the insertion of the suspensory ligament; to the right of this cleft it is perforated for the lodgement of the gall-bladder. No. 807 is the cystic lobe of the same species, showing that the gall-bladder is situated in the middle of the substance of the large lobe. ('Catalogue, Gallery, Phys. Series,' vol. i.) Blumenbach remarks that the ductus choledochus forms a pouch between the coats of the intestine for receiving the pancreatic duct in the Cat. No. 821 in the Museum of the College of Surgeons displays a portion of the duodenum, with the termination of the hepatic and pancreatic ducts of a lion. A black bristle is passed into the ductus communis choledochus, and a white one into the pancreatic duct; the mucous coat of the intestine is laid open to show their junction. The orifice of a distinct pancreatic duct is preserved. No. 837 is the spleen, with a portion of the duodenum and pancreas of a domestic cat. The spleen is of an elongated trihedral form, attached to the stomach by a duplicature of peritoneum inclosing its vessels; this duplicature passes off from the angle formed by the two lesser sides. The splenic vein is seen passing from the spleen along the pancreas, which extends from it to the duodenum. No. 840 exhibits the stomach and duodenum, spleen, pancreas, and great omentum of a small carnivorous animal, apparently of a cat. The parts have been injected, and show remarkably well the principal peculiarities in the form and disposition of these parts as they exist in the feline tribe. A part of the œsophagus has been inverted, to show the transverse rugæ of its lining membrane, near its termination. The stomach exhibits the broad dilated cardiac and the narrow tubular pyloric divisions, which are acutely bent upon each other; in the duodenum may be observed its regular extended curve, and its broad mesentery, by which much greater freedom of motion is allowed to this portion of the intestinal canal than in the human subject. The small omentum is seen attached, not in a regular line along the lesser arch of the stomach, but advancing in an irregular scolloped manner upon its anterior surface; an analogous process of peritoneum is attached posterior to the lesser curvature. The great omentum anteriorly is continued from the greater arch of the stomach, from the left end of which it is continued down the spleen, and posteriorly along the pancreas, which is thus seen to have an entire investment of peritoneum; from the pancreas it extends to the pylorus, where it becomes continuous with the anterior layer, completing the circle, and leaving a large aperture behind the lesser arch of the stomach, which leads into the omental cavity analogous to the foramen Winslowi. The form of the pancreas and its division into the transverse or greater lobe and the circular or duodenal lobe are well shown, and also the form and situation of the spleen. ('Catalogue, Gallery, Phys. Series,' vol. i.)

The terrific roar with which the larger animals of this family rush on their prey is well known, and well calculated to paralyse the nervous system of the victim with fear. Stealing on the victim with noiseless tread till couched within the proper distance for their spring, these destroyers leap on it with a horrid sound which salutes its ear in the same moment almost that it feels the blow of the deadly talons and the murderous gripe of the teeth. The cartilages of the larynx of a lion, the large size of the vocal organ, and the rounded contour of the epiglottis, may be seen in preparation No. 1172 (Gallery) of the Museum of the Royal College of Surgeons. From the narrowness of the thyroid cartilage anteriorly, there is a considerable interval at that part between the thyroid and cricoid cartilages, a structure which, as the 'Catalogue' tells us, obtains in all the feline animals. No. 1129 consists of the heart and lungs of a kitten, and shows principally the subdivision of the lungs into many lobes, and more especially the small azygos lobe of the right lung, filling up the space which intervenes between the heart and diaphragm in this and most other quadrupeds. Vicq-D'Azyr and Blumenbach notice the two delicate membranes lying under the ligamenta glottidis of the cat, which probably cause the purring noise peculiar to it.

"The structure of the kidney in *Mammalia*," observes Mr. Lawrence, in his notes to Blumenbach's 'Comparative Anatomy,' "displays two very opposite varieties, which may be called the simple and the conglomerated kidneys. In the former there is a single papilla, which is surrounded by an exterior crust of the cortical substance. This is the case in all the *Feræ*, and in some other animals, as many *Rodentia*." "In some animals," says John Hunter, "the kidney is a very oblong body, extending in length for a considerable way, and very narrow, as in some fish, while in other animals it is almost globular, as in the leopard. . . . In the lion kind, cat kind, as also in the hyæna, we find that perhaps one-half of the veins get on the external surface, and are either strongly attached to or pass in a doubling of the capsule of the kidney, and then pass along like the veins of the pia mater, afterwards joining the trunks from the inside just as they pass out. . . . The veins of the kidneys have in general nothing particular respecting them. They in common attend the arteries, or at least ramify similarly to the arteries, excepting in the lion and cat kind, as also in the hyæna, where some of the veins ramify on the surface, while the others are attending the arteries." The reader will find in the Museum of the College of Surgeons some beautiful preparations illustrative of the kidneys, &c., of the *Felidæ*: they are numbered 1200 to 1205 both inclusive, 1218 to 1221 both inclusive, and 1284. (Gallery.)

Blumenbach observes that in some species of the Cat kind the glans is covered with retroverted papillæ, which, as these animals have no vesiculæ seminales, may enable the male to hold the female longer in his embraces. Most of the Cats are retromingent, but not, as has been so often and erroneously repeated from the time of Aristotle, retrocopulant.

Brain, Nervous System, and Senses.—Blumenbach observes that the bony tentorium cerebelli constitutes in most species of the Cat kind a uniform bony partition which leaves a quadrangular opening in the lower part of the cranium. In the cat the brain forms $\frac{1}{156}$ of the body; the proportion of the weight of the cerebellum to the cerebrum is as 1 to 6, and the breadth of the medulla oblongata after the pons Varolii is to that of the brain as 8 to 22. In the Museum of the Royal College of Surgeons, No. 1324 (Gallery), is the brain of a tiger. The pia mater has been removed from the medulla oblongata, showing the transverse tract of medullary matter posterior to the tuber annulare, called corpus trapezoideum; this is traversed by the corpora pyramidalia. The development of the cerebrum is such as not only to cover the optic lobes or bigeminal bodies, but also the anterior half of the cerebellum itself; and the surface of the cerebrum is augmented by convolutions, of which one is analogous to the single convolution in the agouti, and extends parallel with the fissure dividing the hemispheres; a second runs parallel with and external to the preceding; a transverse one proceeding from the mesial fissure marks off what may be regarded as the anterior lobes, which, together with the lateral regions of the hemispheres, are traversed by other anfractuosities. No. 1325 is the brain of a lion, closely resembling the preceding in general form and disposition of the convolutions. No. 1326 is the brain and part of the spinal chord of a young lion, with the vessels of the pia mater minutely injected. The left lateral ventricle is exposed, showing the pes hippocampi and the choroid plexus. The fourth ventricle is also laid open, and contains a similar plexus of minute arteries. Bristles are inserted into the hollow olfactory and the optic nerves, and black threads are tied round the origins of the remaining cerebral nerves of the right side. A small quill is placed in the infundibulum; but the pituitary gland, which may be seen in both the preceding specimens, is here removed. The union of the vertebral arteries to form the basilar artery, the great length of that vessel, and its division to join with the internal carotids in the formation of the circle of Willis, are well displayed. No. 1326 is a portion of the basis of the brain of a lion, prepared to show the form and relative proportions of the bigeminal bodies or optic tubercles; of these, the posterior, though smaller in longitudinal diameter, are broader, and rise above the level of the anterior pair. No. 1372 and No. 1373 are two highly interesting preparations of the spinal chord and cauda equina of the lion. ('Catalogue,' vol. iii.)

Blumenbach enumerates the Cat kind among the animals remarkable for their acuteness in the sense of smelling, and as affording examples of a very complicated formation of the ethmoid bone, both in regard to the elegant structure of its cribriform lamella, and to the wonderful convolutions of its turbinated portions, which procure as large a surface as possible within the confined space of the nasal cavity, for the application of the Schneiderian membrane. The conchæ narium inferiores are also much convoluted. There is in the Museum of the College of Surgeons (Gallery) a preparation (No. 1552) of a longitudinal vertical section of the head of a leopard, showing the turbinated bones of the left side in situ; and another, No. 1553, of a longitudinal section of the side of the head of a young lion, showing the ossa turbinata in situ also. The following luminous description of the latter is given in the Catalogue ('Physiological Series,' vol. iii.) :—"The superior bone is of a conical form, extending along the whole of the roof of the nasal cavity, with its base opposite to the frontal sinus (which is here exposed), and its apex terminating above the anterior extremity of the inferior turbinated bone. It presents a smooth or uniform surface towards the nasal cavity, as may be seen in the preceding specimen; but the lamella forming this surface has been partially removed, showing the subjacent lamella, which is folded longitudinally: the more complicated disposition of the exterior lamella of the same bone is exhibited on the opposite side of the preparation, where the surface for the extension of the olfactory membrane is augmented by a series of deep arched folds, having their convexity upwards. The middle turbinated bone is also of a pyramidal form, its broad basis being applied to the cribriform plate of the ethmoid bone, and its apex extending between those of the other two turbinated bones, but not reaching so far forwards. The nasal or mesial surface of this bone is complicated by numerous deep furrows, two of which extend longitudinally, parallel with the superior margin of the bone, while the others radiate in an irregular manner from the lower point of attachment. The lateral surface of the bone is less complicated and extensive. The inferior and anterior turbinated bone is of an elongated form, and contracted at both extremities. Its posterior and inferior extremity is attached to the outer parietes of the nasal passage, below the middle of the turbinated bone: from this point it extends obliquely upwards, enlarging as it crosses the anterior extremity of the middle bone, and then diminishing in size to its anterior and superior attachment behind the external nostril: from its position therefore the odorous particles in inspiration must first impinge upon this bone. Its nasal surface is pretty uniform, presenting only one curved groove, parallel with and near to the lower margin of the bone, in this respect differing widely from the lower turbinated bone in the hare: its exterior surface is similarly characterised. In the preparation the outer lamella has been cut away to show the subjacent fold. The whole being minutely injected, the vascularity of the pituitary membrane extended over this vast and complicated surface is well displayed. The pituitary membrane is evidently thickest and most vascular at the anterior part of the cavity, where it must receive the first impression of the external air. A portion of the pituitary membrane is reflected from the base of the middle turbinated bone, showing the fibres of the olfactory nerves spreading over it. In No. 1554 (the opposite section of the same head) and No. 1555 (the intermediate section) this part of the organisation is still further illustrated.

The sense of hearing is acute in most of the Cats. There is, in the greater number of mammiferous quadrupeds, connected with the tympanum, another cavity which Blumenbach compares, with regard to the situation of the bony organ that contains it, to the mastoid cells in the temporal bone of man. In several animals (and the cat is one of them) this organ is a mere bony cavity. The ossicula auditûs, considering the lenticulus as only a process of the incus, are three, as in the human subject. In the Museum of the College of Surgeons there is a preparation (No. 1600, Gallery) of a section of the cranium of a young lion, including the organ of hearing of the left side. A part of the meatus is preserved with the membrana tympani, and the cavity of the tympanum is laid open, showing the convexity of the membrane turned towards it, as in most *Mammalia*. ('Catalogue,' vol. iii.)

Sight is acute in the *Felidæ*, and they have the nictitating membrane very large and moveable. The pigment, as far as is known, is generally speaking of two colours, and the anterior perforation of the iris is formed of two segments of large circles joined, giving it a long and a short axis, the long axis being vertical. In the Museum of the College of Surgeons (No. 1710, Gallery) is the eye of a lion minutely injected by the ciliary arteries, and the sclerotic coat transversely divided, and reflected from the choroid, to show the vascularity of that tunic. No. 1730 is a preparation of the eye of a lion, showing the broad patch of tapetum lucidum below and also a little above the insertion of the optic nerve. The succeeding numbers to No. 1733 inclusive are also illustrative of this part of the organisation in the lion and the leopard. John Hunter, 'Observations on Certain Parts of the Animal Œconomy,' remarks, that when the pigmentum is of more than one colour in the same eye, the lighter portion is always placed at the bottom of the eye, in the shape of a half-moon with the circular arch upwards; the straight line or diameter passing almost horizontally across the lower edge of the optic nerve, so that the end of the nerve is within this lighter coloured part, which makes a kind of semicircular sweep above it: and he observes that the shape is peculiar to the Cat, Lion, Dog, and most of the carnivorous tribe. Professor Owen observes that the Cheetah has the circular pupil of the Lion, Tiger, Leopard, and Jaguar. ('Zool. Proc.,' 1833.)

The osteology of the *Felidæ* presents little for the distinction of species except size, and in no animal does specific character depend upon size and colour more entirely than it does in this family. There are indeed differences: such for instance as that pointed out by Professor Owen between the skull of the lion and that of the tiger; but taken as a whole the skeleton of a cat is very nearly the miniature representation of that of a lion or a tiger. We accordingly find that the disposition of many leading zoologists has been to bring all the numerous species under one genus. Linnæus arranges them under *Felis*, the third genus of his order *Feræ*, placing them between the Dogs (*Canis*) and *Viverra*. Illiger assigns to them a position in his order *Falculata*, with the title *Sanguinaria*. Cuvier places them under the name of Les Chats (*Felis*, Linn.) among his Carnivores, the third family of his Carnassiers, between the Hyænas and the Seals. Temminck regards the genus *Felis* as an indivisible group zoologically, but separates them into two sections, the first comprising those which are found in the Old Continent and its archipelagos, 18 species in number; the second those which occur in the New World, of which he enumerates 9 species. Prince C. L. Bonaparte admits into his family *Felina* the genera *Proteles*, *Hyæna*, and *Prionodon*, a very questionable admission. Dr. Leach gives the Lions a generic distinction with the name of *Leo*. The Lynxes are separated as a genus by Dr. J. E. Gray, under the title of *Lynchus;* and the Hunting Leopard (*Felis jubata*,) is characterised generally by Wagler as *Cynailurus*. The whole family may be popularly divided into Lions, Tigers, Leopards, Lynxes, and Wild Cats, or Cats properly so called—the two latter terms being more particularly applicable to the smaller forms. Under the articles HYÆNINA, CANIS, VULPIDÆ, VIVERRIDÆ, BEARS, MUSTELIDÆ, PHOCIDÆ, will be found other families of *Carnivora*, some of which have been occasionally referred to the *Felidæ*.

Before proceeding to any description or illustration of this family, it will be advantageous to the student to be put in possession of M. Tomminck's well-considered and digested monograph of the genus *Felis*, divided into two sections, according to their geographical distribution.

Section 1.

This comprises the *Felidæ* of the Old Continent and its archipelagos.

Species.

Felis Leo, including the three varieties of Barbary, Senegal, and Persia.

F. Tigris, the Royal Tiger.

F. jubata, the Hunting Leopard.

F. Pardus, the Panther. Of this M. Temminck gives the following character:—When adult, less than the Leopard. Tail as long as the body and the head, its extremity when turned back reaching to the tip of the nose; colour of the fur deep-yellowish fulvous, its internal part marked with rose-like spots of the same hue as the ground-colour of the fur; the numerous spots closely approximated; the rose-like spots from 12 to 14 lines at the utmost in diameter; caudal vertebræ 28.—N.B. The number of caudal vertebræ assigned to the Leopard by M. Temminck is 22. It would appear that there is no correct figure of the true Panther.

The Black Tiger, *Felis melas*, Rimau Kumbang of Sir Stamford Raffles, is considered as only a dark variety of the Leopard.

F. Uncia is considered as also to be erased from the list of species, as it is only the young of the Leopard or Panther.

F. macrocelis, the Rimau-Dahan.

F. Serval, comprising *F. Serval* and *F. Capensis*, Linn., the Chat-Pard of Desmarest, and the Caracal of Bruce.

F. cervaria, the Lynx.

F. Catus.

F. maniculata.

F. minuta, identical with the *F. Javanensis* of Horsfield's 'Zoological Researches in Java,' and therefore not to be adopted.

Section 2.

This comprises the *Felidæ* of the New Western World.

F. concolor, the Puma.

F. Onca, the Jaguar.

F. Jaguarondi.

F. celidogaster. Bought by M. Temminck at the sale of Mr. Bullock's collection for the Museum of the Netherlands.

F. rufa, Guldenst., Bay-Cat of Pennant. With this M. Temminck describes also a specimen brought from Mexico, which may prove distinct. Bought by M. Temminck at Mr. Bullock's sale for the Museum of the Netherlands.

F. pardalis, the Ocelot.

F. macroura.—N.B. These two last confounded together by Linnæus under the name of *F. pardalis*. The Mexican Tiger of Pennant is said to be representative of *F. macroura*.

F. mitis, the Chati, F. Cuv.

F. tigrina.

This monograph, as far as it goes, has been of great benefit; but the student should examine the menageries and museums, as well as the works of other authors, and he will find several Cats noticed both before and since the publication of M. Temminck's Catalogue. Among other authorities the publications of D'Azara, of Sir Stamford Raffles, of F. Cuvier, of M. Desmarest, of Dr. J. E. Gray, of Dr. Horsfield, and Mr. Vigors in the 'Zoological Journal,' of Dr. Horsfield in the 'Zoological Researches in Java,' of Prince Maximilian, of M. Lesson, of Sir William Jardine ('Naturalists' Library,' 'Mammalia,' vol. ii., *Felinæ*), and of Mr. Darwin ('Zoology of the Beagle') may be consulted with advantage.

Dr. Horsfield and Mr. Vigors ('Zool. Jour.,' vol. iv. p. 380) remark that they are not of M. Temminck's opinion, that the determination of species in such groups as these rests upon any examination, however acute, of preserved specimens in cabinets, or in any research, however extensive, into the stores of furriers. Such examination, they think, leads to conjecture; probable and plausible conjecture, it may be true, but still conjecture, and not facts. They add that we are in this way as likely to fall into the error of confounding true species as into that of creating nominal ones, and they express their opinion that the truth can be satisfactorily attained only by diligent researches in the native country of these animals, or by accurate observations on their changes and differences as to sex, age, and season, when in a living state and in confinement.

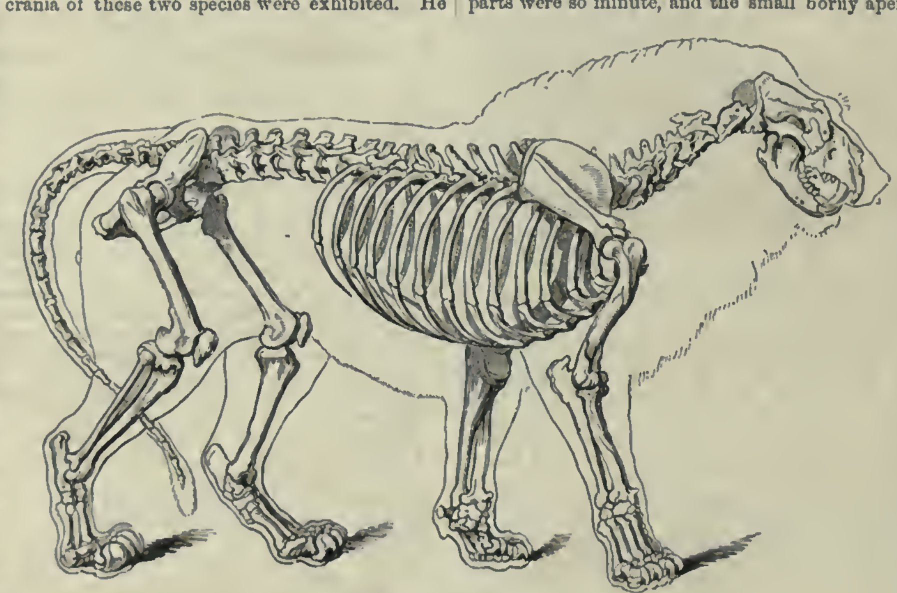
M. Temminck, in his 'Tableau Méthodique' (1827), states that then there were known 30 distinct species of Cats, and 7 or 8 other doubtful indications.

I. The Lions.

Lion is the English name for the form in which carnivorous development is generally considered to be the most perfect: Λέων of the Greeks (Λέαινα, Lioness); *Leo* of the Romans (*Lea* and *Leæna*, Lioness) Leone of the Italians (Leonessa, Lioness); Leon of the Spanish; Lion of the French (Lionne, Lioness; Linceau, whelp); Löwe of the Germans (Löwinn, Lioness). The male is, as a general rule, ornamented with a mane; the female has no such ornament.

There are, it appears, distinguishing characteristics marking the differences between the skulls of the Lion and Tiger. Professor Owen explained these to a meeting of the Zoological Society of London (1834), when several crania of these two species were exhibited. He adverted to the distinctions pointed out by Cuvier in the 'Ossemens Fossiles,' and remarked on the first of them; namely, the straightness of the outline in the lion from the midspace of the post-orbital processes to the end of the nasal bones in one direction, and to the occiput in the other, as not being in all cases available; but he regarded the second distinction—the flattening of the interorbital space in the Lion and its convexity in the Tiger,—as being more constant and appreciable. He pointed out however a distinction which had never, according to his belief, been published, which is, he observed, well marked, and which appears to be constant; for he found it to prevail throughout the whole of the skulls of these animals which he had examined, including ten of the Lion and upwards of twenty of the Tiger. It consists in the prolongation backwards in the cranium of the Lion, of the nasal processes of the maxillary bones to the same transverse line which is attained by the coronal or superior ends of the nasal bones; in the Tiger the nasal processes of the maxillary bones never extend nearer to the transverse plane attained by the nasal bones than one-third of an inch, and sometimes fall short of it by two-thirds, terminating also broadly in a straight or angular outline, just as though the rounded and somewhat pointed ends which these processes have in the Lion had been cut off. Professor Owen noticed also minor differences in the form of the nasal aperture, which in the Tiger is disposed to narrow downwards and become somewhat triangular, while in the Lion its tendency is towards a square shape; in the deeper sinking in a longitudinal depression of the coronal extremities of the nasal bones in the Tiger than in the Lion; in the bounding of this depression above in most of the Tiger's crania by a small but distinct semilunar ridge, which is not found in those of the Lion; and in the larger comparative size, chiefly in their transverse diameter of the infraorbital foramina in the Lion. Professor Owen remarked that it was curious that these foramina were double either on one or both sides in the only four skulls examined of lions which were known to be Asiatic, whilst in all the others the foramen was single on each side.

Another communication to the same society becomes interesting from its being associated with the popular belief that the Lion lashes his sides with his tail to stimulate himself into rage. There was exhibited at one of the meetings a claw obtained from the tip of the tail of a young Barbary Lion presented to the Society's menagerie by Sir Thomas Reade, then his majesty's consul at Tripoli. It was detected on the living animal by Mr. Bennett, and pointed out to the keeper, in whose hands it came off whilst he was examining it. The specimen having been submitted to Mr. Woods for description, that gentleman commenced by referring to the ancient writers quoted by Blumenbach. Homer ('Il.,' xx.), Lucan ('Pharsal.,' i. 208), Pliny ('Hist.,' viii.), among others, who had described the Lion (erroneously) as lashing himself with his tail when angry, or to provoke himself to rage. None of these writers however, he remarked, advert to any peculiarity in the Lion's tail to which so extraordinary a function might, however incorrectly, be attributed; but Didymus Alexandrinus, a commentator on the 'Iliad,' cited by Blumenbach, having found a black prickle-like horn among the hair of the tail, immediately conjectured that he had ascertained the true cause of the stimulus when the animal flourishes his tail in defiance of his enemies, remarking that when punctured by this prickle the Lion becomes more irritable from the pain which it occasions. Mr. Woods then noticed the oblivion into which the subject fell for centuries, till Blumenbach, who observes also that the later commentators, Heyne for instance, had noticed the opinion above stated, revived it, Blumenbach having verified the accuracy of Didymus Alexandrinus as to the fact, though he did not admit the commentator's inference. Blumenbach described the prickle as small, dark-coloured, hard as horn, placed in the very tip of the Lion's tail, surrounded at its base by an annular fold of the skin, and adhering firmly to a singular follicle of a glandular appearance. But Blumenbach remarked that these parts were so minute, and the small horny apex so buried in the tuft of hair, that the use attributed to it by the ancient scholiast can only be regarded as imaginary. Again, according to Mr. Woods, the subject appears to have slumbered till 1829, when M. Deshayes announced ('Ann. des Sci. Nat.,' vol. vii.) that he had found the prickle both of a lion and lioness which died in the French menagerie, and described it as a little nail or horny production, about two lines in length, presenting the form of a small cone, a little recurved upon itself, and adhering by its base only to the skin and not to the last caudal vertebra, from which it was separated by a space of two or three lines. From that period Mr. Woods suffered no opportunity to escape him of examining the tails of every lion, living or dead, to which he could gain access; but in no instance had he succeeded in finding the prickle till the specimen which was then before the committee was placed in his hands, within half an hour after its removal from the living animal, and while yet soft at its base where it had been attached to the skin. He described it as formed of corneous matter like an ordinary nail, and solid throughout the greater part of its length towards the apex, where it is sharp; and at the other extremity as hollow, and a little expanded. Its shape was rather singular, being nearly straight for one-third of its length, then slightly constricted (forming a very obtuse angle at the point of constriction), and afterwards swelling out like the bulb of a bristle to its termination. It was laterally flattened throughout its entire length, which did not amount to quite three-eighths of an inch. It was of a horn-colour, but became darker, nearly to blackness, at the tip. Its appearance, Mr. Woods observed, would lead to the belief that it was deeply inserted into the skin, with which however from the readiness with which it became detached, its connection must have been very slight. It is to this slightness of adhesion that M. Deshayes attributes its usual absence in stuffed specimens; and the same cause will account for its absence in by far the greater number of living individuals; for, as Mr. Woods remarked, its presence or absence does not depend upon age, because the Paris lions in which it was found were of considerable size, while that belonging to the Society was very small and young; nor upon sex, for although wanting in the

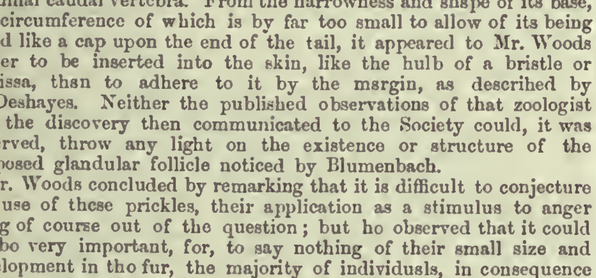


Skeleton of Lion.

female cub of the same litter at the Society's Gardens, it existed iu the lioness at the Jardin du Roi.

Mr. Woods, thinking it probable that these prickles might exist in other species of *Felis*, had previously examined the tails of nearly the whole of the stuffed skins in the Society's Museum, hut failed in detecting it in every instance but one. This was an adult Asiatic Leopard, in which the nail was evident, although extremely small. It was short and straight, but perfectly conical, with a broad base. Mr. Woods observed that it was stated in a note in the 'Edinburgh Philosophical Journal,' where a translation of Blumenbach's paper had been given, that a claw or prickle had also been observed by the editor of that work on the tail of a leopard. No such structure however was detected by Mr. Woods on a living individual in the Society's Menagerie. In the Leopard therefore, as in the Lion, it appears to he only occasionally present. In both it is seated at the extreme tip of the tail, and is altogether unconnected with the terminal caudal vertebra. From the narrowness and shape of its base, the circumference of which is by far too small to allow of its being fitted like a cap upon the end of the tail, it appeared to Mr. Woods rather to be inserted into the skin, like the hulb of a bristle or vibrissa, than to adhere to it by the margin, as described by M. Deshayes. Neither the published observations of that zoologist nor the discovery then communicated to the Society could, it was observed, throw any light on the existence or structure of the supposed glandular follicle noticed by Blumenbach.

Mr. Woods concluded by remarking that it is difficult to conjecture the use of these prickles, their application as a stimulus to anger being of course out of the question; but ho observed that it could not be very important, for, to say nothing of their small size and envelopment in tho fur, the majority of individuals, in consequence of tho readiness with which the part is detached, are deprived of it for the remainder of their lives. ('Zool. Proc.,' 1832.)



Prickle at the end of Lion's Tail. (Blumenbach.)

Emasculation, it is stated, prevents the development of the mane; and tho lion so mutilated is said never to roar.

The True Lions belong to the Old World exclusively, and they were formerly widely and plentifully diffused; but at present they aro confiued to Asia and Africa, and they are becoming every day more aud more scarce in those quarters of the globe. That lions were once found in Europe there can be no doubt. Thus it is recorded by Herodotus that the baggage camels of the army of Xerxes were attacked by lions in the country of the Pæonians and Crestonæi, on their march from Acanthus (near the peniusula of Mount Athos) to Therme, afterwards Thessalonica (now Saloniki): the camels alone, it is stated, were attacked, other beasts remaining untouched as well as men. Tho same historian also observes that the limits in Europe within which lions were then found were the Nessus or Nestus, a Thracian river running through Abdera and the Achelous, which waters Acarnania. (Herod., vii. c. 125-126, Schweighæuser.) Aristotle (vi. 31) says that the lion is in fact an animal hut little known. "In tho whole of Europe, for example, thero are no lions except between the Achelous and the Nessus." Again, the same author (viii., xxviii. 33 of Scaliger's division) mentions Europe as abundant in lions, and especially in that part which is between the Achelous and Nessus; apparently copying the statement of Herodotus. Pliny (viii. 16) does the same, and adds that the lions of Europe are stronger than those of Africa and Syria. Pausanias copies the same story as to tho attack of tho lions on the camels of Xerxes; and ho states moreover that lions often descended into the plains at the foot of Olympus, which separates Macedonia from Thessaly; and that Polydamas, a celebrated athlete, a contemporary of Darius Nothus, slew one of them, although he was unarmed. The passage in Oppian ('Cyneg.,' iii. 22) which some have considered as indicating the existence of lions up to the banks of the Danube, fails as an authority for placing the Lion in that locality, because, as Cuvier observes, the context shows plainly that the name of Ister is there applied to an Armenian river either by an error of the author or of the transcribers.

Nor is Europe the only part of the world from which the form of the Lion has disappeared. Lions are no longer to be found in Egypt, Palestine, or Syria, where they once were evidently far from uncommon. The frequent allusions to the Lion in the Holy Scriptures and the various Hebrew terms there used to distinguish the different ages and sex of the animal (see particularly Jer., li. 38; Ezek., xix. 2; Nah., ii. 13; Ezek., xix. 2, 3; Psalm xci. 13; Prov., xix. 12, &c.; Nah., ii. 12, &c.; Job, iv. 10—x. 16; Prov., xxvi. 13; Hosea, v. 14—xiii. 7; Prov. xxx. 30) prove a familiarity with the habits of the race. Even in Asia generally, with the exception of some countries between India aud Persia, and some districts of Arabia, these magnificent beasts have, as Cuvier observes, become comparatively rare, and this is not to ho wondered at. To say nothing of the immense draughts on the raco for the Roman arena—and they were not inconsiderahle, for, as Zimmerman has shown, there were a thousand lions killed at Rome in the space of forty years—population and civilisation have gradually driven them within narrower limits, and their destruction has been rapidly worked in modern times when fire-arms have been used against them instead of the bow and the spear. The African Lion is annually retiring before the persecution of man farther and farther from the Cape. Mr. Bennett ('Tower Menagerie') says of the Lion: "His true country is Africa, in the vast and untrodden wilds of which, from the immense deserts of the north to the trackless forests of the south, he reigns supreme and uncontrolled. In the sandy deserts of Arabia, in some of the wild districts of Persia, and in the vast jungles of Hindustan, he still maintains a precarious footing; but from the classic soil of Greece, as well as from the whole of Asia Miuor, both of which were once exposed to his ravages, he has been utterly dislodged and extirpated."

Lions of the Old World.—Zoologists generally distinguish tho Lion by its uniform yellow colour, the tuft of hair at the end of the tail, and the mane covering the head and shoulders of the male. This last ornament, as we shall presently see, is very much reduced in one variety with which we were made well acquainted some years ago by Captain Smee; indeed so scanty is it that it hardly deserves the name of a mane at all.

If we go back to an early period, we shall find varieties of this great cat, usually considered as the strongest of the family, depending on the greater or less inteusity of colour for the most part, meutioned by ancient writers on natural history. Thus, Aristotle (ix. 44) distinguishes two kinds of lions, one rounder than the other (*στρογγυλώτερον*), and which has the mane more curled (*οὐλοτριχώτερον*), which he states to be the most timid (*δειλότερον*); the other longer and with a well-developed mane (*εὔτριχον*), which he says is more courageous (*ἀνδρειότερον*). Pliny (viii. 16) remarks that the Lion is most noble when a mano covers his neck and shoulders; and he also (loc. cit.) alludes to a maneless lion, the offspring of a monstrous counection. ("Leoni præcipua generositas, tunc cum colla armosque vestiunt jubæ. Id enim ætate contingit e leone conceptis. Quos vero pardi generavere, insigni hoc carent.") In Africa, he goes on to remark, such connections are frequent: "Multiformes ibi animalium partus, vario fœminis cujusque generis mares aut vi aut voluptate miscente;" whence, he adds, the Greek vulgar saying, that Africa is always producing something new. In the same chapter, Pliny, after alluding to the European lions and their comparative boldness, as above stated, repeats the observation of Aristotle, that there are two kinds of lions, one compact and short with curled mane, which are more timid than those with a long and simple one ("longo simplicique villo"); which last despise the wounds inflicted on them. In the 17th chapter of tho same book, Syria is stated to be the locality of a hlack lion: "cæteris uuus cujusquo generis color est. Leonum tantum in Syria niger." Ælian (xvii. 26) distinguishes the lions which como from India from other lions, stating that the skin of the Indian lions is hlack. Oppian (iii.), towards the beginning of that book, notices the differences between the lions of Armenia, Arabia ('Ερεμβῶν ἄρουρα), Lihya, and Ethiopia.

These distinctions are altogether rejected by Buffon, who denies that there are different kinds of lions. He denies, also, that any lion has a curled mane, which, by the way, Aristotlo does not assert, for he only says that one kind has the mane more curly than the other. Buffon further affirms that the lions of Africa and Asia entirely resemble each other; and declares that if the lions of the mountains differ from those of the plains, the difference is less in the colour of the skin than in the size of the respectivo animals.

Linnæus, in his last edition of the 'Syst. Nat.,' notices no varieties: he places *Felis Leo* at the head of his genus *Felis,* with Africa only as tho habitat. Neither does Gmelin distinguish any varieties, but he much increases the distrihutiou; for he speaks of tho Lion as inhabiting Africa, especially in the interior, as being rarer in the deserts of Persia, India, and Japan, and as having formerly occurred in other warmer parts of Asia, in Palestine, in Armenia, and in Thrace.

Pennaut ('Hist. Quad.,' 3rd edition) appears to coincide in opinion with Buffon, Linnæus, aud Gmelin; for he mentions no distinctions, and describes the Lion as "au inhabitant of most parts of Africa, and rarely of the hot parts of Asia, such as India and Persia; and a few are still met with in the deserts between Bagdat aud Bassorah, on tho hanks of the Euphrates. Mr. Niebuhr also places them among the animals of Arabia; but their proper country is Africa, where their sizo is the largest, their numbers greatest, and their rago more tremendous, being inflamed by the influence of a burning sun upon a most arid soil. Dr. Fryer says that thoso of India are feeble and cowardly. In the interior parts, amidst the scorched and desolate deserts of Zaara, or Biledulgerid, they reign sole masters; they lord it over every beast, and their courage never meets with a check, where the climate keeps mankind at a distance; the nearer they approach the inhabitants of the human race, the less their rago, or rather the greater is their timidity: they have often experienced tho unequal combat, and finding that there exists a being superior to them, commit their ravages with more caution. A cooler climate again has the same effect; but in the burning deserts, where rivers and fountains are denied, they live in a perpetual fever—a sort of madness fatal to every animal they meet with."

Dr. Leach raised the form to the rank of a genus under the name of *Leo*.

M. Lesson, in his 'Manuel' (1827), gives four varieties, namely, the lion of Barbary, the lion of Senegal, the lion of Persia or Arabia, and the lion of the Cape.

Cuvier ('Règne Animal,' 1829) places at the head of the great genus *Felis*, "Le Lion (*Felis Leo*, Linn.)," and describes it as distinguished by its uniform yellow colour, the tuft of hair at the end of the tail, and the mane which covers the head, neck, and shoulders of the male. "It is," continues Cuvier, "the strongest and the most courageous of the animals of prey. Spread, at one time, over all the parts of the ancient world, it would appear at the present day nearly confined to Africa and some neighbouring parts of Asia."

M. Temminck, in his 'Monograph,' includes three varieties under *Felis Leo*, namely, the lions of Barbary, Senegal, and Persia, and these are retained in Dr. Fischer's 'Synopsis.'

Mr. Bennett ('Tower Menagerie,' 1829) notices the Bengal Lion, the Cape Lion, and the Barbary variety (figuring the two former), and observes upon their distinctions.

Sir William Jardine ('Naturalists' Library,' '*Mammalia*,' vol. ii., *Felinæ*, 1834), in addition to other plates, has given a figure of the Asiatic variety from a specimen in the Surrey Zoological Gardens, and, after noticing that the lions of Africa and India have been described as varieties, states his strong suspicions that future observations will prove these animals to be in reality distinct species, and notices them separately under the names of *Leo Africanus* and *Leo Asiaticus*; he also alludes to the Maneless Lion.

Mr. Swainson ('Classification of Quadrupeds,' 1835) places the African Lion (*Leo Africanus*, Sw.) at the head of the *Felidæ*. In his arrangement at the end of the volume he notices the form under the designation of "*Leo Antiquorum* (Lions). Head and neck furnished with a mane of long hair; tail tufted." The next genus, *Felis L.* (Cats), he characterises thus: "No mane; tail long, not tufted." In his 'Animals in Menageries,' 1838, the Lion does not appear to be noticed.

Of the African Lions Temminck notices two varieties—that of Barbary and that of Senegal. M. Lesson adopts these two varieties, and adds the Lion of the Cape, of which he gives two varieties.

The Lion of Barbary.—This lion is described as having a deep yellowish-brown fur, and the mane of the male is stated to be very much developed.

The Lion of Senegal is characterised by a fur of a more yellow tint, the mane in the male being less thick, and nearly wanting upon the breast and insides of the legs.

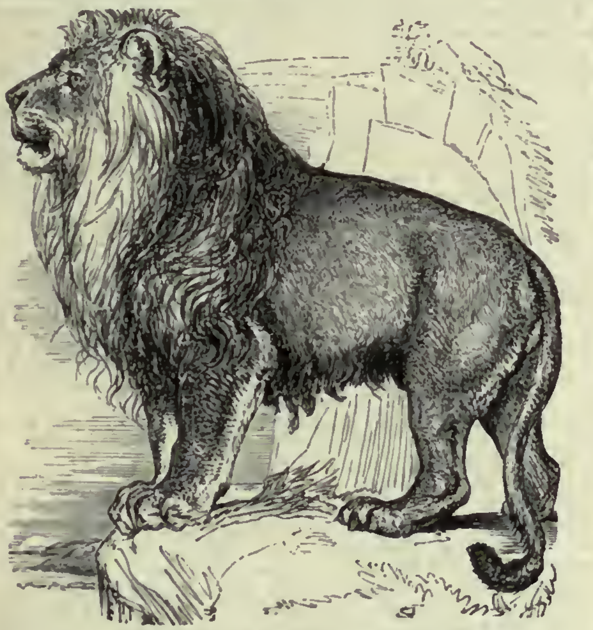
The Lion of the Cape presents two varieties, one yellowish and the other brown: the latter is regarded as the most ferocious and formidable. The Dutch colonists speak of the "blue and the black" kinds, and it seems indeed that there is a black-maned lion, one of which, accompanied by his lioness, Mr. Burchell appears to have encountered in his travels in Africa.

Mr. Burchell well observes, that 'King of the Forest' is a title not very applicable to an animal which he at least never met but on the plains; nor did he ever meet with one in any of the forests where he had been. The low cover that creeps along the sides of streams, the patches that mark the springs, or the rank grass of the valley, seem to be the shelter which the African Lion for the most part seeks. Of the strength of this variety we have most extraordinary examples on record. To carry off a man—and there are dismal accounts of this horrible fact, which there is no reason to doubt—appears to be a feat of no difficulty to this powerful brute. Indeed, when we find that a Cape lion seized a heifer in his mouth, and, though the legs dragged upon the ground, seemed to carry her off with the same ease as a cat does a rat, leaping over a broad dike with her without the least difficulty—that another, and a young one too, conveyed a horse about a mile from the spot where he had killed it—and that a third, which had carried off a two-year old heifer, was followed on the spoor, or track, for five hours by horsemen, when it appeared that throughout the whole distance the carcass of the heifer was only once or twice discovered to have touched the ground (Sparrman)—the asportation of a man shrinks into insignificance as a demonstration of strength. There seems to be an idea that the Lion prefers a human prey; but be this as it may, the inhabitants of certain districts have, it appears, been under the necessity of resorting to a curious expedient to get out of their reach. Messrs. Schoon and M'Luckie, in 1829, penetrated to the eastward of Kurrichaine, situated about 200 miles to the north-east of Litakou. They discovered, east of Kurrichaine, or Chuan, as it is more properly named, the river Moriqua, which rises in the south between the 25th and 26th degrees of latitude, and 29th and 30th degrees of longitude, taking a north-easterly course, and about 100 miles from the ford enters a high ridge of mountains. From hence, according to the natives, it flows into the sea, through the country of the Mantatees. About 70 miles to the eastward, the range of mountains takes a direction north and south. At the distance of 14 miles to the south, along the base of the mountains, is a place called Ongo-rutcie-Fountain, where there is a large tree containing seventeen conical huts. These are used as dormitories, being beyond the reach of the lions, which, since the incursion of the Mantatees, when so many thousands of persons were massacred, have become very numerous in the neighbourhood, and destructive to human life. The branches of these trees are supported by forked sticks or poles, and there are three tiers or platforms, on which the huts are constructed. The lowest is nine feet from the ground, and holds ten huts; the second, about eight feet high, has three huts; and the upper story, if it may be so called, contains four. The ascent to these is made by notches cut in the supporting poles, and the huts are built with twigs, thatched with straw, and will contain two persons conveniently. The travellers had previously visited several deserted villages, similarly built, between the Moriqua and Leutlecan rivers, as well as in other places; but these were erected on stakes about eight feet above the ground and about forty feet square, larger in some places, and containing about seventy or eighty huts. The inhabitants sit, it is stated, under the shade of these platforms during the day, and retire to the elevated huts at night.*

The general prey of the African Lion consists of the larger herbivorous quadrupeds, very few of which it is unable to master, and it is a severe scourge to the farmer, who is consequently ever on the look-out for lions, and generally a most imperturbable and unerring shot. Though mortal accidents frequently happen in these huntings, the cool sportsman seldom fails in using his rifle with effect. Lions when roused, it seems, walk off quietly at first, and if no cover is near, and they are not pursued, they gradually mend their pace to a trot, till they have reached a good distance, and then they bound away. Their demeanour upon these occasions has been described to us by eye-witnesses to be of a careless description, as if they did not want a fray, but if pressed were ready to fight it out. If they are pursued closely, they turn and couch, generally with their faces to the adversary; then the nerves of the sportsman are tried. If he is collected and master of his craft, the well-directed rifle ends the scene at once; but if, in the flutter of the moment, the vital parts are missed, or the ball passes by, leaving the lion unhurt, the infuriated beast frequently charges on his enemies, dealing destruction around him. This however is not always the case, and a steady unshrinking deportment has, in more instances than one, saved the life of the hunter. Mr. Burchell gives an interesting account in his African travels of his confronting one of these animals. "The day was exceedingly pleasant, and there was not a cloud to be seen. For a mile or two, we travelled along the banks of the river, which, in this part, abounded in tall mat-rushes. The dogs seemed much to enjoy prowling about, and examining every bushy place, and at last met with some object among the rushes which caused them to set up a most vehement and determined barking. We explored the spot with caution, as we suspected, from the peculiar tone of their bark, that it was what we suspected it to be,—lions. Having encouraged the dogs to drive them out, a task which they performed with great willingness, we had a full view of an enormous black-maned lion and lioness. The latter was seen only for a minute, as she made her escape up the river, under the concealment of the rushes; but the lion came steadily forward, and stood still to look at us. At this moment we felt our situation not free from danger, as the animal seemed preparing to spring upon us, and we were standing on the bank, at the distance of only a few yards from him, most of us being on foot and unarmed, without any visible possibility of escaping. I had given up my horse to the hunters, and was on foot myself; but there was no time for fear, and it was useless to attempt avoiding him. . . . I stood well upon my guard, holding my pistols in my hand, with my finger upon the trigger; and those who had muskets kept themselves prepared in the same manner. But at this instant the dogs boldly flew in between us and the lion, and surrounding him, kept him at bay by their violent and resolute barking. The courage of those faithful animals was most admirable: they advanced up to the side of the huge beast, and stood making the greatest clamour in his face, without the least appearance of fear. The lion, conscious of his strength, remained unmoved at their noisy attempts, and kept his head turned towards us. At one moment, the dogs perceived his eye thus engaged, had advanced close to his feet, and seemed as if they would actually seize hold of him; but they paid dearly for their impudence, for, without discomposing the majestic and steady attitude in which he stood fixed, he merely moved his paw, and, at the next instant, I beheld two lying dead. In doing this he made so little exertion, that it was scarcely perceptible by what means they had been killed. Of the time which we gained by the interference of the dogs, not a moment was lost: we fired upon him; one of the balls went through his side, just between the short ribs, and the blood began to flow, but the animal still remained standing in the same position. We had now no doubt that he would spring upon us: every gun was instantly reloaded; but happily we were mistaken, and were not sorry to see him move quietly away, though I had hoped in a few minutes to have been enabled to take hold of his paw without danger." Even where the hunter has been

* See 'South African Journal,' September, 1830; and Steedman's 'Wanderings and Adventures in the Interior of Southern Africa, where the reader will find a drawing of the inhabited tree above described, taken by Mr. Moffat of Litakou, who also visited this spot.

seized with a panic and pursued, a timely recovery of self-possession has saved him. Sparrman relates that Jacob Kok of Zee-Koe-Rivier, one day walking over his lands with his loaded gun, unexpectedly met a lion. Being an excellent shot, he thought himself pretty certain, from the position in which he was, of killing it, and therefore fired his piece. Unfortunately he did not recollect that the charge had been in it for some time, and consequently was damp; so that his piece hung fire, and the ball falling short, entered the ground close to the lion. In consequence of this he was seized with a panic and took directly to his heels; but being soon out of breath and closely pursued by the lion, he jumped up on a little heap of stones, and there made a stand, presenting the butt end of his gun to his adversary, fully resolved to defend his life as well as he could to the utmost. This deportment had such an effect on his pursuer, that he also made a stand, and lay down at the distance of a few paces from the heap of stones seemingly quite unconcerned. Jacob, in the mean time, did not stir from the spot; besides he had in his flight unfortunately dropped his powder-horn. At length, after waiting a good half-hour, the lion rose up, and at first went very slowly, and step by step only, as if he had a mind to steal off; but as soon as he got to a greater distance, he began to bound away at a great rate. There is hardly a book of African travels which does not teem with the dangers and hair-breadth escapes of the lion-hunters, and hardly one that does not include a fatal issue to some engaged in this hazardous sport; but our limits will not allow us to enter into further details on this part of the subject, and we must refer to such works for accounts—and they are very interesting—of the different modes of destruction employed against this powerful beast, from the poisoned arrow of the Bushman to the rifle of the colonist.



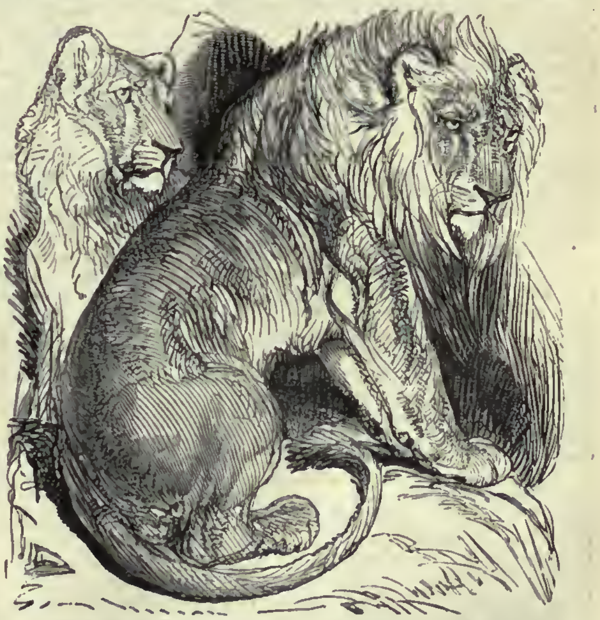
Africaa Lion (*Leo Africanus*). (Barbary.)

The following extracts from an anonymous work entitled 'Zoological Anecdotes' embody some of the observations made by Mr. Cuming, whose collection of stuffed animals from Africa were so long exhibited at Hyde Park Corner:—

"The following powerfully-drawn picture conveys a most accurate idea of the fearful banquets held in the primæval forests of Africa, and at the same time is full of interest from the light it throws on the habits of the *Carnivora*. Mr. Cuming had shot three rhinoceroses near a fountain, and soon after twilight had died away he came down to the water to watch for lions. With him was his Hottentot Kleinboy. 'On reaching the water I looked towards the carcass of the rhinoceros, and to my astonishment I beheld the ground alive with large creatures, as though a troop of zebras were approaching the water to drink. Kleinboy remarked to me that a troop of zebras were standing on the height. I answered 'Yes;' but I knew very well that zebras would not be capering around the carcass of a rhinoceros. I quickly arranged my blankets, pillow, and guns in the hole, and then lay down to feast my eyes on the interesting sight before me. It was bright moonlight, as clear as I need wish. There were six large lions, about twelve or fifteen hyænas, and from twenty to thirty jackalls, feasting on and around the carcasses of the three rhinoceroses. The lions feasted peaceably, but the hyænas and jackalls fought over every mouthful, and chased one another round and round the carcasses, growling, laughing, screeching, chattering, and howling, without any intermission. The hyænas did not seem afraid of the lions, although they always gave way before them; for I observed that they followed them in the most disrespectful manner, and stood laughing, one or two on either side, when any lions came after their comrades to examine pieces of skin or bones which they were dragging away.' The following account of an attack by one of these man-eaters, as they are called (for having once tasted human flesh they will eat nothing else if it can be obtained), makes the blood run cold. Mr. Cuming and his party had, unknown to them, pitched their camp in the proximity of a lion of this description. All had retired to rest, when (says Mr. C.) 'suddenly the appalling and murderous voice of an angry bloodthirsty lion burst upon my ears within a few yards of us, followed by the shrieking of the Hottentots. Again and again the murderous roar of attack was repeated. We heard John and Ruyter shriek, 'The lion! the lion!' Still for a few moments we thought he was but chasing one of the dogs round the kraal, but the next instant John Stofulus rushed into the midst of us, almost speechless with fear and terror, his eyes bursting from their sockets, and shrieked out, 'The lion! the lion! He has got Hendrick! He dragged him away from the fire beside me. I struck him with the burning brands upon his head, but he wouldn't let go his hold. Hendrick is dead! O God! Hendrick is dead! Let us take fire and seek him.' The rest of my people rushed about shrieking and yelling as if they were mad. I was at once angry with them for their folly, and told them that if they did not stand still and keep quiet the lion would have another of us, and that very likely there was a troop of them. I ordered the dogs which were nearly all fast to be made loose, and the fire to be increased as far as could be. I then shouted Hendrick's name; but all was still. I told my men that Hendrick was dead, and that a regiment of soldiers could not now help him; and hunting my dogs forward, I had everything brought within my cattle kraal, when we lighted our fire and closed the entrance as well as we could. It appeared that when the unfortunate Hendrick rose to drive in the ox the lion had watched him to his fireside, and he had scarcely lain down when the brute sprang upon him and Ruyter (for both lay under one blanket) with his appalling murderous roar; and roaring as he lay, grappled him with his fearful claws, and kept biting him on the breast and shoulder, all the while feeling for his neck; having got hold of which, he at once dragged him away backwards round the bush into the dense shade. As the lion lay on the unfortunate man he faintly cried, 'Help me! help me! O God! men, help me!' After which the fearful beast got hold of his neck, and then all was still, except that his comrades heard the bones of his neck cracking between the teeth of the lion.' It is satisfactory to know that on the following day Mr. Cuming took revenge on the lion, whose huge grisly hide is to be seen in his collection at Hyde Park Corner."

Of Asiatic Lions three kinds are mentioned—the Bengal Lion, the Persian or Arabian Lion, and the Maneless Lion of Guzerat.

The Bengal Lion.—Mr. Bennett points out the characteristics by which the Asiatic race is distinguished from that of Southern Africa, as consisting principally in the larger size, the more regular and graceful form, the generally darker colour, and the less extensive mane of the African. He gives a beautiful cut of the Bengal Lion, executed by Harvey, in the 'Tower Menagerie,' from a very fine specimen little more than five years old, then in that collection, but called by the keepers 'The Old Lion.' The magnificent development of the mane is very striking in this figure.



Lion (mane not quite fully developed) from Eastern Asia, with Lioness.

The Persian or Arabian Lion.—This is stated to be distinguishable by the pale Isabella colour of the fur, and those which have been exhibited in England as Persian Lions certainly bear out this remark; but Captain Smee observes that the Persian Liou formerly exhibited at the Surrey Zoological Gardens seemed to him to differ but little from individuals known to be brought from Africa.

Persian Lion.

The Maneless Lion of Guzerat.—The reader will bear in mind the passage quoted from Pliny (viii. 16), touching lions which have no mane, and of the origin attributed to them. Cuvier notices the statement that maneless lions had been found on the confines of Arabia, and merely refers to Olivier, observing that there is no detailed description given of them. A zoological description is doubtless not to be found in Olivier; but he enters somewhat minutely into the subject, as the reader will here see. "The lion," says Olivier ('Voyage dans l'Empire Othoman, l'Egypte, et la Perse,' tom. iv.), "which inhabits the part of Arabia and Persia near the river of the Arabs, from the Persian Gulf to the environs of Helle and of Baghdad, is probably the species of lion of which Aristotle and Pliny have spoken, and which they regarded as a different species from that which is spread over the interior of Africa. The Liou of Arabia has neither the courage, nor the stature, nor even the beauty of the other. When he would seize his prey he has recourse to cunning rather than force; he crouches among the reeds which border the Tigris and Euphrates, and springs upon all the feeble animals which come there to quench their thirst; but he dares not to attack the boar, which is very common there, and flies as soon as he perceives a man, a woman, or even a child. If he catches a sheep, he makes off with his prey; but he abandons it to save himself, when an Arab runs after him. If he is hunted by horsemen, which often happens, he does not defend himself unless he is wounded and has no hope of safety by flight. In such a case he will fly on a man, and tear him to pieces with his claws, for it is courage more than strength that he wants. Achmed, pasha of Baghdad from 1724 to 1747, would have been torn by one after breaking his lance in a hunt, if his slave Suleiman, who succeeded him in the pashalik, had not come promptly to his succour, and pierced with a blow of his yataghan the lion already wounded by his master."

"We saw," continues Olivier, "five individuals of this race in the menagerie of the pasha of Baghdad; they had been there five years, and had been taken young in the environs of Bassora. There were three males and two females; the former were a little larger than the latter; and all much resembled the African species, excepting that they were smaller, and had no mane. We were assured that they never had any, and that no lion of those countries had one. We have often regretted that we did not ask the pasha for two of them, in order to a close comparison with the African species, and to satisfy ourselves whether the Lion of Arabia ought to be regarded as a species distinct from the other, or as a degenerated race."

In December 1833, Captain Walter Smee exhibited to a meeting of the Zoological Society of London the skins of a lion and lioness killed by him in Guzerat, and selected from eleven obtained there by him, eight of which he had brought to this country. This lion, he stated, is distinguished from those previously known by the absence of a mane (that is, it is maneless as compared with other lions) from the sides of the neck and shoulders, the middle line of the back of the neck being alone furnished with longer hairs, which are erect, like those in the same situation in the Cheetah (*Felis jubata*). The under surface of the neck has long loose silky hairs, and there is a tuft at the angle of the anterior legs. Besides the absence of the extensive mane, the tail is shorter than that of ordinary lions, and is furnished at its tip with a much larger brush or tuft. In this tuft there existed in the oldest of Captain Smee's lions, subsequently to the arrival of the skin in England, a short horny claw or nail, similar in form to, but somewhat larger in size than that described by Mr. Woods, and above alluded to.

Captain Smee, ('Transactions of the Zoological Society,') enters into a very minute description of the arrangement of the hair in this variety, both in the male and the female, observing that both the African and Guzerat Lion are subject to considerable variations in intensity of colouring. In both the colour is fulvous; but in some individuals, he says, this is much paler than in others, and in the darker specimens there occurs a tinge of red. The middle of the back is the most deeply coloured part, and the under surface is much paler and almost white. Among the hairs there is an intermixture of some which are entirely black, and the greater or less proportion which these bear to the paler ones is the principal cause of the variations in depth of colour that occur in different individuals. Of the Guzerat Lions the oldest individual is the lightest in colour. The tail becomes gradually paler towards its extremity, passing into grayish white; its terminal brush consisting of black hairs slightly tinged with brown. Above each eye is a pale space, in which is included a darker-coloured spot for the implantation of the supraciliary vibrissæ, from twelve to fifteen in number, and of which the longest reaches nearly to the ears. In the African Lion these vibrissæ are implanted in a darker spot, but this spot is less defined, and is only partially bounded by a paler space. In both the points of insertion of the moustaches are darker than the surrounding parts. Captain Smee does not speak with certainty of the comparative form of these two varieties; but he states his impression to be that the Liou of Guzerat is comparatively more rounded and bulky in its body, and rather shorter in its limbs; and that its head especially is shorter, has less of the square form which distinguishes the open face of the male African Lion, and is more rounded on the forehead. But, as he observes, this difference may be chiefly owing to the long hairs which conceal the forehead in the one, while that feature is defined and visible in the other. The cranium of the Lion of Guzerat generally resembles that of the African race. Professor Owen had remarked that the infra-orbital foramina were double in the only lions known to be Asiatic examined by him; in one, killed in North Guzerat, this occurs on both sides; in the other, killed near Assund, it is found on one side only. Captain Smee states that in a young skull of the Maneless Lion there exists on one side a double infra-orbital foramen, and that the existance of the same structure in another skull contained in one of the skins had been ascertained. A male Maneless Lion killed by Captain Smee measured, including the tail, 8 feet 9½ inches in length, and his total weight, exclusive of the entrails, was 35 stone (14 lbs. to the stone); the impression of his paw on the sand measured 6¼ inches across, and his height was 3 feet 6 inches. A female killed at the same time was 8 feet 7 inches long and 3 feet 4 inches high.

These Maneless Lions are, according to the author last quoted, found in Guzerat along the banks of the Sombermuttee near Ahmedabad. During the hot months they inhabit the low bushy wooded plains that skirt the Bhardar and Sombermuttee rivers from Ahmedabad to the borders of Cutch, being driven out of the large adjoining tracts of high grass jungle (called Bheers) by the practice annually resorted to by the natives of setting fire to the grass, in order to clear it and ensure a succession of young shoots for the food of the cattle upon the first fall of the rains. They extend through a range of country about 40 miles in length, including various villages, and among others those of Booroo and Goliaua, near which Captain Smee killed his finest specimens. They were so common in this district that he killed no fewer than eleven during a residence of about a month; yet scarcely any of the natives, except the cattle-keepers, had seen them previously to his coming among them. The cattle were frequently carried off or destroyed, but this they attributed to tigers. Captain Smee however observes, that the tiger does not exist in that part of the country. Those natives to whom the lions were known gave them the name of Ontiah Baug, or Camel-Tiger, an appellation derived from their resemblance in colour to the camel. They appear to be very destructive to the domesticated cattle, and the remains of a considerable number of carcasses of bullocks were found near the place where Captain Smee's specimens were killed. About ten days previously, four donkeys had been destroyed at the village of Cashwah. Captain Smee could not learn that men had been attacked by them. When struck by a ball, they exhibited great boldness, standing as if preparing to resist their pursuers, and then going off slowly and in a very sullen manner; unlike the tiger, which on such occasions retreats springing and snarling. Captain Smee states that these lions are also found on the Runn near Runpoor, and near Puttun in Guzerat, and that some persons who saw them in Bombay said that they also occur in Sinde and in Persia. He further observes, that should subsequent inquiries prove that Olivier was correctly informed as to the locality from which the Maneless Lions seen by him at Baghdad were obtained, and prove also their identity with those of Guzerat, a more extensive geographical range will be established for this curious race than Captain Smee is at present disposed to regard as probable.

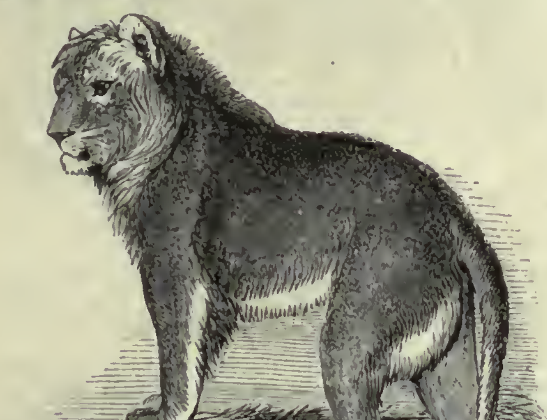
Captain Smee remarks that he is aware that the existence of these Maneless Lions in Guzerat had been previously although by no means generally known, and quotes Colonel Sykes as having this knowledge. Sir Charles Malet had also seen lions on the banks of the Sombermuttee, and though he makes no mention of the absence of the mane, Captain Smee thinks that they in all probability belonged to this maneless race, and indeed Sir Charles attributes to his lion the native name noticed by Captain Smee above.

Our author makes the following remarks on the passages to be found in the ancient writers bearing on this subject : "Having alluded in the commencement of this communication, to the opinion that a maneless lion was known to the ancients, it might be expected that I should here bring forward and discuss the several passages which have been looked upon as supporting this view. Where however the critics are at fault, it would be presumptuous in me to attempt to decide. I own that I do not find in the passages usually referred to any evidence at all satisfactory as regards the existence of lions destitute of mane; and I am even far from willing to admit that the crisped hairs noticed by Aristotle as distinguishing one race of lions from another, in which the hairs were either dense or straight, must of necessity be considered as those of the mane rather than of any other part of the body. The language of Oppian is equally obscure, and even the expressions used by him are warmly contested by the critics. Another Greek writer, Agatharchides, the Peripatetic, speaks of the Arabian and especially the Babylonish Lions, in terms that recall Olivier's description of those of Baghdad, but still with no definite application to the want of a mane. Pliny alone, so far as I am aware, mentions the absence of mane as a distinctive mark of one race of lions; but to this race he attributes a monstrous generation, and he was probably altogether misled with respect to it."

We may here remark that a maneless lion is said to be represented on the monuments of Upper Egypt.

Captain Smee thus characterises his Maneless Lion :—

Felis Leo, Linn., var. *Goojratensis*.—Mane of the male short, erect; tuft at the apex of the tail very large, black. ('Zool. Proc.,' 1833; and also 'Zool. Trans.,' vol. i.)



Maneless Lion of Guzerat.

The habits of the Asiatic Lions do not differ much from those of Africa, excepting that the former, from the state of the country frequent jungles. In India the elephant is generally employed in the chace, which is even now conducted with more pomp and circumstance than in Africa. The grand Asiatic huntings of former times, those of Genghis Khan for instance, will occur to many of our readers. The accounts of most Asiatic modern sportsmen give a most courageous bearing to the lions in these encounters. One of these states that the lions in India, instead of running away when pursued through a jungle, seldom take to cover as a refuge at all. On the approach of their enemies, they spring out to meet them open-mouthed in the plain. They are thus easily shot; but if they are missed or only slightly wounded, they are most formidable adversaries. They are even said to have sprung on the heads of the largest elephants, and to have fairly pulled them to the ground, riders and all.

The lioness is said to go with young five months, and produces generally from two to three or four at a litter, which are born blind. Three, two males and a female, were whelped in the Tower on the 20th October 1827, the day of the battle of Navarino; but the number seems generally to be two. In captivity the lioness usually becomes very savage as soon as she becomes a mother; and in a state of nature both parents guard their young with the greatest jealousy. Mr. Bennett relates that in the commencement of the year 1823, General Watson, then on service in Bengal, being out one morning on horseback armed with a double-barrelled rifle, was suddenly surprised by a large male lion, which bounded out upon him from the thick jungle at the distance of only a few yards. He instantly fired, and the shot taking complete effect, the animal fell dead almost at his feet. No sooner had the lion fallen than the lioness rushed out, which the general also shot at, and wounded severely, so that she retired into the thicket. Thinking that the den could not be far distant, he traced her to her retreat, and there dispatched her, and in the den were found two beautiful cubs, a male and a female, apparently not more than three days old. These the general brought away; they were suckled by a goat and sent to England, where they arrived in September 1823, as a present to George IV., and were lodged in the Tower. The male was the animal from which Mr. Bennett gives his figure and description of the Bengal Lion, and the female was the mother of the cubs whelped in the Tower, above alluded to. ('Tower Menagerie.') The young are at first obscurely striped, or brindled, and somewhat tiger-like in the coat. There is generally a blackish stripe extending along the back, from which numerous other bands of the same colour branch off, nearly parallel to each other on the sides and tail. The head and limbs are generally obscurely spotted. When young they mew like a cat; as they advance the uniform colour is gradually assumed, and at the age of ten or twelve months the mane begins to appear in the males; at the age of eighteen months this appendage is considerably developed, and they begin to roar. (Bennett.) F. Cuvier states that it is nearly the third year before the mane and the tuft on the tail appear, and that they are not fully developed before the seventh or eight year. It should however be borne in mind that the Bengal Lion mentioned by Mr. Bennett, and figured by him, was magnificently maned, and he was little more than five years old. The period of shedding the milk-teeth is very often fatal to the young animals in a state of captivity. The natural period of a lion's life is generally supposed to be 20 or 22 years. Such is Buffon's limitation, but the animal will it seems live much longer. Pompey, the great lion which died in 1760, was said to have been in the Tower above 70 years; and one from the river Gambia is stated to have since died there at the age of 63.

The lion, from its power and supposed generosity of disposition, has been popularly hailed as the King of Beasts, and considered as the emblem of majesty and might. It is the symbol of the British nation, and is borne in the royal arms, of which it forms one of the supporters, and which it surmounts as the crest. Captain Smee remarks, in allusion to the hybrid mentioned by Pliny, that it is by no means improbable that the maneless feline beast which occurs in the older armorial bearings may have been intended to represent a lion leoparded. This term, he observes, is still in use among the heralds of France, but is employed by them with reference only to the position of the head; if the full face is shown, the animal, whether maned or maneless, is in their language a leopard; if the side face alone is seen, it is a lion. Hence with them the lions passant and gardant of the arms of the kings of England would be either lions leoparded or leopards maned. He goes on to state that the omission of the mane, in rude tricking, would indeed reduce them to leopards, and as such they were originally regarded. The emperor Frederic II., in choosing his present of three leopards to our Henry III., was actuated, according to Matthew Paris, by the bearing in the royal shield of England, "in quo tres leopardi transeuntes figurantur." ('Zool. Trans.')

The generosity of disposition so liberally accorded to this powerful beast has been much and eloquently praised. It seems almost sacrilegious to dissipate the glowing vision which Buffon has raised; but if there is any dependence to be placed on the observations of those travellers who have had the best opportunities of judging, and have the highest character for veracity, we must be compelled to acknowledge that Buffon's lion is the lion of poetry and prejudice, and very unlike the cautious lurking savage that steals on its comparatively weak prey by surprise, overwhelms it at once by the terror, the weight, and the violence of the attack, and is intent only on the gratification of its appetites. "At the time," says Mr. Burchell, "when men first adopted the lion as the emblem of courage, it would seem that they regarded great size and strength as indicating it; but they were greatly mistaken in the character they had given of this indolent animal." The fact of the lion sparing the dog that was thrown to him, and making a friend of the little animal that was destined for his prey, has been much dwelt on; but these and other such acts of mercy, as they have been called, may be very easily accounted for. If not pressed by hunger, the lion will seldom be at the trouble of killing prey; and the desire for a companion has created much stronger friendships between animals in confinement than that between a lion and a little dog.

The lion is easily tamed, and capable of attachment to man. The story of Androdus, frequently called Androcles, is too well known to need more than allusion, and we learn from Bell's 'Travels' that the monarch of Persia had on days of audience two great lions chained on each side of the passage to the state-room, led there by keepers in golden chains. Every wild-beast show almost has its tame lion, with which the keeper takes the greatest liberties—liberties which the beast will suffer, generally speaking, from none but him. All these exhibitions however were entirely eclipsed by the feats of Mr. Van Amburgh, who exercised a complete control over the lions and other great *Felidæ* which he had subjected to his will. The imitators of Van Amburgh however have not been so successful, and instances have occurred in which persons have forfeited their lives by their temerity. An instance of this kind occurred a few years ago in England, in which a young woman, who was called the Lion Queen, lost her life in this way.

Hybrids.—The Lion and Tigress will, under certain circumstances, produce young. This has happened twice in England. Sir William Jardine gives the figure of one of a litter so bred, and exhibited in Atkins's collection, where they were whelped, in 1827: they died young. Sir William Jardine correctly describes the colour of the whelps as brighter than that of the Lion, and the bands as better marked than they generally are in the true-bed young lion. The specimen figured by Sir William is in the Edinburgh Museum. Another litter from similar parents was whelped at Windsor; but these also died before they came to maturity. There does not seem to be much difficulty in promoting this union.

Lion-Tiger Cubs.

The Puma, or American Lion.—The uniformity of colour in this great cat, combined with considerable ferocity, were probably the reasons which induced early travellers in America, who heard of it perhaps with circumstances of exaggeration, or caught hasty glimpses of it not unaccompanied with terror, to state that there were lions in America. Thus John de Laet (1633) says, that lions are found in Peru, though they be few, and not so ferocious as they are in Africa, and that they are called in the native tongue Puma. In an old tract (1649), entitled 'A Perfect Description of Virginia,' we find among the "beasts great and small," "Lyons, Beares, Leopards, Elkes," &c.; and Garcilasso tells us of the Puma, or Lion of Peru. In Hernandez (Romæ, 1651) there is a long account of the animal under the name of 'Puma, seu *Leo Americanus*;' and reasons are given to show that it is not a true lion. In Piso the animal is noticed as the Cuguacuara, and by Marcgrave as the Cuguacurana of the Brazilians; hence the French name Couguar. Charlevoix describes it clearly enough under the name of Carcajou, or Quincajou; this name Pennant thinks that Charlevoix gives by mistake. In d'Azara's Gouazouara of Paraguay we again trace the French name of this animal. Lawson and Catesby both describe it under the name of the Panther, by which designation it is known to the Anglo-Americans up to this day. It is the *Felis concolor* of Schreber and of zoologists generally, and though Linnæus is often quoted as the author of the name, it will not be found in his last edition of the 'Systema Naturæ.' In Gmelin's edition it appears as *Felis concolor* (an error for *concolor*), with Schreber's description. It is the *Felis Puma* of Traill.

The reader will find in the 'Proceedings of the Zoological Society of London' a detailed account of the dissection of a Puma that died at the Society's Garden. In one point the Puma differs considerably from other cats. This point is that part of the structure which is connected with the organs of voice, and, as Mr. Martin observes, some according modification must necessarily produce the deep-toned roar of the Lion, the snarl of the Jaguar, and the hissing cry of the Puma. "The distance between the tongue and the larynx in the Lion," says Mr. Martin, "has been brought more than once under the notice of the society; in the Jaguar this distance, comparatively speaking, is nearly as great; but in the Puma, an animal equal, or nearly so, in size to the Jaguar, the distance is reduced to an inconsiderable space, an inch or an inch and a half, according as the tongue is more or less protruded. In addition to this it is worthy of observation that the circumference of the larynx in the Puma is also very inconsiderable; compare, for example, the larynx of the Jaguar with that of the present animal, both natives of the wilds of the American continent. In the Jaguar we find a larynx indicating, from its general magnitude, considerable depth in the intonations of the voice; whereas in the Puma, if we take either its diameter or its distance from the termination of the palate and base of the tongue, we are led to expect neither the roar of the Lion nor the growl of the Jaguar, but the shrill tones of an animal, ferocious indeed, but of all others of the genus perhaps the most stealthy and insidious."

The adult male has no mane. Silvery fawn above, sometimes reddish, the tawny hairs of the upper parts whitish at the tips; nearly white beneath, and on the inside of the limbs, whitish on the throat, chin, and upper lip. Head black and gray irregularly mixed; ears on the outside, and particularly at their base, sides of the muzzle, whence the whiskers spring, and end of the tail (which has no tuft), black. Length from nose to tail about 4 feet; tail rather more than 2 feet. Female coloured like the male. Head small when compared with his.

Young.—Back marked with three chains of spots, which are generally of a blackish-brown; dispersed spots or markings on the neck, shoulders, and sides. As the animal advances in age these markings become more and more obscure, till they are at last lost in the uniform colour.

A specimen of a young Puma, exhibited at a meeting of the Zoological Society in 1831, was, like the young of the other species of *Felis*, variously spotted and striped, the depth of its markings approaching nearly to black, and being more intense than that observed in the Lion. The muzzle was nearly black, as was also the greater part of the tail. This young one had been recently brought forth at the Society's Garden, but died immediately; it was strongly contrasted with a specimen of the adult placed on the table for comparison.

This animal is found in North and South America. There is reason to think that it was formerly to be found from Canada to Patagonia, with an extensive range to the east and west, but its geographical area has been very much diminished, and is daily becoming more and more contracted before that civilisation which is in our own times obliterating more species than one. Mr. Washington Irving ('Astoria') mentions it as being about the mouth of the Columbia River.

Lawson (Carolina) gives the following characteristic account of the Puma. "The Panther is of the cat's kind; about the height of a very large grayhound, of a reddish colour, the same as a Lion. He climbs trees with the greatest agility imaginable, is very strong-limbed, catching a piece of meat from any creature he strikes at. His tail is exceeding long, his eyes look very fierce and lively, are large, and of a grayish colour; his prey is swine's flesh, deer, or anything he can take; no creature is so nice and clean as this in his food. When he has got his prey he fills his belly with the slaughter, and carefully lays up the remainder, covering it very neatly with leaves, which if anything touches he never eats any more of it. It purrs as cats do; if taken young, is never to be reclaimed from his wild nature. He hollows like a man in the woods when killed, which is by making him take a tree, as the least cur will presently do; then the huntsmen shoot him; if they do not kill him outright he is a dangerous enemy when wounded, especially to the dogs that approach him. This beast is the greatest enemy to the planter of any vermin in Carolina. His flesh looks as well as any shamble's meat whatsoever; a great many people eat him as choice food, but I never tasted of a panther, so cannot commend the meat by my own experience. His skin is a warm covering for the Indians in winter, though not esteemed among the choice furs. This skin dressed makes fine women's shoes or men's gloves."

We may here observe, without throwing doubt on other parts of Lawson's description, which is, generally speaking, confirmed by others, that, like many other writers, he has been too hasty in speaking of the irreclaimable nature of his animal. We can testify to the amiable qualities of the late Mr. Edmund Kean's 'Tom.' The Puma so called which belonged to this extraordinary actor was perfectly tame, and followed him about like a dog. Nor is this the only instance of the docility of this species. Mr. Bennett observes that in captivity the Puma readily becomes tame, and that his manners closely resemble those of the domestic cat; "like it," continues Mr. Bennett, "he is extremely fond of being noticed, raises his back and stretches his limbs beneath the hand that caresses him, and expresses his pleasure by the same quiet and complacent purring. They soon become attached to those with whom they are familiar; and numerous instances might be mentioned in which they have been suffered to roam almost at large about the house without any injurious results." ('Tower Menagerie.')

Charlevoix ('Journal,' vol. i.) gives a rather curious account of the Carcajou going a hunting with three foxes; and of his lying in wait on a tree for the elk, and leaping down upon him as he passes under.

It seems to be generally agreed that the Puma is a most destructive species; for when it meets with a herd of animals it will slay in all directions, sucking only a small portion of blood from each victim. To sheep, fifty of which it is said to have been known to kill in one night, it is most destructive, and the squatter well knows the ravages that it will make among his hogs. Though an expert climber, it is said to haunt in South America the marshy meadow-lands bordering on the rivers, rather than the forest. In the Pampas it must affect the comparatively open country; for there, as we shall presently see, it is commonly taken by the lasso. In the northern districts the swamps and prairies are its principal haunts; and its prey, where flocks and herds are not, deer principally, upon which it is said to drop in the manner described by Charlevoix with regard to the elk.

The chace of this animal is conducted, in different parts of the American continent, according to the prevailing manners of the people who go forth to hunt it. Thus Captain Head relates that as soon as the dogs unkennel a Lion (Puma) or Tiger (Jaguar) they pursue him until he stops to defend himself. If the dogs fly upon him, the Guacho jumps off his horse, and whilst he is engaged with the dogs, knocks him on the head with the balls; but if the dogs bay and do not go boldly in, the Guacho throws his lasso over him, and gallops off, dragging him along the ground, while the hounds rush upon him and tear him. In the north he generally falls by the rifle, after he is 'treed' by the hunting party. Audubon gives a most lively account of an expedition of this kind, headed by a squatter on the banks of the Coldwater River, which ended in the Puma's death. The 'cougar,' or 'panther,' as Audubon terms him, was driven 'to tree' twice, and each time received balls in that situation. Several go in company generally, for when the infuriated animal has had to deal with one hunter only, the consequences have been sometimes fatal to the latter.

Puma (*Felis concolor*).

Cuvier remarks, that as it would appear that this animal extends or did extend from California to Patagonia, he has been careful in his researches to discover whether there were not many species, or at least varieties, in this great extent of country; the conclusion at which he arrived was, that one species only existed.

The reader must bear in mind that there is another Cat of a uniform colour, *Felis unicolor*, Traill, which is said to inhabit the forests of Demerara, and is one-half less than the Puma. The Black Couguar (*F. discolor*), is allowed by some zoologists and rejected by others.

Sir William Jardine describes as the Black Puma an animal about 33½ inches long, without including the tail, which is about 13 inches, and of which he gives a figure taken from a specimen brought in a merchant vessel to Greenock. He gives as synonyms El Negro of D'Azara and the Black Cat of America (Griffith's 'Synopsis'), both with a note of interrogation. Sir William adopts Puma as a genus, and gives the following species:—*P. concolor, P. nigra, P. Yaguarundi, P. Eyra, P. Pajeros, and P. chalybeata.* Figures of *P. Yaguarundi* and *P. Pajeros* are given in the 'Zoology of the Voyage of H.M.S. Beagle,' edited by Mr. Darwin.

II. Tigers.

Although there is but one species of Tiger, properly so called, the Tiger-Cats, or those species of the genus *Felis* in which the tigerine character predominates, may be also treated of under the title before us.

The Royal Tiger, *Felis Tigris*, claims our first notice; and although poets and poetical zoologists have joined to elevate the lion with his majestic mane to the sovereignty, it may be doubted whether the Tiger is not the type of the ferocious and blood-thirsty genus *Felis*.

Some have thought that this species was but little known to the ancients; but, we think, with no sufficient grounds. The numerous passages in which the word *Tigris* (τίγρις) occurs in Greek and Latin authors leave little room for doubting this knowledge; and Hyrcania, with which it is so frequently associated by the Roman writers, is a locality well suited to what we now know of its geographical distribution.

When Aristotle ('Hist. Anim.,' viii. 28), treating of hybrid animals which spring from an intermixture of different races, says that people pretend that the dogs of India are bred from the Tiger (τοῦ τίγριος) and a bitch, not indeed at the first union, but at the third, we see no reason, considering the locality which he assigns to the *Tigris*, and the opportunities which the conquests of Alexander gave him of knowing the animals of India, why the word should be rendered otherwise than by Tiger in our present acceptation of the term. "The tiger," writes Pliny ('Nat. Hist.,' viii. 18), "is produced in Hyrcania and India;" following this up with an allusion to the 'tremendous swiftness' of the animal, and the strong attachment which the tigress, notwithstanding accidental exception, is known to manifest for her cubs. Again ('Nat. Hist.' vi. 20), he notices the Indian nations as abounding in wild tigers. Of course he does not omit the story of the origin of the Indian dogs from the Tiger, and the rejection of the two first litters as too ferocious, while the third is taken and brought up. ('Nat. Hist.,' viii. 40). But further, it is quite clear from the same authority, that the *Tigris* had been exhibited at Rome, and that Pliny and others well knew the distinction between that species and leopards and panthers. After mentioning the last two, and referring to an ancient decree of the senate that African beasts should not be imported, but stating that the tribune Cneius Aufidius caused a plebiscitum to be passed which permitted their importation for the Circensian games, he states the numbers brought first by Scaurus, and then by Pompey the Great and Augustus; adding that Augustus was the first who showed a tame tigress (tigrin) in a den at Rome, upon the dedication of the Theatre of Marcellus, during the consulship of Q. Tubero and Fabius Maximus, and that the emperor Claudius showed four together. ('Nat. Hist.,' viii. 17). Suetonius ('Aug.,' xliii.) states that it was the habit of Augustus, besides the exhibitions at the great spectacles, to show to the public any rarity that was brought over, "ut rhinocerotem apud septa; tigrim in scena; anguem quinquaginta cubitorum pro comitio:" and Dion remarks that the tigers (τίγρεις) first seen by the Romans, and as he thinks by the Greeks also, were those sent by the Indians as gifts when they were suing for peace from Augustus. The emperor Philip on one occasion exhibited ten tigers, together with thirty-two elephants, ten elks, sixty lions, thirty leopards, ten hyænas, one hippopotamus, one rhinoceros, forty wild horses, twenty wild asses, and numbers of deer, goats, antelopes, and other beasts; the brutal exhibition being crowned by the mortal combat of 2000 gladiators.

Gordian III. also exhibited ten tigers, and they were present in the shows of Antoninus and Elagabalus. Aurelian, in his triumph over Zenobia, showed four, together with a giraffe, an elk, and other rare animals.

Oppian cannot be mistaken when he writes ('Cyneg.,' iii. 130)—

> Παρδάλιες τε θοαί, καὶ τίγριες αἰολόνωτοι;

for here we have leopards and tigers in the same line, and the epithet αἰολόνωτος (having a variegated back) is quite applicable to the latter.

The Latin poets abound with allusions to the *Tigris*, that in most instances can hardly be allotted to any animal but the Royal Tiger; for though Virgil in his fourth 'Georgic' (l. 407), applies the epithet 'atra' (black) to 'tigris' in the passage where Cyrene is warning Aristæus as to the forms into which Proteus will transform himself, the word evidently does not there allude to colour, but to ferocity. In the fourth 'Æneid,' Dido, in her exclamation against Æneas, says—

> ——"Duris genuit te cautibus horrens
> Caucasus, *Hyrcanæque* admôrunt ubera *tigres*."

The tigers of Bacchus may be considered more doubtful. In the 'Gemmæ et Sculpturæ Antiquæ' there is a representation of a large female *Felis* with the thyrsus from a carnelian (corgnola), with the superscription, 'Tigre di Bacho;' but though the figure generally might pass for a Tiger, the tail of the animal is terminated by a shaggy tuft, and no tiger's tail is. Claudian comes much nearer to the mark where he describes Iacchus as marching crowned with ivy, and clad in the skin of the Parthian Tiger. When Virgil describes Orpheus, as 'mulcentem tigres' as 'soothing tigers' ('Georg.' iv., l. 510), and Horace, with nearly the same thought, addresses Mercury—

> "Tu potes tigres comitesque sylvas
> Ducere"

('Carm.,' iii., 'Ode,' ii.); and again, in his epistle to the Pisos ('De Arte Poeticâ,' l. 393), says of Orpheus—

> "Dictus ab hoc lenire tigres, rabidosque leones;"

they make the Tiger personify the greatest ferocity, and they certainly could not have chosen a more apt representative.

Martial speaks of the Tiger in the time of Titus and Domitian. ('Spect.,' Epig. 18, and lib. i., Epig. 105.)

To conclude this branch of the subject, we shall advert to one more literary proof, and one piece of pictorial evidence: and we think that no doubt can exist that, although the Royal Tiger was not so abundant in the Roman shows, particularly the earlier ones, as the leopard and the panther, its form and colouring, as distinguished from the other great cats, were as well and familiarly known to that people.

Pliny, in his chapter 'De Atlantis Arboribus et Cedrinis Mensis,' &c. ('Nat. Hist.,' xiii. 15), speaking of the grain or pattern of these tables, says that where it was oblong or lengthened, they were called tigrine, but where it was wreathed or curled (intorto), they were termed pantherine.

The pictorial evidence (so to speak) was furnished by the mosaic found at Rome near the arch of Gallienus. In this work of art, executed not improbably in commemoration of the exhibition of Claudius above noticed, four Royal Tigers, each devouring his prey, are well represented.

Our zoological societies and menageries have so increased in number during a long period of peace, that it becomes almost superfluous to describe a form so well known. But as a description of an animal holding so important a rank in the animal kingdom may be expected, we select that of Mr. Bennett, who remarks that the Tiger, closely allied to the Lion in size, in power, in external form, in internal structure, in zoological characters, in prowling habits, and in sanguinary propensities, is at once distinguished from it, and from every other of their common genus, by the peculiar markings of its coat. "On a ground which exhibits in different individuals various shades of yellow," says Mr. Bennett, "he is elegantly striped by a series of transverse black bands or bars, which occupy the sides of his head, neck, and body, and are continued upon his tail in the form of rings, the last of the series uniformly occupying the extremity of that organ, and giving it a black tip of greater or less extent. The under parts of his body and the inner sides of his legs are almost entirely white; he has no mane; and his whole frame, though less elevated than that of the lion, is of a slenderer and more graceful make. His head is also shorter and more rounded."

There is a paler variety, almost approaching to whitish, and with the stripes visible only in particular lights: this has been exhibited in this country. According to Du Halde, the Chinese Tiger (Lou-chu, or Lau-hu) varies in colour, some being white, striped with black and gray.

The size of the Tiger varies also; but the dimensions of the form, when fully developed, are, if we are to give credit to some accounts, the veracity of which has not been impugned, most formidable. Buffon notices an individual which was (tail included) 15 feet long; and it is on record that Hyder Ali presented to the Nabob of Arcot one which measured 18 feet in length. The average height varies from about four feet to about three feet, and the length from about eight or nine feet to six feet.

The Tiger is met with in Asia alone, and not in the south of Africa, as Buffon erroneously states; but authors generally agree that the Tiger is now rarely, if ever, met with on this side of the Indus. It is said to be found in the deserts which separate China from Siberia, and as far as the banks of the Oby; and in the south of China, and the larger East Indian Islands (Sumatra, for instance), it is common. Pennant states that it is found as far north as China and Chinese Tartary, and about Lake Aral and the Altaic Mountains. "It inhabits Mount Ararat," says the same author in continuation, "and Hyrcania, of old famous for its wild beasts; but the greatest numbers, the largest, and the most cruel, are met with in India and its islands. In Sumatra the natives are so infatuated that they seldom kill them, having a notion that they are animated by the souls of their ancestors. They are the scourge of the country; they lurk among the bushes on the sides of rivers, and almost depopulate many places. They are insidious, blood-thirsty, and malevolent, and seem to prefer preying on the human race." Hindustan may be considered the head-quarters of this destructive animal; there it is that he reigns unawed even by the lion, with which he disputes the mastery, and which is comparatively rare in that peninsula.

The bound with which the ambushed tiger throws himself upon his prey is as wonderful in its extent as it is terrible in its effects. Pennant justly observes that the distance which it clears in this deadly leap is scarcely credible. Man is a mere puppet in his gripe; and the Indian Buffalo is not only borne down by the ferocious beast, but carried off by his enormous strength. If he falls, it has been said that he makes off. This may be true in certain instances, but in general he does not slink away, but pursues the affrighted prey with a speedy activity which is seldom exerted in vain. This leads us to the observation of Pliny celebrating its swiftness, for which the Roman zoologist has been censured, most unjustly, apparently; nor is he the only author among the ancients who notices its speed. Oppian ('Cyneg.,' i. 323) speaks of the swift tigers as being the offspring (γενέθλη) of the zephyr. "Pliny," says Pennant, "has been frequently taken to task by the moderns for calling the tiger "animal tremendæ velocitatis;" they allow it great agility in its bounds, but deny it swiftness in pursuit. Two travellers of authority, both eye-witnesses, confirm what Pliny says: the one indeed only mentions in general vast fleetness; the other saw a trial between one and a swift horse, whose rider escaped merely by getting in time amidst a circle of armed men. The chase of this animal was a favourite diversion with the great Cam-Hi, the Chinese monarch, in whose company our countryman, Mr. Bell, that faithful traveller, and the Père Gerbillon, saw these proofs of the tiger's speed." Bell's 'Travels,' Du Halde.

In the "Ἑκατοντάς, seu Centuria Imaginum Hieroglyphicarum' (clo. loc. xxiii.) is a wood-cut (here copied) that may refer to such a scene.

Tiger pursuing a man on horseback.

Ferocious as the tiger is, and much as it may deserve the odium heaped upon it, the general chorus of the herd of authors who eulogise "the courage, greatness, clemency, and generosity" of the lion, contrasting it with the unprovoked ferocity, unnecessary cruelty, and poltroonery of the tiger, becomes ridiculous, though led by such names as Buffon and Pennant. The lion has owed a good deal to his mane and his noble and dignified aspect; but appearances are not always to be trusted. Mr. Barrow, with much more truth, characterises the king of beasts as powerful but treacherous. "Happy," says that traveller, "for the peasantry, the Hottentots, that those animals that are the objects of its destruction, were its noble and generous nature, that so oft has fired the imagination of poets, realised, and that his royal paw disdained to stain itself in the blood of any sleeping creature! The lion, in fact, is one of the most indolent of all the beasts of prey, and never gives himself the trouble of a pursuit unless hard pressed by hunger."

Pennant gives the following as an instance, after stating that there is a sort of cruelty in the devastations of the tiger unknown to the generous lion, as well as poltroonery in its sudden retreat on any disappointment: "I was informed by very good authority, that in the beginning of this century some gentlemen and ladies, being on a party of pleasure under the shade of trees, on the banks of a river in Bengal, observed a tiger preparing for its fatal spring; one of the ladies, with amazing presence of mind, laid hold of an umbrella and furled it full in the animal's face, which instantly retired, and gave the company an opportunity of removing from so terrible a neighbour."

This is a very pretty story, and the heroine deserves all praise, though it is not very clear what is meant by furling an umbrella, so as to make the alleged act square with the context, and the tiger was undoubtedly very polite. But tigers spring from a considerable distance, 15 or 20 feet, and from ambush; and we suspect that a cross-examination of the parties concerned might have slightly damaged the anecdote. Granting however that this bold lady walked up to a crouched tiger, and suddenly opened an umbrella in its face (for that, we presume, is the action meant), we may easily conceive that the surprise may have utterly confounded him; but this is not poltroonery. Indeed the same author immediately afterwards gives a tolerable proof of the animal's daring: "Another party had not, the same good fortune: a tiger darted among them while they were at dinner, seized on one gentleman, carried him off, and he never was more heard of."

But there is another story, a very sad one, which is pregnant with proof of the tiger's hardihood; we allude to the distressing death of Sir Hector Monro's son. Mr. Wood ('Zoography') relates the horrible occurrence in a few words:—

"This unfortunate gentleman," says Mr. Wood, "accompanied by three of his friends, went on shore, December 22, 1792, on Sawgar Island to shoot deer. They continued their sport till the afternoon, when they retired to the edge of a jungle to refresh themselves; where they had not remained long before one of the party, who was leaving the rest to shoot a deer, heard a dreadful roar, and saw a large tiger spring on poor Monro, and rush with him into the jungle with the greatest ease, dragging him through everything that obstructed his course, as if all were made to yield to his amazing strength. All that his companions could do to rescue their friend from this shocking situation was to fire at the tiger; and it is evident that their shots took place, since, in a few minutes after, Mr. Monro staggered up to them covered with blood, and fell. Every medical assistance that the ship afforded was procured for him immediately, but in vain; he expired in the course of twenty-four hours in the greatest agonies. His head was torn, his skull fractured, and his neck and shoulders covered with wounds made by the claws of the savage beast. It is worthy of observation, that neither the large fire that was blazing close to them, nor the noise and laughter which it seems they were making at the time, could divert this determined animal from his purpose." This story may be contrasted with the one related by Sparrman, and referred to above, of the lion retreating when boldly confronted, and certainly one animal cannot more than the other be charged with poltroonery.

But if any doubt as to the courage of the tiger be entertained, Father Tachard's account of a combat between that beast and two elephants at Siam will be sufficient proof. He relates that a lofty bamboo palisade was erected, occupying an area of about 100 feet square. Into this inclosure two elephants were introduced with their heads and trunks shielded by a kind of mask. A large tiger was now brought from its den, and held with cords till one of the elephants approached and inflicted two or three blows on its back with his trunk, so heavily laid on that it fell stunned, as if dead. Then they loosed the tiger. No sooner did he recover than he sprang with a dreadful roar at the elephant's trunk stretched ont in act to strike him; but the wary elephant drew up his trunk, and receiving the tiger on his tusks, hurled him into the air. This checked the fury of the tiger, as it well might, and he gave up the contest with the elephant; but he ran several times round the palisade, frequently springing at the spectators. Afterwards three elephants were set upon him, and they in turn dealt him such heavy blows that he again lay senseless, and would have been killed, if the combat, as it is most incorrectly called, had not been stopped. Nothing could be more unfair towards the tiger than the whole of this proceeding; and we will venture to say that no quadruped except a British bull-dog could have shown more 'pluck,' to use a common but expressive term, than this shamefully treated beast.

The older authors generally state that after the tiger has secured its prey it plunges its head into the body of the animal up to its very eyes, as if to satiate itself with blood till the corpse is exhausted, before it tears it to pieces. The best modern accounts tend to prove that the tiger is not more bloodthirsty and has no more blood-sucking propensities than the other great Cats; and that this blood-drinking habit is grossly exaggerated.

The tigress brings forth three or four, or four or five cubs at a time; and she is a very fond mother, braving every danger for them, and furiously attacking man and beast in their defence. The ancients knew this well. See Martial (lib. iii. Epig. 44):—

"Non tigris catulis citata raptis," &c.;

and Juvenal ('Sat.' vi.):—

"Tunc gravis illa viro, tunc orba tigride pejor:"

and though it is on record that a tigress in modern times devoured her cub, one should remember that this unnatural act was done in captivity, and that rabbits, sows, and cats, have done the same. But that in a state of nature the maternal feeling is very strong in the tigress, there can be no doubt. Captain Williamson, for example, relates that two tiger-cubs were brought to him when he was stationed in an Indian district. The country-people had found four in the absence of the tigress. The two brought to the captain were put in a stable, where they made a loud noise for several nights. The bereaved mother arrived at last, replying to their cries with fearful howlings, and the cubs were let loose under the apprehension that the infuriated tigress might break in. In the morning it was found that she had carried them away.

Various devices have been put in requisition to take or annihilate this destructive quadruped, and we shall mention one or two of them before we advert to the chase of the animal upon a grander scale. Ten rupees were formerly offered by the East India Company for every tiger destroyed within the provinces where their power and influence extended: a small reward, but sufficient, conjointly with the depredations of the animal, to stimulate the poorer classes to destroy it.

A kind of spring-bow was formerly laid in its way, and discharged a poisoned arrow, generally with fatal effect, when the animal came in contact with a cord stretched across its path; and this method is said to be still in use in some places. Again, a heavy beam was suspended over the way traversed by the tiger, which fell and crushed him on his disengaging a cord which let the beam fall. A Persian device is said to consist of a large spherical strong interwoven bamboo cage, or one made of other suitable materials, with intervals throughout three or four inches broad. Under this shelter, which is picketed to the ground in the tiger's haunt, a man provided with two or three short strong spears takes post by night, with a dog or a goat as his companion, wraps himself in his quilt and goes to sleep. A tiger arrives, of whose presence the man is warned by the dog or the goat, and generally after smelling about, rears himself up against the cage, upon which the man stabs him resolutely with his short spear through the interstice of the wicker-work. It seems ludicrous to talk of taking a tiger with bird-lime: but it is said to be so captured in Oude. When a tiger's track is ascertained, the peasants, we are told, collect a quantity of leaves resembling those of the sycamore, and common in most Indian underwoods; these they smear with a kind of bird-lime, which is made from the berries of an indigenous and by no means scarce tree, and strew them with the adhesive substance uppermost in some gloomy spot to which the tiger resorts in the heat of the day. If he treads on one of the limed leaves he generally begins by trying to shake it from his paw, and not succeeding proceeds to rub it against his jaw in order to get rid of it. Thus his eyes and ears become agglutinated, and the uneasy animal rolls, perhaps among many more of the smeared leaves, till he becomes enveloped: in this state he has been compared to a man who has been tarred and feathered. The tiger's irritation and uneasiness find vent in dreadful howlings, on which the peasants hasten to the spot, and shoot him without difficulty.

The plan of the box-trap and looking-glass, a device to be found in ancient sculpture, according to Montfaucon, is said to be practised among the Chinese at the present day.

So much for the trapping of the tiger. The tiger-hunt is perhaps the grandest and most exciting of wild sports. Upon such occasions the whole neighbourhood is on the move, and two hundred elephants have been known to take the field. From ten to thirty of these gigantic animals, each carrying sportsmen armed with rifles, have not unfrequently started for the jungle.

Captain Mundy gives a short but spirited description of a tiger-hunt. The party, he tells us, found immense quantities of game, wild hogs, hog-deer, and the neilghie: they however strictly abstained from firing, reserving their whole battery for the nobler game of which they were in pursuit. They had to pass through a thick forest, and the author gives a very interesting description of the power and dexterity of the elephants in overthrowing trees to make a road:—"On clearing the wood," says he, "we entered an open space of marshy grass not three feet high; a large herd of cattle were feeding there, and the herdsman was sitting singing under a bush, when, just as the former began to move before us, up sprang the very tiger to whom our visit was intended, and cantered off across a bare plain dotted with small patches of bush-jungle. He took to the open country in a style which would have more become a fox than a tiger, who is expected by his pursuers to fight and not to run, and as he was flushed on the flank of the line only one bullet was fired at him ere he cleared the thick grass. He was unhurt; and we pursued him at full speed. Twice he threw us out by stopping short in small strips of jungle, and then heading back after we had passed; and he had given us a very fast trot of about two miles when Colonel Arnold, who led the field, at last reached him by a capital shot, his elephant being in full career. As soon as he felt himself wounded the tiger crept into a close thicket of trees and bushes, and crouched. The two leading sportsmen overran the spot where he lay, and as I came up I saw him through an aperture rising to attempt a charge. My mahout had just before, in the heat of the chase, dropped his ankors, or goad, which I had refused to allow him to recover, and the elephant being notoriously savage, and further irritated by the goading he had undergone, became consequently unmanageable; he appeared to see the tiger as soon as myself, and I had only time to fire one shot when he suddenly rushed with the greatest fury into the thicket, and falling upon his knees nailed the tiger with his tusks to the ground. Such was the violence of the shock that my servant, who sat behind, was thrown out, and one of my guns went overboard. The struggles of my elephant to crush his still resisting foe, who had fixed one paw on his eye, were so energetic that I was obliged to hold on with all my strength to keep myself in the houdah. The second barrel too of the gun, which I still retained in my hand, went off in the scuffle, the ball passing close to the mahout's ear, whose situation, poor fellow, was anything but enviable. As soon as my elephant was prevailed upon to leave the killing part of the business to the sportsmen they gave the roughly-used tiger the coup-de-grace. It was a very fine female, with the most beautiful skin I ever saw."

In the 'Asiatic Annual Register' for 1804, a gentleman who had been present at the killing of above thirty tigers gives an account of a hunting-party of the Nawab Asuf-ud-Dowlah. After describing the immense cavalcade of the nawab he says:—"The first tiger we saw and killed was in the mountains. We went to attack him about noon; he was in a narrow valley, which the nawab surrounded with above two hundred elephants; we heard him growl horribly in a thick bush in the middle of the valley. Being accustomed to the sport, and very eager, I pushed in my elephant; the fierce beast charged me immediately; the elephant, a timid animal, turned tail and deprived me of the opportunity to fire. I ventured again, attended by two or three other elephants; the tiger made a spring, and nearly reached the back of one of the elephants on which were three or four men; the elephant shook himself so forcibly as to throw these men off his back, and they tumbled into the bush; I gave them up for lost, but was agreeably surprised to see them creep out unhurt. His Excellency was all this time on a rising ground near the thicket looking on calmly, and beckoning to me to drive the tiger towards him. I made another attempt, and with more success; he darted out towards me on my approach, roaring furiously and lashing his sides with his tail. I luckily got a shot and hit him; he retreated into the bush, and ten or twelve elephants just then pushed into the thicket, alarmed the tiger, and obliged him to run towards the nawab, who instantly gave him a warm reception, and with the assistance of some of his omras, or lords, laid the tiger sprawling on his side. A loud shout of 'wha! wha!' proclaimed the victory."

There is in Bishop Heber's 'Journal' a most graphic description of a tiger-hunt, but our limits will not permit us to indulge in more of these stirring accounts.

Those who have represented the tiger as untameable have no ground for the assertion. It is as capable of being tamed, and of attachment, even to fonduess, for its keeper as any other animal of its kind. We have seen many instances of this mutual good understanding between the man and the beast, and Mr. Bennett mentions a remarkable example in his 'Tower Menagerie.' A tigress of great beauty, in the Tower when he wrote, and scarcely a year old, had been during her passage from Calcutta allowed to range about the vessel unrestricted, and had become perfectly familiar with the sailors, showing not the slightest symptoms of ferocity. On her arrival in the Thames the irritation produced by the sight of strangers instantly changed her temper, rendering her irascible and dangerous. So sulky and savage was she that Mr. Cops, who then kept the lions in the Tower, could hardly be prevailed on by her former keeper, who came to see her, to allow him to enter her den; but as soon as the tigress recognised her old friend she fawned on him, licked him, caressed him, and manifested the most extravagant signs of pleasure; and when at last he left her, she cried and whined for the remainder of the day. The tame tigers of the mendicant priests, or fakirs, of Hindustan are well known.

But whilst there can be no doubt of the tameable qualities of the tiger, and indeed of all the great Cats, they are not to be incautiously trusted. The natural disposition is always ready to break out; and the mildest of them, though

——"Ne'er so tame, so cherish'd, and lock'd up,
Will have a wild trick of his ancestors."

Thus Bontius states that in 1628 a tiger at Batavia, which had been brought up from a cub, and accustomed to men all its life, escaped from its cage, fastened on a horse which was feeding near, and killed it; so that the citizens rose upon the tiger with fire-arms, and slew it in its turn to prevent further mischief.

Royal Tiger (*Felis Tigris*).

We conclude this part of our sketch with the account given by John Mason, who formerly kept the beasts in Exeter 'Change, to Mr. Wood, of his fearful encounter with one of these captives.

About the year 1802 a tiger had been purchased by Mr. Alpey to send to the Emperor of Germany, and placed in the Tower, there to remain for a few days till the ship destined to convey the animal abroad was ready. The beast was confined in a large sufficiently-ventilated wooden case, lined with iron hoops, some of which he ripped off during the first night of his confinement, and gnawed the case partly through. This being perceived, the next day the case was repaired by the addition only of a strong piece of wood nailed on the outside. "The consequence," says Mr. Wood, "might well be expected. The tiger renewed his efforts, and in the course of the following night made his escape, and sprung upon a wall ten feet high, where he remained till Mason came in the morning. The fear of losing such a valuable animal induced this poor fellow, for a reward of ten guineas, to hazard his life in an attempt to secure the tiger. For this purpose he engaged a sergeant and some other persons to assist him, whom he placed in a room, the door of which opened upon the leads, from whence he could reach the animal. He then provided himself with a strong rope, one end of which he gave through the window to his companions, and with the other, having a running noose upon it, he slowly approached the tiger, and threw it over its neck. This was the critical moment: the people within were directed to pull the rope and secure the beast. Unfortunately the noose slipped off, and the enraged animal immediately sprung upon the keeper, fixing his teeth into the fleshy part of his arm, and tearing his breast and hand in a dreadful manner with his claws. In this shocking situation the poor man lay under the tiger; while the sergeant cut a bullet into four parts, and, having loaded his musket, he fired through the window at the animal, who the moment he received the shot quitted his hold, and after staggering for a few minutes expired. The bullet however which destroyed the tiger had nearly been equally fatal to the man, one of the quarters having glanced against his temple, and deprived him of all sense and motion for a considerable time. Nevertheless, after keeping his bed a fortnight, he gradually recovered, and is now (1807) perfectly well, though he will carry the marks of his enemy about with him as long as he lives." ('Zoography,' vol. i.)

In the East the Tiger is associated emblematically with power. Thus the Chinese mandarins covered their seats of justice with its skin. In plate 17 of the atlas to Sir George Staunton's 'Embassy to China,' representing a military post, two swordsmen are habited and shielded so as to exhibit a tigerine aspect. The tiger-soldiers of Hyder Ali and Tippoo Saib were amongst the choicest of their troops. The tiger's head, gorgeous with jewels, that formed the principal ornament of the throne of Hyder and Tippoo, and was taken by the British among the spoils of the latter at Seringapatam, is well known; as is the automatic representation, clumsy enough it must be admitted, of a royal tiger tearing to pieces a soldier in the pay of the British, and imitating the growling of the beast and the cries of the man, taken also upon the same occasion. (See the Museum at the India House.)

Tiger-Cats.—We now proceed to speak of those species of *Felis* which, on account of their resemblance to the tiger, are called after that animal Tiger-Cats.

Asiatic Tiger-Cats.

Felis Nepalensis, Horsfield and Vigors. Size of the *Felis Javanensis*, Horsf., but its habit more slender, the tail and neck proportionally elongate. Ground-colour gray, with a very slight admixture of tawny; bands and spots of the head, back, neck, throat, abdomen, and thighs, deep black; superior longitudinal bands resembling those of *F. Javanensis*. Ground-colour of throat and abdomen nearly white; the lower flanks marked with a faint tawny longitudinal streak. Cheeks streaked with two parallel longitudinal lines, at the termination of which follows a transverse lunar mark which passes with a bold curve to the angle of the mouth, near which a very narrow band crosses the throat. Sides of the neck appearing marked with two broad waving bands, at the termination of which stands an oblong regularly transverse band. Neck underneath nearly immaculate. Shoulder and flanks exhibiting irregular diversified marks, the anterior oblong, the posterior angular, of a mixed tawny and black, and, individually, above or posteriorly with a broad dash of saturated black: they are scattered over the sides without any regular longitudinal disposition, but they have generally an oblique direction. Abdomen marked throughout with uniform oval spots; anterior thighs within exhibiting one broad black band, the posterior thighs two. Rump and thighs marked externally with roundish or oblong spots; tail above, to within about an inch of the tip, with uniform roundish spots, arranged posteriorly in regular transverse bands. Head above and ears agreeing generally with those of *F. Javanensis*. Length from extremity of nose to root of tail, 1 foot 10½ inches. Length of tail, 10½ inches. (Vigors and Horsfield.)

Nepaul Tiger-Cat (*Felis Nepalensis*).

Dr. Horsfield and Mr. Vigors observe that the distinguishing characters of this species are its comparatively lengthened habit; the slenderness and proportional length of the tail; the disposition of the marks on the flanks, and the character of these marks as far as regards their diversified form; and the saturated black patch with which they are individually marked at their upper or posterior edge.

"In the Bengal Cat," say those zoologists, "these marks have a different disposition; they are oblong, and arranged on the flanks in regular succession longitudinally. The materials contained in the museum at the India House have enabled us to make this statement, which is founded on the examination of a specimen brought by General Hardwicke, and on a careful drawing prepared under the eyes of Dr. Hamilton. We have thus two distinct species of small cats from India, and the elucidation of this point is of some importance, as it appears from the following remark in M. Temminck's monographs, 'l'existence de cette espèce dans l'Inde n'est pas constatée,' that he entertained some doubts on the existence of the Bengal Cat. It is not our intention, at present, to give a comparative analysis of all the species which resemble our animal. The discrimination of many species of *Felis* is at all times a difficult subject; and on many of them naturalists still disagree. Our immediate object is to indicate a new form of *Felis* from the upper provinces of India, differiug essentially from that which is found in the plains of Bengal; and so direct the attention of naturalists in that country to a more careful investigation of the various oriental species of this interesting genus."

The same authors state that a specimen was presented hy Captain Farrer, of the East India Company's service, to the Zoological Society of London. It came immediately from Calcutta, where it was said to have been sent from Nepaul. It lived some time in the Society's Garden, but was extremely wild and savage. It generally remained in a sitting posture, like that of the common domestic cat, and never paced its den in the manner of most other animals of the group. ('Zool. Journ.,' vol. iv.)

African Tiger-Cats.

Felis Serval, the Serval. Upper parts clear yellowish, with hlack spots; lower parts white, with black spots also, hut they are less numerous. Upon the head and neck the markings are most conspicuous, and form symmetrical lines on each side directed towards the shoulders. On the other parts of the body they are placed irregularly. On the hack they are lengthened, and show a disposition to form four rows; on the body and thighs they are larger and round, and they are smaller hut equally round on the extremities. Upon the face and muzzle they are minute. Back of the ears hlack at the base, succeeded by a transverse white har; tips of the ground-colonr of the body. On the inside of the fore limbs two conspicuous black transverse bars; the hind limbs with similar markings, hut less defined; last joints of the limbs of a paler tint than the rest of the body, the spots on them round and very small. Tail with eight black rings; tip of the same colour. Length, exclusive of tail, 1 foot 11½ inches; tail 9 inches. Height, when standing erect, about 12 inches at the shoulder, and 15 inches at the hind quarters. (F. Cuvier.)

Serval (*Felis Serval*).

The animal from which the above description was taken was a very yonng male. Its temper was mild and gentle, and its disposition sportive. It played like a domestic cat, or rather kitten, chasing its tail, and amusing itself with anything that it could roll with its paw.

The Serval is a native of Southern Africa. There are generally some living specimens in our menageries. It has been exhihited in that of the Zoological Society of London.

American Tiger-Cats.

It is in America that the Tiger-Cats are most numerons and beautiful, and there their manners have been hest noticed hy competent observers. We select three examples of the varieties of form and colouring exhihited hy this group in that quarter of the globe.

Felis pardalis (Linn.), the Ocelot. This, the most beautiful perhaps of all the Tiger-Cats, almost defies description. Mr. E. Bennett has however given a very faithful acconnt from two living specimens, one existing, when he wrote, in the Tower of London, and the other in the Garden of the Zoological Society in the Regent's Park. His description is as follows:—

"Body when full grown nearly three feet in length; tail rather more than one foot; medium height about 18 inches. Ground-colour of fur gray, mingled with a slight tinge of fawn, elegantly marked with numerous longitudinal hands, the dorsal one continuous and entirely black, the lateral (six or seven on each side) consisting for the most part of a series of elongated spots with hlack margins, sometimes completely distinct, sometimes running together. The centre of each spot of a deeper fawn than the ground-colour external to them; this deeper tinge is also conspicuous on the head and neck, and on the outside of the limbs, all of which parts are irregularly marked with full black lines and spots of various sizes. From the top of the head between the ears, there pass hackwards, towards the shoulders, two or more freqnently four uninterrupted diverging bands, which are full black anteriorly, but generally hifurcate posteriorly, and inclose a narrow fawn-colour space with a black margin; between these there is a single longitudiual, somewhat interrupted, narrow black line, occupying the centre of the neck above. Ears short and rounded, externally margined with black, surrounding a large central whitish spot. Under parts of the body whitish, spotted with black, and the tail, which is of the same ground-colour with the body, also covered with black spots." (Bennett, 'Tower Menagerie.')

Ocelot (*Felis pardalis*).

Mr. Bennett remarks that he has, in the above description, stated the length of the tail at more than a foot; and that in all the known Ocelots, as well as in all the species (of which there are several) that approach it in form and colouring, the proportionate length of the tail is at least equal to that which he has given as its average measurement. The tail however of the Tower specimen did not exceed six or seven inches; its extremity was overgrown with hair, and there was no cicatrix. Still, its equality throughout and its abrupt stumpiness induced the helief that this ahbreviation was purely accidental; and he felt hy no means inclined to regard that specimen as a new species, to be distinguished hy the excessive shortness of that appendage, by the unusually pale colour of its markings, and by some slight peculiarity in the mode of their arrangement, which, he observes, varies in every individual that he had seen.

This animal is a native of Mexico, Paraguay, and prohahly Peru.

The Ocelot remains in the deep forests during the day, sallying forth at night in quest of smsll quadrupeds and birds, the latter of which it successfully chases in the trees, for it is a very expert climher. If it he, as is generally supposed, the Tlacoozelotl, Tlalocelotl, *Catus Pardus Mexicanus* of Hernandez, it is said to stretch itself out as if dead on the limb of some tree when it spies monkeys in the neighhourhood. They, urged by curiosity, proceed to examine the supposed defunct, and fall victims to their curiosity.

The Ocelot has been so completely tamed as to he left at liberty, and it is said to be capable of strong attachment to its master. Mr. Bennett states that the specimen in the Tower, a male, was perfectly good-tempered, exceedingly fond of play, and had much of the character and manners of the domestic cat. Its food consisted principally of rabbits and birds; the latter it plucked with great dexterity, and always commenced its meal with the head, of which it seemed particularly fond; hut it did not eat with the ravenous avidity which characterises nearly all the animals of this tribe.

Felis mitis (F. Cuvier), the Chati; Chibiguazu of D'Azara (?); *Felis Chibiguazu* (Desm.). Ahout a third larger than the domestic cat: length, exclusive of tail, rather more than two feet; tail, 11 inches; height to middle of back, about 1 foot 2 inches. Ground-colour of fur on the upper parts, pale yellowish; on the lower, pure white; at the roots, dull gray, and very thick and close. Body covered with irregular dark patches; those upon the back entirely black, and disposed longitudinally in four rows; those upon the sides surrounded with hlack, with the centres of a clear fawn, arranged in nearly five rows. Spots upon the lower part of the body, where the ground-colour of the fur is white, full, and arranged in two lines composed of six or seven patches on each side. Limbs covered with nearly round spots of smaller dimensions: on the fore legs, near the body, two transverse hands. On the throat a sort of half-collar, and on the under jaw two crescent-shaped spots. Behind each eye two bands about two inches long, terminating opposite the ear. Forehead bordered hy two lines, between which are numerous spots, and, at their origin, a hlackish mark from which the whiskers spring. Outside of the ear hlack, with a white spot upon the small lobe. Base of the tail spotted with small hlotches, which towards the end run into half-rings, which are hroadest on the upper surface. Pupil round. (F. Cuvier.)

This animal, a female, was extremely gentle; and if those with whom it was familiar passed its cage or did not approach it, it would express its discontent hy a short cry. It manifested great delight when it was caressed. It lived in the Paris menagerie, and was procured from a dealer in Brest. The Chati is a native of South America.

Desmarest and others identify this animal with the Chibiguazu of D'Azara. Temminck, who received a skin from Rio de Janeiro, considers it distinct.

Chati (*Felis mitis*).

D'Azara's description comes very near to that above given, as far as colouring is concerned; but he gives the average length as 3 feet 6 inches: the individual which he described, the largest male he had seen, was 4 feet all but an inch in length; tail, 13 inches; height at shoulders, 1 foot 6 inches, and behind 1 foot 7½ inches. It was so fat, that immediately after death it weighed 35 lbs.: the females, he says, are rather less.

The same acute observer, speaking of his Chibiguazu, remarks that some of the Guaranese call the domestic cat Chibi, and others Mbracayá. In the same manner, he says, some give the wild animal of which he is treating the name of Chibi-Guazu, and others that of Mbracayá-Guazu; both appellations signifying Great Cat. Many Spaniards, he adds, call it Onza (Ounce).

He states that the species is so common that his friend Noseda captured eighteen individuals in two years, within two leagues of his village; but he adds that, notwithstanding this abundance, few are acquainted with it, the huntsman and dogs never falling in with it, and being unable to penetrate its haunts: he very much doubts whether any quadruped hides itself more effectually. He describes it as remaining by day in the most impenetrable places, and as coming forth after dusk, especially on dark stormy nights, when the chibiguazus daringly enter the corrals and court-yards, though no instance is known of their detection by the dogs. When the moon shines they abstain from visiting inhabited spots, and never are trapped: to lie in wait for them with a gun is hopeless, so sharp a look-out do they keep. They carry off domestic fowls from trees which they climb, sometimes six in one night, and often leave several dead. Men and dogs are avoided by them with extreme caution, and each pair is supposed to live in a separate district, for a male and female, and no more, are always caught in the same place. Noseda formed a trap of strong stakes, with three divisions: in the middle he placed a white fowl, so that it might not only be heard but seen at a distance: the other divisions were so framed as to shut by the falling of the planks as soon as the chibiguazus entered. This trap was set in the places to which they resorted for prey, and those caught were turned into a great den in Noseda's court-yard. Some of these got away, and were taken again two or three times in the same trap; they were recognised by ear-marks and other proofs. D'Azara infers from this that the idea of danger was obliterated from their recollection by their desire to possess the fowl. He remarked that all which were kept in the den deposited their excrements in their drinking-place, and when he substituted a narrow-necked jug to prevent this, they mounted to its edge for that purpose, and never missed the vessel or its immediate neighbourhood. Nearly the whole day was spent by them rolled up in a ball, and when a chibiguazu wished to stretch himself, he first licked the one at his side. When straw was put into their den, or so that they could reach it by thrusting their paws through the bars, it was always found that on the day following they had placed it in a heap, after having divided it into bits some quarter of an inch long, and on this they reposed. The small sticks and twigs with which the inside of their den was furnished were broken and torn to pieces in like manner. Twilight and night were passed in pacing to and fro close to the sides of their den; and if crossed or interrupted by another, they fuffed and gesticulated like an angry cat, but without using their paws. They never quarrelled, unless they were very much irritated, and then they struck at each other with their fore paws. They devoured five pounds of flesh per day when first caught, but afterwards three sufficed. A portion was prepared for each of the twelve or fourteen individuals confined, and they took it with their paws according to the length of time they had been there, without any interference on the part of the others. If however the animal whose turn it was did not take his portion, or disregarded it, another immediately snatched at it without any defence on the part of the right owner except by sneezing, and sometimes by blows with its fore paws. A walk was made for them, inclosed by a sort of hurdle, so that rats, fowls, ducks, or young dogs could be introduced into it: upon opening the cage it was observed that usually one only went out for each victim, and almost always according to the order of their confinement. Cats and dogs they seized with their mouth by the nape of the neck, overlaid them, and then kept them so that they could not stir, till they were dead. Cats' flesh appeared to produce the mange, fretting the chibiguazus, making them mew like cats, and at last destroying them. Snakes, vipers, and toads were also eaten by them, but this diet occasioned violent and continued vomiting; they wasted to skeletons, and died in a few days. If the dog introduced equalled them in size, they touched him not, for it appears that they do not assist each other. If a chibiguazu cannot master any prey alone, he leaves it. Birds were caught by the head and neck, and thoroughly stripped of their feathers before they were eaten. No unnecessary cruelty was manifested. Noseda observed that one did not kill a fowl put into his den till the third day. D'Azara and his friend frequently closed the doors of the yard, and opened the den that the chibiguazus might leave it: those lately caught went first; and sometimes the old ones would not go out even when their den was entered that it might be swept. They were left at liberty for several hours, during which they examined every crevice, and then lay down to sleep. When boys persecuted them with sticks, they retreated to their den without turning on their persecutors, even when severely beaten. A male on one occasion becoming very lazy, on entering his den he was abused and bitten by his female, as if to punish him. Some individuals were incarcerated for more than a year without exhibiting any sign of love. In the night their eyes shone like those of a domestic cat, and they resembled that animal in their form and habits, in lying down, licking and cleaning themselves, washing their faces with their paws, fuffing, sneezing—in fact, in every way. D'Azara concludes by stating that his friend caught a young one, and it became so thoroughly tame that it slept in the skirts of his clerical gown, and went about loose. He affirmed that no animal could be more tractable: but it devoured the poultry of his neighbours, and they killed it.

Felis Pajeros, the Pampas-Cat, Pajero, or Jungle-Cat. Fur of great length; longer hairs of the back upwards of 3 inches, and those of the hinder part of the back from 4½ to 4¾ inches in length. General colour pale yellow-gray; numerous irregular yellow or sometimes brown stripes running obliquely from the back along the sides of the body. On each side of the face two stripes of yellowish or cinnamon commencing near the eye, and extending backwards and downwards over the cheeks, on the hinder part of which they join, and form a single line, which encircles the lower part of the throat. Tip of the muzzle and chin white; a spot in front of the eye, and a line beneath the eye, of the same colour; belly, inner side and hinder part of fore legs, white also. An irregular black line running across the lower part of the chest, and extending over the base of the fore legs externally; above this line two other transverse dark markings more or less defined on the chest. On the fore legs three broad black bands, two of which encircle the leg; on the posterior legs about five black bands externally, and some irregular dark spots internally. Feet yellowish, and under side of tarsus of a slightly deeper hue. On the belly numerous large irregular black spots. Ears moderate, with long white hairs internally; externally of the same colour as the head, except at the apex, where the hairs are black, and form a slight tuft. Tail short somewhat

Pampas-Cat (*Felis Pajeros*). 'Zool. of the Beagle.'

bushy, and devoid of dark rings or spots—the hairs are in fact coloured as those on the back. On the upper part of the body each hair brown at the base, then yellow, and at the apex black. On the hinder part of the back the hairs almost black at the base, and, on the sides of the body, each hair gray at the base; there is then a considerable space of yellowish-white colour: towards the apex they are white, and at the apex black. The greater number of the hairs of the moustaches white. Length from nose to root of tail 26 inches; of tail (fur included), 11 inches. Height of body at shoulders, 13 inches. Size about equal to that of the common wild-cat of Europe; but the Pampas-Cat is stouter, its head smaller, and its tail shorter. (Waterhouse.)

Mr. Waterhouse ('Zoology of the Beagle') observes that the markings of this animal vary slightly in intensity: those on the body, he remarks, are generally indistinct; but the black rings on the legs are always very conspicuous.

D'Azara says that he knows not, nor has he heard, that this species exists in Paraguay, although it formerly may have been seen there; but as the country became tolerably well peopled, and there were fewer plains, the inhabitants probably extirpated it. He caught four in the Pampas of Buenos Ayres, between 35° and 36° S. lat., and three others on the Rio Negro. He says they are found on both sides of the La Plata.

Darwin ('Zoology of the Beagle') gives as its habitat Santa Cruz, Patagonia, and Bahia Bianca. He states that it is common over the whole of the great plains which compose the eastern side of the southern part of America; and he says he has reason to believe, from the accounts he received, that it is found near the Strait of Magellan, which would give it a range of nearly 1400 miles in a north and south direction, D'Azara having stated that it extends northward as far as 30° S. lat. One of Mr. Darwin's specimens was obtained in 50° S. lat., at Santa Cruz.

D'Azara says that the natives call this animal Gato Pajero, because it lives on the plains, concealing itself in jungles, without entering into the woods and thickets. Guinea-Pigs (*Aperea*), according to him, form its principal food. Mr. Darwin states that it takes its name from 'paja,' the Spanish word for straw, from its habit of frequenting reeds. The specimen taken by him at Santa Cruz was met with in a valley where thickets were growing. When disturbed it did not run away, but drew itself up and hissed.

III. Leopards.

The larger Spotted Cats are known by this name. They are found in both the Old and New Worlds.

The form seems to have its most perfect development in the ancient continent and the islands of the Old World, though it must be admitted that the American Jaguar, in point of size, strength, and sturdiness of make, excels the Leopards of Asia and Africa.

Felis Pardus (the Panther) of Linnæus first claims our notice. It has been a question whether the Leopard and Panther are distinct species, or only varieties. Linnæus, in his last edition of the 'Systema Naturæ,' included under the specific name of *Felis Pardus* the *Panthera*, *Pardalis*, *Pardus*, and *Leopardus* of Gesner; *Pardus* mas., *Panthera* femina of Alpin (Egypt); *Pardalis* of Ray; *Tigris Mexicana* of Hernandez; and *Pinuum Dasypus*, Nieremb., 'Nat.' Under the specific name of *Onca* he includes *Pardus*, seu *Lynx Brasiliensis* of Ray, and the *Jaguara* of Maregrave. He has no species named *Leopardus*; but Gmelin has, and in his edition we find the following species:—1. *F. pardus*—*F.* cauda elongata, corpore maculis superioribus orbiculatis; inferioribus virgatis—(the description of Linnæus) Schreb., 'Säugethiere,' iii. p. 384, t. xcix., with the following references and synonyms:—*Felis* ex albo flavicans, maculis nigris in dorso orbiculatis, in ventre longis, Briss. 'Quadr.'; the names of Gesner and Ray as quoted above; *Pardus* maculis seu scutulis variis, Ludolf, Æthiop.; Panthère of Buffon. 2. *F. Unica*, Once, Buffon. 3. *F. Leopardus*—*F.* cauda mediocri, corpore fusco maculis subcoadunatis nigris. Erxl., 'Syst. Mamm.,' p. 509. n. 5; Schreb., 'Säugeth.,' iii. p. 387, t. ci.; *Uncia*, Caj., 'Op.,' p. 42, Gesn., 'Quadr.,' p. 825; Leopard of Buffon. 4. *F. Onça*, the Jaguar.

Cuvier separates the Panther from the Leopard specifically. The Panther, La Panthère, he makes the *Felis Pardus* of Linnæus, and the *Pardalis*, ἡ Πάρδαλις of the ancients. He describes the Panther as yellow above, white beneath, with six or seven rows of black spots in the form of roses, that is to say, formed by an assemblage of five or six small simple spots on each side; the tail of the length of the body not reckoning the head. This species he speaks of as being spread throughout Africa and in the warm countries of Asia, as well as in the Indian Archipelago; and he states that he has seen individuals where the ground-colour of the fur is black, with spots of a still deeper black (*Felis melas*, Pér.), but that they do not form a species, observing that both yellow and black cubs have been seen sucking the same mother (1829). Pennant ('Hist. Quadr.,' 1793) figures a Black Leopard, and describes the variety as follows:—"In the Tower of London is a black variety, brought from Bengal by Warren Hastings, Esq. The colour universally is a dusky black, sprinkled over with spots of a glossy black, disposed in the same forms as those of the Leopard. On turning aside the hair, beneath appears a tinge of the natural colour."

Felis Leopardus (the Leopard) of Linnæus, as he quotes it (but it is not mentioned by Linnæus in his last edition of the 'Syst. Nat.;' it appears, as we have seen, in Gmelin's edition), Cuvier assigns to Africa, remarking that it is similar to the Panther, but with ten rows of smaller spots. These two species, he adds, are smaller than the Jaguar; and he says that there is a third, a little lower on the legs, with the tail equalling the body and head in length, and with more numerous and smaller spots (*Felis chalybeata*, Herm. Schreb., 101).

Cuvier does not notice the Panther, ὁ Πάνθηρ of Aristotle ('Hist. Anim.,' vi. 35), and indeed this animal is supposed by many not to have been one of the Leopard kind. In a note to *Felis chalybeata* Cuvier states that it is to that species M. Temminck applies the name of Panther; but the former adds it is certain that the Panther so well known to the ancients, and which appeared so often in the Roman shows and games, could not be an animal from the recesses ('fond') of Eastern Asia.

Cuvier does not insert in the text of his 'Règne Animal' the Ounce of Buffon; but in a note to the second edition he speaks of it as differing from the Panthers and the Leopards by more unequal spots, more irregularly scattered, partly notched or ringed, &c., and as appearing to be found in Persia; adding that his knowledge of it is only derived from Buffon's figure, and from that which Mr. Hamilton Smith has inserted in the English translation of the 'Règne Animal' from an individual which had been seen living in London.

The Panther and the Leopard were once regarded by M. Temminck as varieties of the same species, *F. Leopardus*, but he has separated them specifically in his 'Monograph.'

Colonel Smith's Ounce was detected by him in the Tower when that fortress included a menagerie among its attractions. The animal is said to have been brought from the Gulf of Persia, but we only learn that it was very distinct from all other species in make, markings, and general appearance.

The same author describes the Panther of the ancients as standing higher than the Jaguar, and as approaching in its form, which is slender, to that of the Hunting Leopard (*F. jubata*), though much larger in proportion.

M. Lesson enumerates the following Leopards as belonging to the old continent:—

F. Panthère, *F. Pardus*, Linn., Temm., 'Monog.' Less than the Leopard; tail as long as the body and head. Locality, Bengal; and probably does not exist in Africa.

F. Leopard, *F. Leopardus*, Linn. (Gmel.), Temm.; *F. Pardus*, Cuv.; Faahd of the Arabs. Rather less than a lioness. Tail (22 vertebræ) of the length of the body. Locality, Africa and India.

F. jubata, the Cheetah, or Hunting Leopard. Locality, Southern Asia.

Among those *Felidæ* which are distributed in the Polynesian group of islands (Iles Asiatiques de la Polynesie) M. Lesson notices—

F. melas, Péron, observing that this animal, which M. Temminck believed to be a variety of the Leopard, constitutes, on the contrary, a species entirely confined to Java, and especially in the most isolated eastern districts, such as Blambangan (Brambanan?). The size of the animal he states to be that of the Panther; its fur of a deep black, on which are traced zones of the same colour, but less lustrous. This leopard, which is called Arimaou by the Javanese, is used for the singular combats of the 'Rampok,' for the details of which M. Lesson refers to the 'Zool. de la Coquille,' t. i. p. 139. He adds that he saw a beautiful specimen belonging to the resident of Sourabaya, and he was assured that *F. melas* was not rare in the island. He also refers to *F. macrocelis*, Horsfield. Localities, Sumatra and Borneo. (1827.)

Mr. Bennett ('Gardens and Menagerie of the Zoological Society,' 1830) says, "Whether the Leopard and the Panther are in reality distinct species, and if so on what particular characters the specific distinction depends, are questions that have been so variously solved by writers of the highest eminence that we cannot, without better opportunities for comparison of specimens than we at present possess, adopt the conclusions to which any one of them has come upon the subject. Linnæus, not perceiving any sufficient grounds of distinction, referred both names to one and the same animal; Buffon added a third, that of the Ounce, and increased the confusion by describing as the Panther of the ancients and an animal of the old continent the Jaguar, which is now known to be peculiar to the new continent; Cuvier subsequently founded a distinction upon the greater or smaller number of rows of spots disposed along the sides of the body; and Temminck, rejecting these characters as unimportant, has lately fixed upon the comparative length of the tail as affording the only sure means of discrimination. In this uncertainty the question remains for the present; but there can be no doubt of the complete distinction between both the animals involved in it and that which we have figured, the mistaken Panther of Buffon, the Jaguar of Brazil, and *Felis Onça* of systematic writers. It may not however be useless to observe, that of the figures given by Buffon as Panthers and Jaguars that which is entitled the male Panther is in all probability a Leopard; the female is unquestionably a Jaguar; the Jaguars of the original work, and of the supplement, are either Ocelots or Chatis; and that which purports to be the Jaguar or Leopard, although probably intended for a Cheetah, is not clearly referrible by its form and markings to any known species."

Mr. Swainson, in his 'Classification of Quadrupeds' (1835), leaves the question untouched. In his 'Animals in Menageries' (1838) he gives the following species:—

The Leopard; Leopard, Cuvier; *F. Leopardus*, H. Smith, in Griff., Cuvier.

The Panther, *F. Pardus*, Linn., Hamilton Smith; Panthère, Cuvier. Panther of the Ancients, *F. Pardus Antiquorum*, Hamilton Smith, in Synopsis of Griff., Cuv.

Under the title 'Leopard' Mr. Swainson says, "Although the names of Leopard and Panther have been long familiar in common language, and have conveyed the idea of two distinct species, yet it is perfectly clear that no scientific writer of the last generation either described, or indeed appeared to know, in what respects the animals differed. It seems that numerous specimens of what is called the Leopard are in the Zoological Gardens, and one has been figured in the book so entitled; but Mr. Bennett has not made the slightest attempt to investigate the subject, or to throw any light upon this difficult question. In this dilemma we shall therefore repose on the opinions of Major Hamilton Smith, whose long experience and accuracy of observation are well known, and whose authority in this department of nature deservedly ranks above that of any other naturalist of this country. The Leopard, as defined by Major Smith, when compared with the Jaguar and the Panther of naturalists, is uniformly of a paler yellowish colour, rather smaller, and the dots rose-formed, or consisting of several dots partially united into a circular figure in somé instances, and into a quadrangular, triangular, or other less determinate forms in others: there are also several single isolated black spots, which more especially occur on the outside of the limbs. The Panther, according to Professor Lichtenstein of Berlin, 'resembles the Jaguar in having the same number of rows of spots, but is distinguished by having no full spots on the dorsal line.' But, as Major Smith observes, it does not appear that full spots on the dorsal line always make a specific character of the Jaguar; and the Asiatic Leopard is sometimes distinguished by this peculiarity, though it does not in other respects resemble the American animal. When therefore it is said that the Panther much resembles the Jaguar, it is always to be strongly suspected that the type whence the observations have been taken is in reality an American animal." Mr. Swainson then, after copying Major Smith's scientific description of the Leopard, proceeds to say, "Our own opinion of the specific dissimilarity between the Leopard and the Panther, judging from what has been written on the subject, is in perfect unison with that of Major Smith; while the following remark of that observing naturalist, incidentally inserted in his account of the Panther of antiquity, seems to us almost conclusive:—'The open spots which mark all the Panthers have the inner surface of the annuli or rings more fulvous (in other words darker) than the general colour of the sides; but in the Leopard no such distinction appears, nor is there room, as the small and more congregated dots are too close to admit it.' In truth, if there is any reliance to be placed in the most accurate figures hitherto published, the small spots of the leopard and the large ones of the Panther must strike even a casual observer, and lead him to believe that the two animals were called by different names."

Leopard (*Felis Leopardus*). Senegal.

In the 'Gemmæ et Sculpturæ Antiquæ' of Gronovius there is an engraving of a boy driving a car drawn by two Panthers, rather high on their legs, from a carnelian, headed 'Carro di Bacho;' but Gronovius thinks that though this 'reda' may be attributed to Bacchus, it may nevertheless be taken for a representation of one from the Circensian games, for which opinion he gives his reasons. Captain Smyth, R.N., in his interesting 'Descriptive Catalogue of a Cabinet of Roman Imperial Large Brass Medals,' notices a medal of Commodus, on the reverse of which the emperor on horseback galloping across the field, with a chlamys floating behind him, is in the act of casting a dart at a Panther, which is 'showing fight.' He also refers to the figure of a Lynx or Panther on the reverse of one of Septimius Severus, and to that of a Panther (among other animals) on the smaller coins of Gallienus.

With regard to the *F. Pardus Antiquorum* of Smith, Mr. Swainson remarks that the species, if such it really be, is supposed to be the animal known to ancient writers by the name of *Panthera*. It is however, he adds, now so rare, or has been so little distinguished, that Major Smith is only acquainted with one example, which is in the museum of the elector of Hesse Cassel, in whose menagerie it had probably lived. Nothing was known of its native country or of its manners. (See H. Smith's description, including characters intermediate between the Jaguar of America and the Panthers and Leopards of the Old World.)

Mr. Swainson also notices the Ounce in the same work, referring to Major Smith's description, and regretting that that able zoologist had not entered into further particulars. Mr. Swainson states that, judging from the figure engraved from Mr. Smith's drawing, he should term it a lower and more thick-set animal than the Panther; the spots larger, more irregular, and much fewer, but differing more especially in having the tail decidedly annulated with black rings, while those of all the Panthers are spotted. The body, he adds, is described as whitish; while yellow or fawn-colour is the universal tint both of the Panthers and Leopards.

In June, 1837, Dr. Gray brought before the notice of a meeting of the Zoological Society of London some *Mammalia* which he had lately purchased for the British Museum from a collection made by the late Colonel Cobb in India, among which was an adult specimen of the Once of Buffon ('Hist. Nat.'), on which Schreber formed his *F. Uncia*, which has been regarded by Cuvier, Temminck, and most succeeding authors as a Leopard, but which, continued Dr. Gray, "is as a distinct species, easily known by the thickness of its fur, the paleness of its colour, the irregular form of the spots, and especially by the great length and thickness of the tail." Dr. Gray observed that a more detailed description of this animal was unnecessary, as it agreed in all particulars with the young specimen described by Buffon.

Ounce (*Felis Uncia*). From the specimen in the British Museum.

Of the manners of the true Leopards in a state of nature not much seems to be known. They are very active, climb well, and take their prey by surprise. In captivity they are playful, but apt to be treacherous. Mrs. Bowdich won the heart of a Leopard by kindness, and by presenting him with lavender-water in a card-tray, taught him to keep his claws sheathed. The luxurious animal revelled in the delicious essence almost to ecstacy; but he never was suffered to have it if he put forth his claws. We regret that our limits will not allow us to give this lady's graphic account of her amiable favourite 'Sai,' which the reader will find in Loudon's 'Magazine.'

Among the larger Spotted Cats of the Old World we must notice the Rimau-Dahan, *F. macrocelis*, Temm., Horsfield; *F. nebulosa* (?), H. Smith, Griffith.

This species partakes in some measure of the markings of both the Tiger and Leopards, though it seems to be more nearly allied to the latter than to the former.

Probable size when full grown about 4 feet from the nose to the root of the tail, which may be reckoned at 3 feet 6 inches; height at shoulder about 1 foot 10 inches. Colour whitish-gray, with an inclination to ashy or brownish-gray, no yellow or red tint. Stripes and spots dark, oblong, irregular, and broad on the shoulders, interrupted and angular on the sides, posterior edges of the broad spots and stripes marked by a line of deep velvet black; limbs stout, feet and toes robust; tail very long, large, and lanuginous.

It inhabits Sumatra. M. Temminck thinks it is also found on the continent of India, having received mantles belonging to the Diakkers made of the skin of this species.

The specimen brought to England alive by Sir Thomas Stamford Raffles was taken when very young in the forests of Bencoolen, and died during the process of dentition soon after its arrival. Dr. Horsfield gives the following dimensions: sex, femalo :—

	Ft.	In.
Length of the body and head, from the extremity of the nose to the root of the tail	3	0
Length of the tail	2	8
Height at the shoulders	1	4
Height at the rump	1	3
Circumference of the abdomen	2	0
Circumference of the neck	1	2

Sir Stamford Raffles gives the following account of the manners of the species from personal observation made on two individuals :—"Both specimens, while in a state of confinement, were remarkable for good temper and playfulness; no domestic kitten could be more so; they were always courting intercourse with persons passing by, and in the expression of their countenance, which was always open and smiling, showed the greatest delight when noticed, throwing themselves on their backs, and delighting in being tickled and rubbed. On board the ship there was a small Musi Dog, who used to play round the cage and with the animal, and it was amusing to observe the playfulness and tenderness with which the latter came in contact with his inferior-sized companion. When fed with a fowl that died, he seized the prey, and after sucking the blood and tearing it a little, he amused himself for hours in throwing it about and jumping after it in the manner that a cat plays with a mouse before it is quite dead. He never seemed to look on man or children as prey, but as companions; and the natives assert that when wild, they live principally on poultry, birds, and the smaller kinds of deer. They are not found in numbers, and may be considered rather a rare animal, even in the southern part of Sumatra. Both specimens were procured from the interior of Bencoolen, on the banks of the Bencoolen River. They are generally found in the vicinity of villages, and are not dreaded by the natives, except as far as they may destroy the poultry. The natives assert that they sleep and often lay wait for their prey on trees; and from this circumstance they derive the name of Dahan, which signifies the fork formed by the branch of a tree, across which they are said to rest and occasionally stretch themselves. Both specimens constantly amused themselves in frequently jumping and clinging to the top of their cage, and throwing a somerset, or twisting themselves round in the manner of a squirrel when confined, the tail being extended and showing to great advantage when so expanded." ('Zool. Journ.,' vol. i.)

Rimau-Dahan (*Felis macrocelis*).

Dr. Horsfield, in the work above quoted, confirms the account of Sir Stamford from his own observation on the individual that was lodged on its arrival in Exeter 'Change. The Doctor, who does not appear to acquiesce in the identity of *F. nebulosa* with the Rimau-Dahan, gives in the same paper a most elaborate and accurate description of the latter, to which we must refer our readers. He also gives a figure (pl. xxi.) from a drawing made by the late William Daniell, Esq., R.A., a few days after the animal had been placed in Exeter 'Change.

We now come to a very interesting form, one of those gradations by which Nature appears to pass from one type to another. The *Felis jubata* of Schreber, Chetah, Cheetah, or Hunting Leopard, exhibits both in its external form and habits such a mixture of the Feline and Canine tribes as to justify apparently the appropriate name *Cynailurus*, employed by M. Wagler to designate it as a genus. Thus, as Mr. Bennett observes ('Tower Menagerie'), the Hunting Leopard, uniting to the system of dentition, the general habit, and many of the most striking peculiarities of the cats, some of the distinguishing features, and much of the intelligence, the teachableness, and the fidelity of the dog, becomes a sort of connecting link between two groups of animals otherwise completely separated, and exhibiting scarcely any other character in common than the carnivorous propensities by which both are in a greater or less degree actuated and inspired. "Intermediate," continues Mr. Bennett, "in size and shape between the leopard and the hound, he is slenderer in his body, more elevated on his legs, and less flattened on the fore part of his head than the former, while he is deficient in the peculiarly graceful and lengthened form, both of head and body, which characterises the latter. His tail is entirely that of a cat; and his limbs, although more elongated than in any other species of that group, seem to be better fitted for strong muscular exertion than for active and long-continued speed." From these and other indications Mr. Bennett is of opinion that the animal approaches much more nearly to the cats than the dogs, and continues it among the former. The anatomy of the Cheetah, as subsequently demonstrated by Professor Owen at a meeting of the Zoological Society of London, shows indeed that, in internal structure, this leopard is undoubtedly feline: of its habits we shall hereafter have occasion to speak. In the paper last above alluded to, 'On the Anatomy of the Cheetah, *Felis jubata*, Schreb.,' Professor Owen commenced by remarking on *Felis* as a truly natural genus, and by observing that the anatomical structure of the animals composing it offers even fewer differences than their outward forms. The principal deviation from the common type was stated to be that which obtains in the organs of voice of the Lion (and, as Mr. Martin has observed, in those of the Jaguar also), where the larynx is situated at a considerable distance from the posterior margin of the bony palate, the soft palate and the tongue being proportionally increased in length, thus forming a gradually expanded passage, which leads from the glottis, where the air is rendered so sonorous, to the mouth. This structure, Professor Owen remarks, may contribute in the Lion to produce the peculiar roar of that animal.

Cheetah (*Felis jubata*; *Cynailurus jubatus*, Wagl.).

In the Cats generally, it was stated, the connection of the os hyoides to the cranium is not by a long elastic ligament, as in the Lion, but by an uninterrupted series of bones. This latter structure exists in the Cheetah. The Cheetah has also the circular pupil of the Lion, Tiger, Leopard, and Jaguar, and is perhaps the most diurnal of the genus. In the form of the œsophagus, and in the transverse rugæ of its lower half, the Cheetah was stated to agree with the Lion; and, as in it and in the other species of *Felis*, the œsophagus was not prolonged into the abdomen, but terminated immediately after passing through the diaphragm in the stomach. This organ, according to Professor Owen, has in the Cheetah all the peculiarities which are found in the genus *Felis*. The intestines also agree in character with those of that group; and the cæcum, as usual in it, is simple, having none of the convolution which is found in the Dog. The liver, pancreas, and spleen resembled those of the Cats generally; as did also the kidneys in the arborescent form of their superficial veins—a form however equally common, Professor Owen remarks, to the *Viverridæ* and the *Felidæ*, which also agree in having spiculæ on the tongue. The viscera of the thorax in the Cheetah agreed with those of the Cats. The lytta, or rudiment of the lingual bone, so conspicuous in the Dog, is reduced in it, as in the other feline animals, to a small vestige. There was no bone of the penis, and the glans had retroverted papillæ. The elastic ligaments of the ungual phalanges existed in the same number and position as those of the Lion; they were however longer and more slender, their length alone occasioning the incomplete retraction of the claws as compared with the rest of the *Felidæ*. Professor Owen concluded by observing that in the circulating, respiratory, digestive, and generative systems, the Cheetah conformed to the typical structure of the genus *Felis*. ('Zool. Proc.,' 1833.)

Mr. Bennett gives the following description of the Cheetah:—Ground-colour bright yellowish fawn above; nearly pure white beneath; covered above and on the sides by innumerable closely approximating spots, from half an inch to an inch in diameter, which are intensely black, and do not, as in the leopard and others of the spotted cats, form roses with a lighter centre, but are full and complete. These spots, which are wanting on the chest and under part of the body, are larger on the back than on the head, sides, and limbs, where they are more closely set: they are also spread along the tail, forming on the greater part of its extent interrupted rings, which however become continuous as they approach its extremity, the three or four last rings surrounding it completely. The tip of the tail is white, as is also the whole of its under surface, with the exception of the rings just mentioned; it is equally covered with long hair throughout its entire length, which is more than half that of the body. The outside of the ears, which are short and rounded, is marked by a broad black spot at the base, the tip, as also the inside, being whitish. The upper part of the head is of a deeper tinge; and there is a strongly marked flexuous black line, of about half an inch in breadth, extending from the inner angle of the eye to the angle of the mouth. The extremity of the nose is black, like that of a dog. The mane not very remarkable; consisting of a series of longer, crisper, and more upright hairs which extend along the back of the neck and the anterior portion of the spine. Fur with little of the sleekness which characterises that of the cats, but exhibiting on the contrary a peculiar crispness not to be found in any other of the tribe. ('Tower Menagerie.')

According to Mr. Bennett the Cheetah is found in Asia and Africa. He says, "Chardin, Bernier, Tavernier, and others of the older travellers, had related that in several parts of Asia it was customary to make use of a large spotted cat in the pursuit of game, and that this animal was called Youze in Persia and Chetah in India; but the statements of these writers were so imperfect, and the descriptions given by them so incomplete, that it was next to impossible to recognise the particular species intended. We now however know with certainty that the animal thus employed is the *Felis jubata* of naturalists, which inhabits the greater part both of Asia and Africa. It is common in India and Sumatra, as well as in Persia, and is well known both in Senegal and at the Cape of Good Hope; but the ingenuity of the savage natives of the latter countries has not, so far as we know, been exerted in rendering its services available in the chase in the manner so successfully practised by the more refined and civilised inhabitants of Persia and Hindustan."

Mr. Swainson states ('Classification of Quadrupeds,' 1835) that the Hunting Leopards appear to be of two species—one inhabiting Africa, the other India; and that it deserves attention that one of these possesses a sort of mane, of which the other is said to be destitute. The mane however, in specimens from both localities, seems to be much the same. The animal figured by Pennant as the Hunting Leopard was brought from India by Lord Pigot. Three others, captured at Seringapatam among the effects of Tippoo, were presented by Lord Harris to George III., who placed them in the Tower. The couple from which Mr. Bennett made his accurate description came from Senegal. The Cheetah was indeed, as the last-mentioned zoologist remarks, very imperfectly known in Europe till of late years. Linnæus does not appear to have been acquainted with it, and Buffon's Guêpard was described from the skin only. Guêpard is the name by which the skin of the animal was known commercially in reference to the Senegal market; and Mr. Bennett is of opinion that Buffon described it without suspecting its identity with the Asiatic animal, "the trained habits of which, misled probably by the authority of Tavernier, he erroneously attributed to his imaginary Ounce. Subsequent French zoologists had rectified this error, and it was generally believed that the tamed leopard of Bernier, the Youze, the Guêpard, and Tavernier's Ounce, were one and the same animal; but it was not until a year or two ago"—Mr. Bennett wrote the passage quoted in 1829—"that the possession of a living specimen, brought from Senegal, in the menagerie of the Jardin du Roi, enabled M. F. Cuvier to ascertain its characters with precision. The comparison of this African specimen with the skins sent from India, and with the notes and drawings made in that country by M. Duvaucel, at once puts an end to all doubts of the identity of the two animals."

In 1831 Colonel Sykes observed that *Felis jubata*, Linn., and *Felis venatica*, H. Smith (Cheeta of the Mahrattas), appear to be identical, the specific differences deduced from the hair originating in domestication. A skin of the wild animal, according to the colonel, has a rough coat in which the mane is marked, while domesticated animals from the same part of the country are destitute of mane, and have a smooth coat. ('Zool. Proc.')

In the East, where these beautiful animals are employed in the chase, they are carried to the field in low cars whereon they are chained. Each leopard is hooded. When the hunters come within view of a herd of antelopes the leopard is unchained, his hood is removed, and the game is pointed out to him; for he is directed in the pursuit by his sight. Then he steals along cautiously and crouchingly, taking advantage of every means of masking his attack, till he has approached the herd unseen, within killing distance, when he suddenly launches himself upon his quarry with five or six vigorous and rapid bounds, strangles it instantaneously, and drinks its blood. The huntsman now approaches the leopard, caresses him, wins him from his prey by placing the blood which he collects in a wooden ladle under the nose of the animal, or by throwing to him pieces of meat; and whilst he is thus kept quiet hoods him, leads him back to his car, and there chains him. If the leopard fails in consequence of the herd having taken timely alarm he attempts no pursuit, but returns to his car with a dejected and mortified air.

The skin is an article of some importance in the trade of Senegal, but appears to be neglected at the Cape of Good Hope, where the animal is called Luipard by the Dutch colonists; indeed it seems to be of rare occurrence there, for Professor Lichtenstein notices one of the skins as being worn by a Kaffir chief as a badge of distinction.

Of the habits of the Hunting Leopard, in a state of nature, not much is known; but it may be surmised that it captures its prey much in the same way as it does when employed in the chase. Mr. Bennett gives a very pretty picture of the manners of the two that furnished his description, and as it would be spoiled by abridgment we here insert it:—"They are truly," writes Mr. Bennett, "an elegant and graceful pair, having, when led out into the courtyard in their couples, very much of the air and manners of a brace of grayhounds. When noticed or fondled they purr like a cat, and this is their usual mode of expressing pleasure. If, on the other hand, they are uneasy, whether that uneasiness arises from cold, from a craving after food, from a jealous apprehension of being neglected, or from any other cause, their note consists of a short uniform and repeated mew. They are extremely fond of play, and their manner of playing very much resembles that of a cat; with this difference however, that it never, as in the latter animal, degenerates into malicious cunning or wanton mischief. Their character indeed seems to be entirely free from that sly and suspicious feeling of mistrust which is so strikingly visible in the manners and actions of all the cats, and which renders them so little susceptible of real or lasting attachment. The Cheetahs, on the contrary, speedily become fond of those who are kind to them, and exhibit their fondness in an open, frank, confiding manner. There can, in fact, be little doubt that they might with the greatest facility be reduced to a state of perfect domestication, and rendered nearly as familiar and faithful as the dog himself." ('Tower Menagerie,' London, 8vo., 1829.)

Most of the Hunting Leopards brought to England died in no long time after their arrival, and the French seem to have had no better success. The Zoological Society of London succeeded in keeping their specimens very well: the principal food given was lean mutton.

Felis Onça (Linnæus), the Jaguar, or American Panther, is the form of the Leopard found in the New World. It is the Onza of Marcgrave and the Panther or Great Panther of the furriers.

In form the Jaguar is robust, far stouter than the Leopard, and is very strongly, not to say clumsily, built. The body is thicker, the limbs shorter and fuller, and the tail scarcely reaches the ground when the animal is well up on its feet. The head is larger and rather shorter than that of the Leopard, and the profile of the forehead more prominent. When full grown the animal is said to measure from 4 to 5 feet from the nose to the root of the tail. "These differences of form," says Mr. Bennett ('Gardens and Menagerie of the Zoological Society'), "are accompanied by differences in colour and markings equally decisive. The general appearance is at the first glance the same in both; but the open roses of the Leopard are scarcely more than half the size of those of the Jaguar, and they all inclose a space of one uniform colour, in which, unless in some rare and accidental instances, no central spots exist; while in the latter animal most of those which are arranged along the upper surface, near the middle line of the back, are distinguished by one or two small black spots inclosed within their circuit. The middle line itself is occupied in the Leopard by open roses intermixed with a few black spots of small size and roundish form; that of the Jaguar, on the contrary, is marked by one or two regular longitudinal lines of broad, elongated, deep black patches, sometimes extending several inches in length, and occasionally forming an almost continuous band from between the shoulders to the tail. The black rings towards the tip of the latter are also more completely circular than in the Leopard."

But the skin of the Jaguar is subject to much variation, and Sir William Jardine ('Naturalists' Library,' 'Mammalia,' vol ii.) gives three figures from different sources illustrating strongly marked differences in the spots.

It is a native of South America—Paraguay and the Brazils principally—but it is said to have been found from the southern extremity to the Isthmus of Darien.

Mr. Martin, in his anatomical description of a Jaguar that died in the Gardens at the Regent's Park ('Zool. Proc.,' 1832), notices the immense volume of the chest as contrasted with that of the abdominal cavity, a circumstance which might, he thinks, be considered as furnishing an index to the habits and vital energy of this tribe of active and ferocious quadrupeds. That the Jaguar is an animal of great power and frequently of a daring dispositiou there can be no doubt; but the balance of the evidence is against its equalling, if not exceeding, the royal tiger of the east in ferocity. Of its power D'Azara gives the following anecdote. A Jaguar had struck down a horse; and D'Azara gave instructions that the latter should be drawn within musket-shot of a tree wherein he intended to pass the night, in expectation that the Jaguar would returu for his prey. While D'Azara was gone to prepare himself, the Jaguar returned from the opposite side of a river broad aud deep, seized the horse in its mouth, drew it to the water some 60 paces, swam across the river with it, landed it, and drew it into a wood hard by. All this was witnessed by the person whom D'Azara had placed in concealmeut to watch till his return.

Jaguar (*Felis Onça*).

The Jaguar is a most expert climber. Sonnini saw the scratches left by the claws of one on the smooth bark of a tree some 40 feet high without branches. He traced the marks of several slips made by the climber, but the animal had at last reached the top. Humboldt heard the Jaguar's yell from the tops of the trees followed by the sharp shrill long whistle of the terrified monkeys, as they seemed to flee. None of the living quadrumanes or quadrupeds seem to come amiss to it, and birds and fish, which last it is said to take in shallows, are sacrificed to its voracious appetite. The Jaguars will openly seize cattle, horses, and sheep from the enclosures; and the havoc made by them is great, as will be easily imagined when we learn from Humboldt that their numbers are such that 4000 were killed annually in the Spanish colonies, aud 2000 were exported every year from Buenos Ayres only. Nor are the reptiles free from its attacks. The shells of turtles were pointed out to Humboldt as having been emptied of their contents by the Jaguar, which, it seems, watches them as they come to the sandy beeches to lay their eggs, rushes ou them, and turns them on their backs. He then insinuates his paw between the shells, and scoops out the contents as clean as if a surgeon's knife had been employed. As the beast turns many more than he can devour at one meal, the Indians often profit by his dextrous cunning. He will, it is stated, pursue this persecuted race into tho water where it is not very deep, and will dig up and devour the eggs.

With all this the Jaguar does not seem to be very dangerous to man, when boldly confronted, though D'Azara records frequent instances of his attackiug the lord of the creation. The Jaguar will indeed often follow travellers, according to Sonnini and Humboldt, but the latter celebrated naturalist and observer only heard of one instance where a Llanero was fouud torn in his hammock, and that happened opposite tho Island of Achaguas. He relates, on the other hand, a story of two Indian children, a girl and a boy, the one about seven, and the other niue years old, who were at play ou the outskirts of a village, about two o'clock in the afternoon, when a large Jaguar came out of the woods bounding towards them playfully, his head down and his back arched, like a cat. He approached the boy, who was not sensible of his danger, and began to play with him, till at last the Jaguar struck him so hard on the head with his paw as to draw blood, whereupon the little girl struck him smartly with a small switch, and he was bounding back not at all irritated, when the Indians, alarmed by the cries of the girl, came up.

When Mr. Waterton ('Wanderings') was encamped on the banks of the Essequibo, he was visited by one of these prowlers. "Whenever the fire got low the Jaguar came a little uearer; and when the Indian renewed it, he retired abruptly; sometimes he would come within twenty yards, and then we had a view of him, sitting on his hind legs like a dog; sometimes he moved slowly to aud fro; aud at other times we could hear him mend his pace, as if impatient. At last the Indian, not relishiug the idea of having such company, set up a most tremendous yell. The Jaguar bouuded off like a race-horse, and returued uo more. It appeared by the print of his feet next morning, that he was a full grown one."

The Jaguar is said to make its attacks on quadrupeds by springing upon the neck of his prey; then placing one of his paws upon the back of its head, while he turns round the muzzle with the other, he dislocates the neck and deprives it of life.

He, in his turu, falls a victim to man. The Spaniards aud Indians hunt him in various ways. Sometimes he is driven by dogs 'to tree,' in which case he is despatched with the musket or lance; sometimes the pack force him amoug the bushes, and then is exhibited, sometimes a daring feat. A single Indiau, with his left arm euveloped in a sheep-skin, and with a 5-feet lance in his right, goes boldly in to him. The hunter parries the onset of the furious beast with his shielded arm, and at the same time deals him such a thrust with his lance as seldom requires repetition. The lasso is also used with the best effect upon the plains.

There is a black variety of the Jaguar, Le Jaguar Noir of the French, *Felis nigra* of Erxleben, aud probably the Jaguarete of Marcgrave.

This seems to have been the animal noticed by Lieutenat Maw R.N., ('Journal of a Passage from the Pacific to tho Atlautic,' 8vo., Loudon, 1829), at Para, as a 'black onça, or tiger.' It had been procured up the rivers by Mr. Campbell, and, when Mr. Maw saw it, was a formidable animal. "I am not sure," says that gentleman, "that it had the length of limb of a Bengal Tiger, but it was thicker, and, I think, it would have weighed more. When lying dowu, there appeared to be scarcely any leg, but its thigh was like an immense ham." Lieutenant Maw relates some amusing anecdotes about this animal, for which we refer the reader to his interesting book.

IV. The Lynxes.

The name of Lynxes is applied by zoologists to a subdivision of the great genus *Felis*, or Cats, well marked externally, and elevated by Dr. Gray to the rank of a genus, under the appellation of *Lyncus*.

There doos not appear to be any considerable difference between the organisatiou of the Lynxes and that of the other Cats; but it is extremely probable that there is some modification about the boues of the tongue, and the organ of the voice generally, to produce the peculiarly powerful noise aualogous to what is called 'spitting' and 'swearing' in the domestic cat.

Linnæus, in his last edition of the 'Systema Naturæ,' records but one species, *F. Lynx*, to which he assigns the woods and deserts of Europe and Canada as localities. This was probably the European Lynx, aud the descriptions may have been founded on Lyuxes from Canada as well as Europe.

Gmelin, in his edition, adds three other species, *F. Chaus*, *F. Caracal*, and *F. rufa*; and gives two varieties of *F. Lynx*, with Europe, America, Northern Asia, and eveu Japan, as the habitations.

Pennaut notices seveu species of Lynxes—the Mountain Lynx, Cat-a-Mouutain of Ray (North America), the Serval, the Lynx, the Bay Lynx, the Caspiau Lynx, the Persian Lynx, and the Libyau Lynx. He states that the third inhabits the vast forests of the north of Europe, Asia, and America; "not India, though poets havo harnessed them to the chariot of Bacchus, in his conquest of that country." The fourth, he says, is an iuhabitant of the inuer parts of the province (now the state) of New York. To the fifth he assigns the "reeds and woods in the marshy parts that border on the western sides of the Caspian Sea, particularly about the Castle Kislar, on the river Terek," and the Persian provinces of Ghilan aud Mazanderan; adding that it is frequeut about tho mouth of tho Kur, the ancient Cyrus. Persia, India, and Barbary are the countries which he states to be the localities of the sixth; aud Libya and Barbary are mentioned by him as the couutries of the seventh. It is doubtful what animals Pennant meant to designate under some of these names. The Serval is uot considered to be a Lynx.

Cuvier observes that thero aro known iu commerce, under the name of Loups Cerviers (*Lupus cervarius*), four or five sorts of Lynxes, which had long been confouuded by naturalists, and whose specific limits were not perhaps well fixed when he wrote. We shall proceed to notice the arrangement of M. Temminck, and theu return to observo what part of it is adopted by Cuvier.

M. Temminck gives the following as species:—

1. *F. cervaria;* described as nearly equalliug a wolf in size, and possibly the Kattlo of Linnæus and tho Swedes; but it has been remarked that no skius of it are contaiued in the cargoes that arrive from the Baltic. In commerce the skins of *F. cervaria* are said to be only obtained from the markets of Moscow, to which they are brought from the provinces of Asia. It is considered as probable that this species may have been confounded, under tho name of the Canadiau Lynx, with—

2. *F. borealis*, which is intermediate in size betweeu the fox and

the wolf. This comprehends the Canadian but not the Mississippi Lynx of Cuvier, and is said to inhabit the north of both the old and the new continents: its fur, less valuable than that of *F. cervaria*, is stated to be received equally from Sweden and from Hudson's Bay.

3. *F. Lynx* (true Lynx), different from, but nearly allied to *F. cervaria*, *F. borealis*, *F. rufa*, and—

4. *F. pardina*. Size of a badger, but the legs longer, resembling *F. rufa* in form and size; tail short, but longer in proportion than that of *F. Lynx*. *F. pardina* is the Loup-Cervier of Perrault, and is found only in the south of Europe, the centre being the locality of the true Lynx. On this species Colonel Sykes makes the following statement:—"Although Temminck, in his 'Monographie de Mammalogie,' p. 116, in a note, says the skins of this European *Felis* is well-known amongst the furriers as the Lynx of Portugal, I have nowhere been able to meet with a specimen in London; and as amongst my friends scarcely any one appeared to be aware of the existence of a Spanish Lynx, I thought it might be acceptable to the members to exhibit specimens in a state of maturity and nonage. In Andalusia, whence the specimens come, it is called Gato Clavo (clavo meaning the pupil of the eye), illustrative of the spotted character of the skin. Some peasants in Andalusia make short jackets of the skins. The animal inhabits the Sierra Morena. I bought both skins at Seville for thirty reales, about 6*s*. 3*d*. Neither the British Museum nor the Zoological Society has specimens.

"Temminck describes the *Pardina* as 'Toutes les parties du corps lustre, a peu près de la même teinte que dans le caracal.' This is certainly not the description of my animal, the colour of the adult being reddish-grey, and that of the non-adult light fawn; nevertheless there are so many other points common to both, that it would be unadvisable to consider them distinct." ('Zool. Proc.,' 1838.)

5. *F. Caracal*, Nubian Caracal, and Cat of the Desert of Bruce; Persian Cat (Lynx) of Pennant.

6. *F. aurata*. Rather less than the Caracal. Country unknown. Skin purchased from a London dealer.

7. *F. Chaus* (Güldenstedt), figured by Schreber. The other animals described under this name are considered to be referrible to—

8. *F. caligata*, Booted Lynx of Bruce; *F. Libycus* (Olivier); Libyan Caracal of Buffon.

Of these Baron Cuvier notices *F. cervaria* as the finest and largest; *F. borealis*; *F. Lynx* (which has almost entirely disappeared from populous countries, but is still to be found in the Pyrenees, the mountains of the kingdom of Naples, and even it is said in Africa); *F. pardina*, Oken, from the south of Europe; *F. rufa*, Gülden.; and *F. Chaus*, or Lynx of the Marshes of Caucasus, Persia, and Egypt. Cuvier further observes that it is believed at present that the Booted Lynx, *F. caligata*, Temm., may be distinguished from *F. Chaus*; but he remarks that *F. caligata* is at least very nearly approximated to it, and that it has the same habits.

F. Caracal (Persia, Turkey, &c.), which he considers to be the true Lynx of the ancients, closes Cuvier's list of species; but he alludes in a note to *Lynx fasciatus*, *L. Floridanus*, and *L. montanus* of Rafinesque; and to *F. aurata* of Temminck, as belonging to this tribe.

Dr. J. E. Gray places his genus *Lyncus* (sub-family *Felina*) between the genera *Felis*, Linn., and *Prionodon*, Horsfield.

M. Lesson gives the following species:—1. *F. Lynx*, the Loup-Cervier of the furriers, Goupe of the Norwegians, and Wargelue of the Swedes, who recognise three very different varieties of it. He states that the whole of Europe is its habitat, where it has become very rare, and he says that they point out a pale variety *F. rufa*, Pennant (?), and that 'Le capitaine Brooks en indique trois,' which may be, in his (the captain's) opinion, regarded as species. 2. *F. pardina*, Oken, Temm.; Loup-Cervier of the French Academicians; to this Portugal, Sardinia, Sicily, and Turkey are assigned as localities. Next follows *F. Serval*, which cannot be considered a Lynx. 3. *F. cervaria*, Temm. 4. *F. borealis* (Chat du Canada, Geoff.), to which the northern countries of America and Asia are given as its distribution. 5. *F. Caracal*, the Lynx of the ancients (Africa, Persia, and Arabia). M. Lesson describes the differences of the Caracals of Algiers, of Nubia, and of Bengal. 6. *F. Chrysothrix* and *F. aurata*, Temm.; country unknown. 7. *F. Chaus*, Gülden. (Egypt, Nubia, and Caucasus). 8. Booted-Lynx (*F. caligata*, Bruce, Temm.; *F. Libycus*, Oliv.). To this a range is given from Egypt to the Cape of Good Hope in Africa, and the south of Asia. M. Lesson also notices as specifically different the *F. Manul* of Pallas and Desmarest, a species not admitted by Temminck, but which has, according to Pallas, the appearance of the Lynx. ('Mongolian Tartary.')

Sir William Jardine ('Naturalists' Library,' 'Mammalia,' vol. ii. 1834), who adopts the genus *Lyncus* or *Lynchus* of Dr. Gray, as the fifth genus of the *Felinæ*, enumerates the following species: *Lynchus Caracal*; *L. aurata*; *L. Chelidogaster*, inhabits Chili (Temm., Mus. Leyd.); *L. caligata*, Bruce; *L. nigripes*, Burchell, inhabits South Africa; *L. Chaus* (Gülden., Rüpp.); *L. Canadensis*; *L. rufa*, Bay Lynx, inhabits banks of Colombia River, United States, not Canada (Temm.); *L. fasciata*, Banded Lynx (Richardson), inhabits North America, woody countries in the neighbourhood of the Pacific (Lewis and Clark); and *L. Lynx*.

Sir William Jardine remarks that there is yet considerable confusion among the Lynxes of America, and that, except the Canada Lynx, the species are perhaps not well determined. He observes that Mr. Vigors and Dr. Horsfield describe one under the title of *F. maculata* from Mexico.

Sir William further states that another Asiatic Lynx may be perhaps added in the *Felis affinis* of Dr. Gray, figured in his 'Illustrations of Indian Zoology.'

It may be necessary also to call the reader's attention to two species of *Felis*, one in the volume of the 'Naturalists' Library,' *F. Servalina*, figured as *F. ornata*, which Sir W. Jardine at first considered as identical with Dr. Gray's species with the last-mentioned name, but which Dr. Gray considered to be distinct. The figures of both *F. ornata*, Gray ('Illustr. Ind. Zool.'), and *F. Servalina*, Jardine, have small tufts on the tips of their ears, and are otherwise inclined to be lynx-like; as if they formed the passage between some of the smaller Spotted Cats and the Lynxes.

Mr. Swainson ('Natural Hist. and Classification of Quadrupeds,') having compared the two typical forms of the *Feræ* and *Raptores*, observes that it remains to be ascertained which group among the *Feræ* may be likened to the Owls, and he fixes upon the Lynxes, because Lynxes and Owls are both nocturnal animals, both have short tails and comparatively large heads; and because the Owls "are particularly remarkable for certain appendages or tufts which rise above their ears," whilst in the Lynxes the "ears are long, and from the tip of each arises a tuft of lengthened hairs, perfectly analogous to the tufts of lengthened feathers on the Horned Owls, the most typical birds of the family of *Strigidæ*." His only notice of Lynx in the 'Classification' at the end of the volume is "Lynx Antiq., ears tufted with hairs, tail short;" and it appears as the fifth and last subgenus of *Felis*, Linn., the other four being:—1. "*Leo Antiquorum*, Lions, head and neck furnished with a mane of long hair, tail tufted. 2. *Felis*, Linn., Cats, no mane, tail long, not tufted. 3. *Cynailurus*, Wag., Hunting Leopards, claws semi-retractile; and, 4. *Prionodon*, Horsf., affinities uncertain."

The Lynxes may be divided into two groups: the first consisting of those species whose bodies are comparatively slender, and whose tails and tufted ears are comparatively long; the second of those whose bodies are thicker and stout, and whose ears and tail are comparatively short. The Caracal is an example of the first subdivision; and the European and the Canada Lynxes of the second. Sir William Jardine considers the tufts of hair at the tips of the ears as somewhat inconstant, and only present in spring, or at the commencement of the breeding season, like those adorning the ears of many squirrels.

Several forms of Lynx are found in the Old World.

Felis Caracal, the Caracal. M. Temminck describes this species, which is the Siyah Ghush, or Black-Ear, of Charleton and others, as having a pale reddish-brown fur with a vinous tinge, the red becoming paler as it reaches the lower parts. Two spots of pure white above the eyes, the uppermost on the inner side of the eye, the lower at its external angle. Termination and edges of the upper lip, chin, breast, belly, and insides of the legs, pure white; parts whence the whiskers spring, black; back of the ears at the base, deep black, more gray towards the tips, which are tufted with long black hairs. Length, 2 feet 10 inches, of which the tail measures 10 inches: average height about 14 inches.

Mr. Bennett ('Tower Menagerie') describes the Caracal as larger than the Fox, and the whole of the upper surface of the body as of a deep and uniform brown, the hairs being for the most part slightly tipped with gray; the under and inner parts nearly white; and the chin, lower lip, and two spots, one on the inner side of and above the eye, and the other beneath its outer angle, completely white; neck and throat of a lighter and brighter brown than the rest of the fur; the ears long and upright, tapering gradually to a fine tip, surmounted by a pencil of long black hairs, and black externally and whitish within; whiskers short, taking their origin from a series of black lines which occupy the sides of the muzzle; at some distance behind them, in front of the neck on each side, a short and thick tuft of lighter coloured hairs; tail 8 or 9 inches long, of the same uniform colour with the body from base to tip.

The Caracal is found in Persia, India, Barbary (Pennant); Persia, Turkey, &c. (Cuvier); the whole of Africa, from Egypt and Barbary to the extremity of Kaffraria, and the southern half of Asia, at least as far eastward as the Ganges (Bennett). The specimen from which Mr. Bennett took his description is noticed by him as a native of Bengal, and he observes that there is no difference of any importance between it and the African variety. Cuvier, to whom M. Duvaucel sent drawings of the animal from Calcutta, was convinced that this is the case. He refers to the Caracal à Longue Queue of Buffon's 'Supplement,' iii. pl. 45, and observes there is no difference between that and the others, and that the first Caracal of Buffon had a mutilated tail. Localities, Africa, Arabia, Persia (Fischer); Africa, Persia, Arabia (Lesson); Southern India and Africa (Jardine).

This species is said to follow the lion and other large beasts of prey, most probably for the purpose of feeding upon what they leave. But in addition to this it feeds on small quadrupeds and birds, the latter of which it is said to pursue actively on trees. It has obtained the name of 'lion's provider,' most probably from its dogging the footsteps of the lion, and having been found preying upon the carcasses which the former has left. According to M. Temminck, the Caracals hunt in packs like the wild dogs, and so run down their prey. Pennant, quoting Thévénot, notices their feeding on the remains of the prey which the lion leaves, and seems to confirm the account given by M. Temminck, for he states that they are often brought up tame, and used in the chase of lesser quadrupeds and the larger sorts of birds, such as cranes, pelicans, peacocks, &c. When they seize their prey, they hold it fast with their mouth and lie motionless on it. Pennant, quoting Hyde, also states that the Arabian writers, who call it Anak el Ard, say that it hunts like the panther, jumps up at cranes as they fly, and covers its steps when hunting. In captivity the Caracal is generally very ill-natured and irritable, and does not seem to hold out much promise for domestication; but we are aware that it is not safe to come to conclusions of this sort upon the evidence of an unhappy irritable animal shut up in a cage, when nature intended it for unlimited roamings. A young Caracal in the Garden of the Zoological Society at the Regent's Park was very familiar and anxious to be noticed, pleased with being caressed, and playful as a kitten. Dr. Charleton however gives evidence of the fierceness and strength of this species, for he relates that he saw one fall on a hound, which it killed and tore to pieces in a moment, though the dog defended itself to the utmost.

Caracal (*Felis Caracal*).

This animal derives its name of Caracal from the Turkish words 'kara,' black, and 'kulach,' ear: and the Persian name 'Siyah-Gush' or 'Sia-gusch' ('sia,' black, and 'gusch,' ear) is derived from the same characteristic markings.

Authors seem to concur in holding that this is the Λύγξ, Lynx, of the ancients, and though we lean strongly to this opinion, the reader should bear in mind that the latter evidently used the term to denote various animals, as Gesner well remarked. The 'lynces Bacchi variæ' of Virgil ('Georg.' iii. 264) and the skin 'maculosæ lyncis' alluded to by the same author ('Æneid,' i. 323), can hardly be held to apply to the Caracal, though Ovid's line ('Met.' xv. 413)

"Victa racemifero lyncas dedit India Baccho"

may. The truth seems to be that the ancients themselves had no very precise ideas of the animal which was accorded to Bacchus as one of his attributes. The terms Lynx, Panther, and Tiger seem to be all employed to designate this animal or these animals; and if we refer to gems or coins or other ancient monuments, the Lynces, to play somewhat unpardonably perhaps on Virgil's expression, will be found to be sufficiently 'variæ.' The animals represented on the ancient sculptures have generally the round ear of the Lion, Tiger, and Panther or Leopard; and their general contour is that of the Lion, Lioness, or Panther, and Leopard. See, for instance, No. 30, No. 37, in Room i.; Fragments of Terracottas in Room x.; No. 8 (Bacchus and Ampelus), Room iv.; No. 40 (Libera, or Female Bacchus), Room vi.; No. 12, Room iii.; and No. 7, Room ii., of the Townley Gallery in the British Museum, as represented in the 'Library of Entertaining Knowledge':—British Museum; Townley Gallery,' vols. i. and ii. The Lion's skin, with which, as well as that of the Panther and Roe, he was represented, appears on the colossal statue of Bacchus in the Elgin collection in the British Museum. ('Library of Entertaining Knowledge':—British Museum—Elgin and Phigaleien Marbles, vol. ii.) In the edition of the 'Gemmæ et Sculpturæ Antiquæ,' by Gronovius, we find in the 'Carro di Baccho,' as mentioned above, a child in a chariot driving two round-eared spotted great cats; and in the next gem, figured 'Tigre di Bacho,' also a carnelian, we have a round-eared spotless female great cat with a tuft at the end of the tail, which no panther, leopard, or lynx possesses.

In the coin of Septimius Severus, noticed in Captain Smyth's 'Catalogue,' between the figures of Hercules and Bacchus is a lynx or panther, illustrating the verse of Propertius:—

"Lyncibus ad cœlum vecta Ariadne tuis."

Nor does there occur to us any ancient statue, gem, or coin whereon the Lynx of Bacchus is represented with pointed ears tufted at the summit, the characteristic mark of that subdivision of the cats denominated Lynxes by modern zoologists; though we by no means feel sufficient reliance upon our limited experience to consider this negative evidence as conclusive. The animal in the Palestrine Mosaic, with the word 'Lynx' below it, is represented with a tail of considerable length, and cannot be mistaken for one of the animals now called Lynxes; indeed, if we do not err, the Abbé Barthélemi observes that this animal bears a strong resemblance to a horse.

That the Λύγξ of Aristotle, Ælian, and Oppian was not one of the doubtful animals above alluded to, but one of the Lynxes of modern zoologists, there can be, in our opinion, no doubt.

Ælian (xiv. 6) gives such a description of his lynxes, with the tips of their ears tufted, their leaping on their prey, and their tenacity in holding it, as cannot be mistaken; and he quotes two lines of Euripides to show that the animal he is describing is the lynx of that poet. Oppian ('Cyneget.,' iii. v. 84) also gives such an account of his lynxes as can be referrible to no other animals than those on which we are treating. He speaks of two kinds, notices their preying on hares, and leaping upon stags and oryxes.

Pennant conceived that the European Lynx was the Λύγξ of Ælian and Oppian, and the *Chaus* of Pliny; with regard to the former, we think, without due consideration. The Caracal comes much more within Oppian's description than the European Lynx. Oppian expressly notices the ruddy and yellow colours of his two kinds, but mentions no spots. The localities of the Caracal, combined with the other evidence, make it much more probable that it should be the animal designated as a Λύγξ by Aristotle and Ælian, and one, at least, of the two kinds mentioned by Oppian, if his differences were not, as they well might be, those of climate, sex, or age. Mr. Bennett ('Tower Menagerie') thinks that the Caracal is unquestionably identical with the Lynx of the ancients, though the name has been usurped in modern times for an animal of northern origin utterly unknown to the Greeks, and known to the Romans by a totally different appellation.

F. caligata, Bruce, Temm., the Booted Lynx; *F. Libycus*, Olivier; *F. Chaus*, Thumb, Geoff. (part); Lynx des Marais (part), Cuv. (Fischer).

Small, total length about three feet, of which the slender tail measures rather more than one-third, or 13½ inches; ears large, red within, tipped with a pencil of brown short hairs; sole and posterior part of the foot (leg, in common parlance) deep black; upper parts of the body bluish-gray, in some specimens fulvous, clouded with gray

Booted Lynx (*Felis caligata*).

and sprinkled with black hairs; lower parts, including the under parts of the neck and breast, reddish; thighs marked with indistinct bands of rather bright brown; two rather bright ruddy bands on the cheeks; tail at its base colour of the back, black at the tip, and with three or four incomplete rings above it, which rings are separated by intervals of a more or less pure white. The female has generally the tints more yellow. The young have well-defined dark bands upon their sides.

It is a native of Africa, from Egypt and Barbary to the Cape of Good Hope, and of the south of India.

The Booted Lynx preys upon birds and small quadrupeds; of the former the guinea-fowl is much sought after by the African varieties. Like others of the subdivision, it will make a good meal on carrion, and feast on the remains of larger quadrupeds which have fallen before the great beasts of prey.

Felis Chaus (Güldenst.), the Chaus; Lynx des Marais (part), Cuvier; Mota Rahu Manjur, or Larger Wild Cat, of the Mahrattas (Colonel Sykes).

Dr. Rüppell's figure and description have dissipated the confusion that formerly reigned with regard to this and the preceding species. He states that the Chaus is well covered with hair all over, and of this covering that which forms the ground-work is woolly, very soft, and plentifully developed; the hairs are not thickly set. The colour of the woolly hair is of a dirty palish ochre-yellow, darker on the back and lighter on the under parts; the hairs or bristles are of the same colour at bottom, have a dark-brown ring in the middle, and at the tip are of a grayish-yellow, whitish, or saffron-colour; so that the appearance produced is a mixed colouring of grayish-yellow and dirty white. Many of the hairs have a black point, and on the sides, where many lie together, they form pale black perpendicular or oblique spiral lines, and here and there single black points. The hairs of the back are of a light ochre-yellow, with points almost of a saffron-colour, and form from the shoulders to the tail a yellow stripe, which is darkest on the cross. The nose is black: above the eye is a large white spot, and below it a smaller one of the same colour. A black streak runs from the inner corner of the eye to the nose. The edges of the lips are bordered with black, and a fine white ring encircles them. The eyebrows, cheeks, and bristles of the whiskers, are white, and among the latter are a few hairs of a shining black. The inner surface of the ear, towards its outside, is bordered by tufts of hair which are white and yellow; the back of the ear is gray-brown, and the tips are brown, with terminating black tufts, half an inch in length; the cheeks, lower jaw, throat, neck, and chest are ochreous-yellow, and the belly inclines to whitish-yellow with darker spots. Externally the anterior and posterior extremities are of the general colour down to the ankles (which are dirty ochreous-yellow, and black behind), and barred with four or more black transverse bands. The inside of the limbs is yellowish, and there is a large round black spot on the fore legs. The tail is about one-fourth as long as the body, of a grayish colour, blunt and black at the point, towards which are two black rings between two grayish-white ones; but neither of these is very distinct. (Rüppell.)

Chaus (*Felis Chaus*). Rüppell.

It is a native of the north of Africa (how far up the Nile is not ascertained), in the morasses and bushy lowlands that border the Caspian Sea, and on the banks of its tributary rivers. Said to be more numerous in Persia. Noticed in Deccan by Colonel Sykes. The female that served for Dr. Rüppel's description and figure was killed at the lake of Menzale, in the Delta of Egypt.

This species haunts marshes and boggy regions, and goes hunting during the night after birds, small rodents, and fishes; it seldom climbs trees, and is not easily tamed. (Rüppell.)

The Chaus of Pliny ('Nat. Hist.,' viii. 19), which the Gauls called Raphins, with the figure of a wolf and the spots of a pard, first shown at Pompey's games, can hardly, we think, have been this animal.

Felis Lynx (Linn.), the European Lynx; Le Lynx (Buff.).—Fur long

of a dull reddish-gray above, with oblong spots of reddish-gray upon the sides, the spots on the limbs rounder and smaller; whitish below, mottled with black. Length about three feet.

European Lynx (*Felis Lynx*).

This species varies much. In winter the fur is much longer than it is in the summer, and has a hoary appearance in the former season, owing to the long hair being then tipped with grayish-white. The tail, which is black at the end, is short, not more than six or seven inches long.

Some authors confine the locality of this species to Europe; others are of opinion that it increases in numbers as it approaches the borders of Asia, which it also inhabits, and abundantly. France is considered its most northern range. It does not seem to be quite clear that *Felis cervaria* of Temminck is not a variety of this species; but *F. cervaria* inhabits the north of Asia, and skins are sent from Moscow. This is supposed to be the Kattlo of the Swedes by some, while others consider *F. Lynx* to be the Goupe of the Norwegians and the Wargelue of the Swedes. If these differences should prove to be well founded, it may be that there are two European species, or at least varieties, one inhabiting Southern Europe, not higher than France, and the warm parts of Asia, and the other inhabiting the north of Europe and Asia.

The European Lynx feeds upon small quadrupeds and birds, in search of which it often climbs trees.

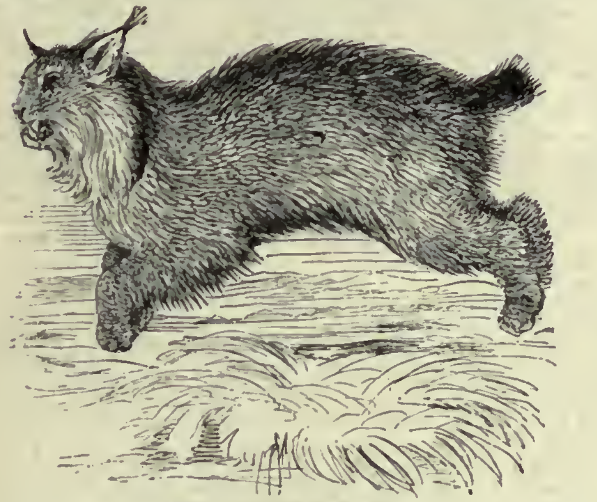
This species is supposed by many to be the *Lupus cervarius* of Pliny ('Nat. Hist.,' viii. 22), and the Chaus (viii. 19) above alluded to. Both are spoken of as shown in the arena by Pompey, and as coming from Gaul. Dr. Fischer, who is of this opinion, supposes it also to be the Lynx mentioned by Pliny in his chapter 'De Ungulis' (viii. 46).

The European and northern Asiatic Lynxes and the Canadian Lynx produce the great supply of furs known by the furriers under the name of 'lynx.' The colder the climate the fuller and the more valuable is the fur.

Felis Canadensis (Geoff.), the Canada Lynx. Sir John Richardson ('Fauna Boreali Americana') states that the early French writers on Canada, who ascribed to this species the habit of dropping from trees on the backs of deer, and destroying them by tearing their throats and drinking their blood, gave it the name of Loup Cervier. The French Canadians, he adds, now term it indifferently Le Chat, or Le Peeshoo. He remarks, that the mistake of Charlevoix in applying to it the appellation of Carcajou, which is proper to the Wolverine, has produced some confusion of synonyms amongst subsequent writers. Other writers however consider that Charlevoix intended to designate the Puma by the name of Carcajou, though he used the term improperly. If the following be the passage alluded to, it can hardly be applied to the Canadian Lynx:—"The elk has other enemies besides the Indians, and who carry on full as cruel a war against him. The most terrible of all these is the Carcajou, or Quincajou, a kind of cat with a tail so long that he twists it several times round its body, and with a skin of a brownish-red. As soon as this hunter comes up with the elk, he leaps upon him, and fastens upon his neck, about which he twists his long tail, and then cuts his jugular," &c. &c. ('Letter' vii.) Now, though there may be a little exaggeration about the length of the tail, and the use which the animal makes of it, the description is generally applicable to the Puma, and not to the Lynx, which has a mere stump of a tail, whilst the Puma has a remarkably long one.

As there is some question about this species—for Pennant notices it as identical with the European Lynx, and M. Temminck describes the species as the same in both hemispheres under the name of *Felis borealis*, whilst M. Geoffroy has named it as a distinct species—we shall give the description of Sir John Richardson, who adopts M. Geoffroy's name, at length:—

"The head is round, the nose obtuse, and the face has much of the form of that of the domestic cat, but the facial line is more convex between the eyes. The ears are erect, triangular, and tipped by an upright slender tuft of coarse black hairs; they are placed about their own breadth apart, and on their posterior surface they have a dark mark beneath the tip, which is continued near both margins downwards towards their bases. On the body and extremities the fur is hoary, most of the hairs being tipped with white; on the crown of the head and for a broad space down the middle of the back there is a considerable mixture of blackish brown, and on the sides and legs of pale wood-brown. In some specimens these colours produce an indistinct mottling, but in general there are no defined markings. A rufous tinge is also occasionally present about the nape of the neck, and on the posterior parts of the thigh. The tail is coloured like the back, except the tip, which is black. The fur is close and fine on the back, longer and paler on the belly. When blown aside it shows on the middle of the back a dark liver-brown colour from the roots to near the tip; but on the sides it is for the greatest part of its length of a pale yellowish-brown, being merely a little darker near the roots. The legs are thick, the toes very thick and furry, and are armed with very sharp awl-shaped white claws, shorter than the fur. There are four toes on each foot, those on the hind foot being rather the largest, but both feet are much spread. Length, 3 feet 1 inch," &c.



Canada Lynx (*Felis Canadensis*).

Sir John Richardson gives the following synonyms, &c.:—Loup-Cervier (Anarisqua), Sagard. Theodat.; Loup-Cervier, or Lynx, Dobbs; Cat-Lynx, Penn., 'Arct. Zool.;' Cat, or Pishu, Hutchins; Lynx, or Wild Cat, Hearne, Mackenzie; *Felis Canadensis*, Geoff., 'Ann. du Mus.,' Sabine, Franklin's 'Journ.,' 'Zoological Museum,' No. 72; Peeshoo, Cree Indians and Canadian Voyagers.

This is the only species of the genus existing north of the Great Lakes and eastward of the Rocky Mountains. It is rare on the sea-coast; does not frequent the Barren Grounds; but is not uncommon in the woody districts of the interior. Found on the Mackenzie River as far north as 66°. (Richardson.)

Timid, incapable of attacking any of the larger quadrupeds, this animal is well armed for the capture of the American hare, its principal prey. "Its large paws, slender loins, and long but thick hind legs, with large buttocks, scarcely relieved by a short thick tail, give it an awkward clumsy appearance. It makes a poor fight when it is surprised by a hunter in a tree; for though it spits like a cat and sets its hair up, it it easily destroyed by a blow on the back with a slender stick, and it never attacks a man. Its gait is by bounds, straight forward, with the back a little arched, and lighting on all the feet at once. It swims well, and will cross the arm of a lake two miles wide; but it is not swift on land. It breeds once a year, and has two young at a time." (Richardson.)

The skin of the Canada Lynx forms a considerable article in the fur trade; the annual importation by the Hudson's Bay Company is stated at from 7000 to 9000. Sir John Richardson says that the natives eat its flesh, which is white and tender, but rather flavourless, much resembling that of the American hare.

V. The Cats.

Among the smaller species of the great feline family our attention is naturally first directed towards that domestic animal which is found in almost every house. "In this case," says the author of that interesting little book 'The Menageries' (London, 12mo., 1830), "unlike that of the dog, there is no doubt which is the original head of the domesticated stock. The wild cat of the European forests is the tame cat of the European houses; the tame cat would become wild if turned into the woods; the wild cat at some period has been domesticated, and its species has been established in almost every family of the old and new continent." There is good authority for this assertion; but the origin of the domestic cat has been attributed to a very different source, and there are not wanting zoologists who even now hold that the parent stock of that useful animal is still undiscovered.

Rüppel during his first travels in Nubia discovered a cat (Kleinpfötige Katze, *Felis maniculata*) of the size of a middle-sized domestic cat, and one-third smaller than the European Wild-Cat (*Felis Catus ferus*, Linn.). All the proportions of the limbs were on a smaller scale, with the exception of the tail, which is longer in *Felis maniculata*. The woolly or ground hair is in general of a dirty ochreous, darker on the back and posterior parts, and becoming gradually lighter on the anterior and lateral parts; longer hair of a swarthy dirty white, so that the appearance of the animal is grayish-yellow. Skin of the edges of the lips and of the nose bare and black. Beard and bristles of the eyebrows shining white, brown at the roots; edges of eyelids black; iris glaring yellow. From the inner corner near the eye there is a dark-brown streak running in the direction of the nose, and there is a white streak as far up as the arch of the eyebrows; between these two streaks is another grayish one extending on the forehead by the side of the ears and under the eyes. Outside of the ears gray, inside white, and without tufts of hair. Eight slender black undulating lines arise on the forehead, run along the occiput, and are lost in the upper part of the neck. Cheeks, throat, and anterior part of the neck, shining white. Two ochreous-yellow lines spring, the one from the outer corner of the eye, the other from the middle of the cheek, and meet both together under the ear; and two rings of the same colour encircle the white neck: below the rings there are spots of ochreous-yellow. Chest and belly dirty-white, with similar spots or semicircular lines. A dark streak along the back becomes lighter as it rises over the shoulders, and darker on the cross. This streak is gradually lost on the upper part of the tail, the lower surface of which is white-yellow. The tail is almost of an equal thickness, rather slender, and with two dark rings at its point. The extremities, which have less hair in proportion on the outer side, are of the general colour, with besides five or six blackish semicircular bands on the fore legs, and six distinct dark cross-streaks on the hind legs. The inner sides are lighter in colour, with two black spots or streaks on the upper parts of the fore legs, and the hind extremities show the cross-streaks winding around the thighs towards the inside. Foot, soles, hind parts of ankles, and wrists shining black. Length 2 feet 5 inches, the tail being about 9 inches: height at the shoulder about 9½ inches. The description was taken from an aged female. M. Rüppell, who

Egyptian Cat (*Felis maniculata*).

found this cat west of the Nile, near Ambukol, in rocky and bushy regions, is of opinion that there can be no doubt that it is descended from the domestic cat of the ancient Egyptians, now to be traced in the cat-mummies and their representations on the monuments of Thebes. In the 'Description de l'Egypte, Hypogées des Thebes,' vol. ii. pl. 45, No. 14, is the representation of a cat. Plate 51, No. 3, shows a cat's mummy, and plate 54, No. 7, the skeleton of a cat's mummy which in size of body, form of head, and length of tail, accords perfectly with *Felis maniculata*. The question then arises whether this domestic cat might not have been transferred or bequeathed to the contemporary civilised Europeans by the Egyptians; and the superintendents of the Frankfort collection agree that the general facts strongly favour the opinion that *F. maniculata* is the type of our Domestic Cat. M. Temminck concurs in opinion with M. Rüppell that this Nubian species is the stock from which it sprang. Sir William Jardine, in his able 'Natural History of the Felinæ' ('Naturalists' Library,' 'Mammalia', vol. ii, small 8vo, Edinburgh and London, 1834), states that the opinion generally accepted before this by most naturalists was, that the Wild Cat of Europe was the original stock; but, he adds, that although, since the introduction of our House Cat to this country, there may have been an accidental cross with the wild native species, an attentive examination of the greater numbers will at once show a very different form from that exhibited by the Wild Cat; the most prominent distinctions being the shortness of the legs, and shortness and thickness of the tail in the latter. "The domestic cat," continues this author, "is the only one of this race which has been generally used in the economy of man. Some of the other small species have shown that they might be applied to similar purposes; and we have seen that the general disposition of this family will not prevent their training. Much pains would have been necessary to effect this, and none of the European nations were likely to have attempted it. The scarcity of cats in Europe, in its earlier ages, is also well known; and in the 10th and 11th centuries a good mouser brought a high price. Although, however, our opinion coincides with that of the above-mentioned authorities, and we think that we are indebted to the superstition of the ancient Egyptians for having domesticated the species described by Rüppell, we have no doubt that since its introduction to this country, and more particularly to the north of Scotland, there has been occasional crossing with our own native species, and that the results of these crosses have been kept in our houses. We have seen many cats very closely resembling the wild cat, and one or two that were very tame, which could scarcely be distinguished from it. There is perhaps no animal that so soon loses its cultivation, and returns apparently to a state completely wild. A trifling neglect of proper feeding or attention will often cause them to depend upon their own resources; and the tasting of some wild and living food, will tempt them to seek it again, and to leave their civilised home. They then prowl about in the same manner as their congeners, crouching among cover, and carefully concealing themselves from all publicity. They breed in the woods or thickets, and support themselves upon birds or young animals. Few extensive rabbit-warrens want two or three depredators of this kind, where they commit great havoc, particularly among the young in summer. They sleep and repose in the holes, and are often taken in the snares set for their prey. I once came upon a cat which had thus left her home: she had newly kittened in the ridge of an uncut corn-field. Upon approaching she showed every disposition to defend her progeny, and beside her lay dead two half-grown leverets."

Before we quit this part of the subject we must not forget that among the animals seen by Rüppell in Kordofan, he discovered a new small species of Cat.

Mr. Bell ('History of British Quadrupeds,' Lond. 8vo., 1827), first addresses himself to the question whether the common wild cat is the original from which all our domestic cats have sprung, according to the general opinion of the older naturalists. He states that there are many reasons for believing that this opinion is entirely erroneous. In the first place, he observes, the general conformation of the two animals is considerably different, especially in the length and form of the tail, which in the wild cat is strong, robust, and at least as large towards the extremity as at the base and middle, whilst that of the domestic cat tapers towards the apex. The fur too of the former, he remarks, is thicker and longer; and although the colours are somewhat like those which occur in some individuals of the ordinary species, there are, even in this respect, distinctions which can scarcely be considered otherwise than as essentially specific; as for instance, the termination of the tail in a black tuft, which invariably marks the wild cat. To these distinctions may be added the difference of length of the intestinal canal; though domestication might account for much of that.

But to return to Mr. Bell. With regard to the alleged crossing between the wild and the domestic breeds, "it is not without much reflection on the matter" that he has "come to the conclusion that this opinion of their intermixture, repeated and transmitted from one to another till it has become an uncontested dogma, is erroneous, and has its foundation in mistaken facts." Mr. Bell then notices Rüppell's *Felis maniculata* above described, and comes to the conclusion that "this species, to which the high authority of Rüppell has assigned the origin of our house cat, is still farther removed from it in essential zoological characters than even the British wild cat, to which it had been previously so generally referred; and that, as in the case of so many of our domesticated animals, we have yet to seek for the true original of this useful, gentle, and elegant animal."

We must confess that we do not see much difficulty in coinciding with the opinion of Rüppell, Temminck, and Sir William Jardine upon the evidence at present known. It is not attempted to be denied that the Egyptians had a domestic cat, and we think that there can be little doubt that the Domestic Cat of the Egyptians was identical with *F. maniculata.* This extraordinary people, whose existence is now only to be traced in their wonderful and enduring monuments, were, when in their high and palmy state, the centre of civilisation, and we can see no reason why other nations, who borrowed so largely from them, should not have also received their domestic cat among other benefits of civilisation. This animal, when introduced, would be liable to all the usual consequences of domestication and of intermixture, according to the localities of the various nations who obtained it. We can see no reason why the domestic cat, from whatever source derived, should not breed with the wild cat in Great Britain, and we believe that it has so bred.

The arguments derived from the difference between the tails of the Wild Cat, of the Domestic Cat, and of *F. maniculata*, do not seem to us to carry much weight. We cannot shut our eyes to the effect of domestication on this organ among the Dogs, which gives us every variety, from the well-clothed tail of the Newfoundland dog, setter, and spaniel, to that of the grayhound, which is so scantily furnished as to owe one of its excellencies to being 'tailed like a rat;' nay, in some varieties, that long tail is reduced to almost no tail at all. There are also tailless cats, as Mr. Bell himself notices.

Still the doubt thrown on the question by a zoologist of so much experience and skill as Mr. Bell is deserving of the most serious consideration, and should stimulate those who have the opportunity to investigate the subject upon every occasion offered to them.

The Domestic Cat is Le Chat of the French; Gatto of the Italians; Gato of the Spanish and Portuguese; Katze of the Germans; Cyperse Kat and Huyskat of the Dutch; Katta of the Swedes; Kat of the Danes; Cath and Gwr Cath of the Welsh; and *Felis domestica, seu Catus* of Ray. It is worthy of remark that all these names are the same as the Latin *Catus*, whence the diminutives *Catulus* and *Catellus*; and this is somewhat in favour of all northern and western Europe having received the Cat through Roman civilisation. We are thus brought nearer to Egypt, its probable origin. The Greek word 'ailúros' (αἴλουρος) is an odd one, and helps us nothing, being apparently a descriptive term. There seems to be a word in Sanscrit for cat, leading to the supposition that amongst the early Indo-Germanic races the cat was not domesticated.

The varieties of the Common Cat, as in all cases of domestication, are endless: among the most noted are the Tabby, the Tortoiseshell, the Chartreux, which is bluish, and the Angora Cat with its long silky hair. The Domestic Cat is but too famous for its attainments in the art of ingeniously tormenting, and it is difficult to say what end is answered by the prolonged agonies of fear and torture which the poor mouse is made to undergo before it receives the coup de grace. This refined cruelty appears to be confined to mice, young rats, and small quadrupeds: if a cat strikes down a bird she does not trifle with it, but, conscious of its chances of escape, bites off its head or wounds it mortally at once.

We insert the following from Pennant, though it has been often quoted, not only as illustrating the manners of a period so distant as that of Howel, who died in the year 948, after a reign of 33 years over South Wales and of 8 years over all Wales, but also on account of the reflection at the end, which we think worthy the consideration of those who are interested in inquiring whence the stock of the Domestic Cat was derived. "Our ancestors," says Pennant, "seem to have had a high sense of the utility of this animal. That excellent prince Howel Dda, or Howel the Good, did not think it beneath him, among his laws relating to the prices, &c., of animals ('Leges Walliæ,' p. 247, 248) to include that of the cat, and to describe the qualities it ought to have. The price of a kitling before it could see was to be a penny; till it caught a mouse, twopence. It was required besides that it should be perfect in its senses of hearing and seeing, be a good mouser, have the claws whole, and be a good nurse; but if it failed in any of these qualities the seller was to forfeit to the buyer the third part of its value. If any one stole or killed the cat that guarded the prince's granary he was to forfeit a milch ewe, its fleece, and lamb; or as much wheat as when poured on the cat suspended by its tail (the head touching the floor) would form a heap high enough to cover the tip of the former. This last quotation is not only curious, as being an evidence of the simplicity of ancient manners, but it almost proves to a demonstration that cats are not aborigines of these islands, or known to the earliest inhabitants. The large prices set on them (if we consider the high value of specie at that time) and the great care taken of the improvement and breed of an animal that multiplies so fast, are almost certain proofs of their being little known at that period." ('British Zoology.')

Felis Catus of Linnæus, the Wild Cat, is Le Chat Sauvage of the French; Gato Montis of the Spaniards; Wilde Katze and Baumritter of the Germans; Vild Kat of the Danes; Cath Goed of the Welsh; *Catus sylvestris* of Klein; and *Felis sylvatica* of Merrett.

Head triangular, strongly marked; ears rather large, long, triangular, and pointed. Body strong, rather more robust than that of the Domestic Cat. Tail of equal size throughout its length, or rather larger towards the extremity. Fur soft, long, and thick; colour of the face yellowish-gray, with a band of black spots towards the muzzle; whiskers yellowish-white; forehead brown; head gray, marked with two black stripes passing from the eyes over and behind the ears; back, sides, and limbs gray, darker on the back, paler on the sides; with a blackish longitudinal stripe along the middle of the back, and numerous paler curved ones on the sides, which are darker towards the back, and become obsolete towards the belly, which is nearly white. Tail annulated with light gray and black; tip of the latter colour. Feet and insides of the legs yellowish-gray; soles black, at least in the male, of which sex Temminck declares it to be a peculiarity. Colours of the female paler, and markings less distinct. Dimensions differing greatly according to the statement of various naturalists. Medium size of full-grown male:—

	Foot.	In.	Lines.
Length of head and body	1	10	0
Length of head	0	3	8
Length of ears	0	2	3
Length of tail	0	11	2

Female rather smaller. (Bell.)

Temminck gives the average length as three feet.

The Wild Cat is found in all the wooded countries of Europe, Germany especially; Russia, Hungary, the north of Asia, and Nepaul. The animal is larger in cold climates, and its fur is there held in higher estimation.

Wild Cat (*Felis Catus*).

In Britain it was formerly plentiful, and was a beast of chase, as we learn from Richard the Second's charter to the abbot of Peterborough, giving him permission to hunt the hare, fox, and wild cat. The fur in those days does not seem to have been thought of much value, for it is ordained in Archbishop Corboyl's canons, A.D. 1127, that no abbess or nun should use more costly apparel than such as is made of lambs' or cats' skins.

The Wild Cat is now rarely found in the south of England, and even in Cumberland and Westmoreland its numbers are very much reduced. In the north of Scotland and in Ireland it is still abundant.

Among the foreign Wild Cats may be enumerated *Felis Chaus*, Guld.; the Mota Rahn Manjur, or Larger Wild Cat, of the Mahrattas (a lynx); and *Felis torquatus*, F. Cuv.; the Lhan Rahn Manjur, or Lesser Wild Cat, of the Mahrattas; *Felis Moormensis*, the Moormi Cat, Hodgson, from the Moormi Hills in Nepaul ('Zool. Proc.' January, 1824). *Felis planiceps*, Vigors and Horsfield, departs in many points from the true cats, and approaches *Prionodon* in others. *Felis Temminckii* of the same zoologists, which is near the Domestic Cat in size, comes nearer in form—it is uniform in colour—to the true Tiger-Cats. We must not omit to notice the *Felis Caffra*, a specimen of which is to be seen in the South African Museum (No. 28), specimens of which have been met with, as the 'Catalogue' informs us, in whatever direction South Africa has yet been explored. "It exhibits certain fixed peculiarities which unequivocally constitute it a distinct species from the Domestic Cat, which is occasionally found wild in the colony, and with which the former has sometimes been erroneously confounded. It possesses a full share of the ferocity of the feline tribe; and dogs which have once had a specimen of its pugnacious will and power show a considerable degree of caution in encountering it a second time. It is frequently found in such flats as chance to be covered with long grass or with a moderate growth of brushwood; and when disturbed by the approach of men or dogs, usually seeks shelter in thickets, or the burrows of other animals. It preys upon small quadrupeds and birds, and is an especial enemy to those of the latter which have their nests upon the ground." ('Catalogue of South African Museum.')

We subjoin a list of the specimens of *Felinæ* in the collection of the British Museum, arranged according to the views of Dr. J. E. Gray.

Felinæ.

1. *Leo Barbarus*, the Lion; *Felis Leo*, Linn.; *Leo Africanus*, Swains.; *F. Leo Barbarus*, Fischer. North Africa.

2. *Leo Goojrattensis*, the Maneless Lion; *Leo Persicus*, Swains. (?); *Felis Leo Goojrattensis*, Smee.

3. *Leo Gambianus*, the Gambian Lion; Lion du Senegal, 'Mam. Lithog.'; *F. Leo Senegalensis*, Fischer. West Africa, interior of Gambia.

4. *Tigris regalis*, the Tiger; *Felis Tigris*, Linn., Buffon. India.

5. *Leopardus varius*, the Leopard or Panther; *Felis Leopardus* and *F. varia*, Schreb.; *F. Pardus*, Linn. (?), Cuv.; *F. minor* Ehrenb.; *F. Panthera*, Erxl.; *F. Antiquorum*, Fischer; *F. melas*, Péron; *F. chalybeata*, Herm.; *F. fusca*, Meyer. Nepaul, snowy region.

6. *Leopardus Uncia*, the Ounce; *Felis Uncia*, Schreb., Buffon; *F. Pardus*, Pallas; *F. Irbis*, Ehrenberg; *F. Panthera*, Erxl. Tibet.

7. *Leopardus neglectus*, the Gambian Leopard; *Felis neglecta*, Gray; *F. servalina*, Ogilby; *F. Senegalensis*, Lesson; *F. celidogaster*, Temm. Gambia, Western Africa.

8. *Leopardus Onça*, the Jaguar; *Felis Onça*, Linn.; *F. Yaguar*, Griffith.; *F. nigra*, Schreb.; *F. Panthera*, Schreb. Tropical America.

9. *Leopardus Serval*, the Serval; *Felis Serval*, Schreb.; *F. Capensis*, Forster; *F. Galopardus*, Desm.; Tiger Boschkatte, Cape colonists. Cape of Good Hope.

10. *Leopardus Moormensis*, the Mirvini; *Felis Moormensis*; Hodgson. Nepaul.

11. *Leopardus concolor*, the Puma; *Felis concolor*, Linn.; *F. discolor*, Schreb.; *F. Puma*, Shaw; Cougouar, Buffon; Gouazoura, Azara; *Puma*, Hernand. Canada.

12. *Leopardus Yagouarondi*, the Yagouarondi; *Felis Yagouarondi*, Lacep.; *F. Darwinii*, Martin. French Guyana.

13. *Leopardus marmoratus*, the Marbled Cat; *Felis marmorata*, Martin; *F. Diardii*, Jardine. Malacca.

14. *Leopardus pardalis*, the Ocelot; *Felis pardalis*, Linn., Schreb., Buffon; *F. Chibiguazu*, H. Smith (?); *F. Smithii*, Swains. (?); *F. Hamiltonii*, Fischer. Tropical America.

15. *Leopardus mitis*, the Chati; *Felis mitis*, F. Cuvier; *F. Onça*, Schreb., Buffon; *F. Chati*, Griffith; *F. Wiedii*, Swains. Tropical America, Guyana (?).

16. *Leopardus macrourus*, the Kuichua; *Felis macroura*, Pr. Max.; *F. Wiedii*, Sching. Mexico.

17. *Leopardus griseus*, the Gray Ocelot; *Felis armillata*, F. Cuvier. Tropical America.

18. *Leopardus pictus*, the Painted Ocelot, Gray. Tropical America.

19. *Leopardus Tigrinus*, the Margay; *Felis Tigrina*, Schreb., Buffon; *F. Margay*, Griffith; *F. Guigua*, Molina. Tropical America.

20. *Leopardus variegatus*, the Variegated Leopard. Tropical America,

21. *Leopardus tigrinoides*, the False Margay. Tropical America.

22. *Leopardus viverrinus*, the Wagati Cat; *Felis viverrinus*, Bennett, Gray; Wagati, Elliot. India.

23. *Leopardus Javanensis*, the Kubouk; *Felis Javanensis*, Horsf.; *F. minuta*, var., Temm.; *F. Diardii*, Griffith; *F. undata*, Fischer; *F. undulata*, Sching. Java.

24. *Leopardus Sumatranus*, the Balu; *Felis Sumatrana*, Horsf.; *F. minuta*, var., Temm.; *F. undata*, var., Fischer.

25. *Leopardus Chinensis*, the Maou; *Felis Chinensis*, Gray. China.

26. *Leopardus Reevesii*, the Chinese Bulu, China; *Leopardus Elliotti*, Elliott's Cat, Gray; *Felis Nepalensis*, Hodgson. Madras.

27. *Leopardus Himalayanus*, Warwick's Cat; *Felis Himalayanus*, Warwick, Jardine. India.

28. *Leopardus inconspicuus*, the Waved Cat, Gray; *Felis torquatus*, F. Cuv.; *F. Bengalensis*, Desm.; *F. Nepalensis*, Vigors and Horsf. India, Gangootra.

29. *Felis Catus*, the Wild Cat, Linn., Buffon. Scotland.

30. *Felis domestica*, the Cat, Brisson; *F. Catus Domesticus*, Schreb.

31. *Felis planiceps*, the Flat-Headed Lynx; Chaus (?); *F. Diardii*, Crawford. Sumatra.

32. *Chaus Lybicus*, the Chaus; *Felis affinis*, Gray; *F. Chaus*, Güldenst, Humb., F. Cuv.; *F. Dongolensis*, Hemp., and Ehr.; *F. caligata*, Bruce; *F. Lybicus*, Oliv.; *F. Catolynx*, Pallas; *Lynchus erythrotus*, Hodgson; *F. Kutas*, Pearson; *F. Ruppellii*, Brant. Nepaul.

33. *Chaus pulchellus*, the Smaller Chaus; *Felis pulchella*, Gray. Egypt.

34. *Chaus servalinus*, the Servaline Chaus; *Felis ornata*, Jardine; *F. servalina*, Jardine. India.

35. *Chaus Caffer*, Caffre Cat; *Felis Caffra*, Desm. (?). Cape of Good Hope.

36. *Caracal melanotis*, the Caracal; *Felis Caracal*, Buffon. Cape of Good Hope.

37. *Lyncus Canadensis*, the Peeshoo, or Canada Lynx; *Felis Canadensis*, Geoff., Richards.; *F. borealis*, Temm.; Cat-Lynx, Penn.; *Carcajou*, Charlevoix. Canada.

38. *Lyncus pardinus*, the Southern Lynx; *Felis pardina*, Oken; Loup-Cervier, Perrault. Sardinia (?), Spain, Sierra Morena.

39. *Gueparda jubata*, the Youze or Cheetah; *Felis jubata*, Schreb.; *F. guttata*, Herm.; *F. Fearonis*, A. Smith (?); *F. venatica*, H. Smith; Hunting Cat, Penn. Cape of Good Hope.

Fossil Felidæ.

In the second or Miocene period of the Tertiary Formations we have hitherto found the first traces of large Fossil Cats. There are no less than four species of these great cats, some as large as a lion, enumerated by Professor Kaup from the Epplesheim sand near Altzey, about twelve leagues south of Mayence. These remains are preserved in the museum at Darmstadt. The professor names these *Felis aphanista*, *F. prisca*, *F. ogygia*, and *F. antediluviana*. In the third and fourth (or Pliocene), divisions of the Tertiary periods, we find that the number of terrestrial herbivorous quadrupeds become more abundant; and, with their numerical importance, the *Carnivora*, whose agency was required for keeping them down, increase also. Dr. Buckland in his 'Reliquiæ Diluvianæ' mentions that Cuvier found the tusks of an extinct lion or tiger in the Breccia of Nice, and that Mr. Pentland had discovered the tooth of the same extinct tiger in the Breccia of Antibes. Bavard, the Abbé Croizet, and Jobert, in the work on 'Fossil Cats,' found, among the remains contained in the Ossiferous Rocks of Auvergne (Puy de Dôme) the following species: *Felis Issidoriensis*, *F. brevirostris*, *F. Pardinensis*, *F. Arvernensis*, and *F. Megantereon*.

The following Fossil Cats are enumerated by Von Meyer:—*Felis spelæa*; *F. antiqua*, Cuv.; *F. Issiodorensis*, Croiz. and Job.; *F. brevirostris*, Croiz. and Job.; *F. Pardinensis*, Croiz. and Job.; *F. Arvernensis*, Croiz. and Job.; *F. Megantereon*, Brav.; *F. cultridens*, Brav.; *F. aphanistes*, Kaup.; *F. ogygia*, Kaup; and *F. prisca*, Kaup.

Dr. Lund, in his 'View of the Fauna of Brazil previous to the last Geological Revolution,' remarks that the Hunting Leopard (*Felis jubata*, Linn.; *Cynailurus*, Wagl.), which differs from the rest of the Cats in many essential characters, has been very properly formed into a separate genus; for its claws are not retractile; it is gregarious, and of so mild a disposition that it is frequently tamed and employed in the chase. But, he observes, as a remarkable contrast to this, that its dental system is upon a more murderous plan than that of the true *Feles*, not having the flat projection on the large tearing molar of the upper jaw, which is found in all the other predaceous genera, and the development of which is in inverse proportion to the animal's carnivorous propensities. Dr. Lund recognised this form of dentition in a small animal of the extinct Fauna of the Brazilian region, which was the scene of his valuable labours, not exceeding a domestic cat in size; and he has named it *Cynailurus minutus*. Besides this he discovered the remains of two species of the normal feline form, one as large as the Long-Tailed Tiger-Cat (*Felis macroura*, Pr. Max.), the other larger than the Jaguar (*Felis Onça*, Linn.), and comparable to the Tiger and the Lion, the largest species of the Old World.

In his 'British Fossil Mammals,' Professor Owen describes four forms of *Felidæ*:—1. *Felis spelæa*, the Great Cave-Tiger; 2. *F. Pardoides*; 3. *F. Catus*; 4. *Machairodus latidens*.

In his account of the first Professor Owen says:—

"It is too commonly supposed that the Lion, the Tiger, and the Jaguar are animals peculiarly adapted to a tropical climate. The genus *Felis* is however represented by species in high northern latitudes, and in all the intermediate countries to the equator; and there is no genus of *Mammalia* in which the unity of organisation is more closely maintained, and in which therefore we find so little ground in the structure of a species, though it may most abound at the present day in the tropics, for inferring its special adaptation to a warmer climate. A more influential, and indeed the chief cause or condition of the prevalence of the larger feline animals in any given locality, is the abundance of the vegetable-feeding animals in a state of nature, with the accompanying thickets or deserts unfrequented by man. The Indian Tiger follows the herds of Antelope and Deer in the lofty Himalayan chain to the verge of perpetual snow. The same species also passes that great mountain barrier and extends its ravages, with the Leopard, the Panther, and the Cheetah, into Bocharia, to the Altan chain, and into Siberia as far as the fiftieth degree of latitude, preying principally on the wild horses and asses. It need not therefore excite surprise that indications should have been discovered in the fossil relics of the ancient Mammalian population of Europe; of a large feline animal the contemporary of the Mammoth, of the tichorine Rhinoceros, and of the gigantic Cave-Bear and Hyæna, and the slayer of the oxen, deer, and equine quadrupeds that so abounded during the same epoch.

"These indications were first discovered in the bone-caves of Germany; and Cuvier in his usual masterly review of the materials which were accessible up to the period of his 'Memoir' on the Cave *Carnivora* in the 'Annales du Muséum' for 1806, concludes that the most characteristic of the fossils of the great feline animal could be referred neither to the existing Lion or Lioness, nor to the Tiger, still less to the Leopard, or Panther, but that it more resembled in the curvature of the lower border of the under jaw the Jaguar.

"Mr. Goldfuss having subsequently obtained an almost entire fossil cranium of the large extinct feline animal, described it under the name of *Felis spelæa*, which name Cuvier adopted in the later edition of his great work, adding to the distinctions which Goldfuss had pointed out between the fossil and the skulls of the existing Felines, including the Jaguar, that the suborbital foramen appeared to be smaller and placed further from the margin of the orbit than in the existing Lion or Tiger. Although in the uniform and gentle curve of the upper contour of the fossil skull it resembles more that of the Leopard than any of the larger Felines, Cuvier subsequently speaks of the extinct species as a lion or a tiger. There is a constant and well-marked character, of which Cuvier appears not to have been aware, by which the skulls of the existing lion and tiger may be distinguished from one another: it consists in the prolongation backwards in the Lion of the nasal processes of the maxillary bones to the same transverse line which is attained by the upper ends of the nasal bones; whilst in the Tiger the nasal processes of the maxillary bones never extend nearer to the transverse line attained by the upper ends of the nasal bones than one-third of an inch, and sometimes fall short of it by two-thirds of an inch, where they terminate by an obtuse or truncated extremity, whilst in the Lion they are pointed. It is very desireable that this character should be determined if possible in the continental specimens of the skulls of the *Felis spelæa*. If the nasal processes of the superior maxillary bones do not extend as far backwards as the nasal bones, it may be concluded that the species was not a lion; but as the shorter processes of the superior maxillary bones are present in the skull of the Jaguar and Leopard as well as the Tiger, the approximation of the fossil to the striped or the spotted species of the genus *Felis* will depend upon other characters."

Portions of the skeleton of *F. spelæa*, more especially the teeth and jaws, have been found in the caves at Kirkdale, Kent's-Hole, Sandford Hill, Hutton, Bleadon, and North Cliff in Yorkshire.

The second species was indicated by Professor Owen from the specimens of a tooth obtained by Mr. Colchester from the Red Crag of Newbourne, near Woodbridge in Suffolk. Teeth of the Bear, Hog, and Deer have been obtained from the same locality. This species seems to have the same antiquity as the *F. aphanista* and *F. antediluviana* of Kaup, both of which were discovered by Dr. Kaup, associated with Dinetheriums and Mastodons in the Miocene of Epplesheim.

F. Catus, the Wild Cat. Fossil remains of a feline animal about the size of the Wild Cat were first noticed by Dr. Schmerling in his description of the caverns in the province of Liège, where they were found in tolerable abundance. He assigns the right ramus of a lower jaw, which exceeds by a few lines the specimen figured above, to a species or variety which he calls *Felis Catus magna*; and the greater proportion of the fossils, which include some entire skulls, to the *Felis Catus minuta*. These however do not vary from the standard of the existing Wild Cat, more than the varieties due to age or sex are now observed to do.

French naturalists have also enumerated a considerable collection of bones of the Wild Cat, discovered in the caverns of Lunel Vale.

"The most authentic specimens of the *Felis Catus*, in relation to their antiquity, which appear yet to have been obtained from British localities, are the right ramus of the lower jaw, retaining the canine tooth, discovered in the brick-earth at Grays, Essex, and a corresponding part of the lower jaw, almost identical in size and shape, but retaining the three molar teeth, from the cave of Kent's-Hole, Torquay. The Essex jaw of the Wild Cat, which was found in the same deposit that has yielded so many remains of the Mammoth, was in the usual condition of the bones of that period; and the specimen from Kent's-Hole, now in the British Museum, precisely accords in colour and chemical composition with the fossils of the extinct quadrupeds from the same cave. The outlines of the pre-molar teeth preserved in this jaw are added above the corresponding empty sockets of the jaw figured, with which they quite agree in size; and both are undistinguishable from the analogous parts of the still existing species of Wild Cat. We seem therefore here to have another instance of the survival, by a smaller and weaker species, of those geological changes which have been accompanied by the extirpation of the larger and more formidable animals of the same genus. Our household cat is probably a domesticated variety of the same species which was contemporary with the spelæan Bear, Hyæna, and Tiger. It appears, at least from an observation recorded by M. De Blainville, that Grimalkin cannot be the descendant of the Egyptian Cat, as M. Temminck supposed. The first deciduous inferior molar tooth of the *Felis maniculata* has a relatively thicker crown, and is supported by three roots; whilst the corresponding tooth in both the Domestic and Wild Cats of Europe has a thinner crown and two roots. The tail of the Domestic Cat is more tapering, and a little longer than in the Wild Cat; but the extent to which this part is shown by a curious propagated variety of tailless cat to be susceptible of modification, ought to warn us against inferring specific distinction from slight differences in the proportions of the tail." (Owen.)

Machairodus latidens. In this island, anterior to the deposition of the Drift, there was associated with the great extinct Tiger, Bear, and Hyæna of the caves, in the destructive task of controlling the numbers of the richly-developed order of the Herbivorous *Mammalia*, a feline animal as large as the tiger, and, to judge by its instruments of destruction, of greater ferocity.

In this extinct animal, as in the *Machairodus cultridens* of the Val d'Arno, and the *M. Megantereon* of Auvergne, the canines curved backwards, in form like a pruning-knife, having the greater part of the compressed crown provided with a doubly-cutting edge of serrated enamel; that on the concave margin being continued to the base, the convex margin becoming thicker there like the back of a knife to give strength, and the power of the tooth being further increased by the expansion of its sides. Thus, as in the *Megalosaurus*, each movement of the jaw with a tooth thus formed combined the power of the knife and saw, whilst the apex in making the first incision acted like the two-edged point of a sabre, the backward curvature of the full-grown teeth enabled them to retain like barbs the prey whose quivering flesh they penetrated. Three of these canine teeth were discovered by the Rev. Mr. Mac Enery in Kent's Hole, Torquay, and were recognised by Dr. Buckland as bearing a close resemblance to the canines of the *Ursus cultridens* of the Val d'Arno. Professor Nesti, to whom Dr. Buckland transmitted casts of these teeth, recognised the same resemblance, but noticed their proportionably greater breadth. The cast of one of the largest of the canines of the *Machairodus cultridens* from the Val d'Arno, presented to Professor Owen by Mr. Pentland, measures eight inches and a half in length along the anterior curve, and one inch and a half in breadth at the base of the crown. The largest of the canines of the *Machairodus* from Kent's Hole measures six inches along the anterior curve and one inch two lines across the base of the crown. The English specimens are also thinner or more compressed in proportion to their breadth, especially at the anterior part of the crown, which is sharper than in the *Machairodus cultridens.* (Owen.)

These differences are so constant and well marked in the British specimens that Professor Owen has proposed for them the above specific name.

We here figure a tooth of *Megalosaurus*, a tooth of *Machairodus* (*Ursus cultridens*), and a cast of another, from specimens in the Museum of the Geological Society of London.

a, tooth, imperfect below, natural size; *b*, outline of cast of tooth, perfect, half natural size; *c*, tooth of *Megalosaurus*, natural size.

Hitherto no parts of the skeleton of *M. latidens* have been found in England so as to throw any additional light on the organisation of this once formidable beast of prey. It must have however equalled, or nearly equalled, in bulk the Spelæan Tiger. "When we are informed," says Professor Owen, "that in some districts of India entire villages have been depopulated by the destructive incursions of a single species of large feline animal, the Tiger, it is hardly conceivable that man in an early and rude condition of society could have resisted the attacks of the more formidable Tiger, Bear, and *Machairodus* of the Cave epoch. And this consideration may lead us the more readily to receive the negative evidence of the absence of well-authenticated human fossil remains; and to conclude that man did not exist in the land which was ravaged simultaneously by three such formidable *Carnivora*, aided in their work of destruction by troops of savage hyænas."

The following is a list of the species of *Felis* to be seen in the Zoological Gardens, Regent's Park:—

F. Leo, var. *Goojrattensis*, Smee; *F. Leo*, Linn. Morocco, Nubia, Ushantee, Mozambique	Lion.
F. Tigris, Linn. Goa, Baroda, Bengal	Tiger.
F. Onça, Linn. Orinoco, Amazon	Jaguar.
F. Pardus, Linn. Western Africa, South Africa, Ceylon, India, Malacca	Leopard.
F. Leopardus, Schreber. Morocco	Panther (?).
F. jubata, Sch. Nubia, South Africa	Cheetah.
F. pardalis, Linn. South America	Ocelot.
F. mitis, F. Cuvier. South America	Ocelot.
F. melanura, Ball. Demerara	Ocelot.
F. ——— (?). Peru	Ocelot.
F. macrocelis. Java	Riman-Dihan.
F. Tigrina, Schreber. South America	Ocelot.
F. Serval, Schreber. South Africa	Serval.
F. Servalina, Ogilby. Gambia	Western Serval.
F. viverrina, Bennett. Bengal	Wagati.
F. Chaus, Guldeustedt. Egypt	Marsh Cat.
F. Caracal, Schreber. Gambia, Bombay, Nubia	Caracal.
F. Canadensis, Geoffroy. North America	Canadian Lynx.
F. concolor, Linn. North America, Chili, Amazon	Puma.
F. Eyra, Desmarest. Paraguay (?)	Eyra.

FELIS. [FELIDÆ.]

FELSPAR, a Mineral which occurs in every part of the earth, and is one of the constituents of granite.

It occurs crystalline and massive. The primary form of the crystal is an oblique rhombic prism. Colour white, gray, green, red, of different shades. Transparent, translucent, or opaque. Lustre vitreous. Specific gravity, 2·5 to 2·6. Hardness, 6·0. Streak grayish-white. Cleavage parallel to the terminal plane and oblique diagonal. Fracture conchoidal, uneven. There are several varieties. That known by the name of *Adularia* occurs in large crystals, especially in Mont St. Gothard. *Moonstone* is a variety which has a pearly lustre, and when cut and polished is chatoyant; the finest specimens of this are from Ceylon. *Sunstone* is similar, but contains minute scales of mica. *Aventurite* Felspar often owes its iridescence to minute crystals of specular or titanic iron. The massive varieties are amorphous. Structure granular, compact. A green variety has been found in Siberia. The several varieties differ but little in composition. *Adularia*, which is one of the purest varieties, according to Vauquelin, consists of:—

Silica	64
Alumina	20
Potash	14
Lime	2
	—100

Felspar is distinguished from *Scapolite* by its more difficult fusibility, and by a slight tendency to a fibrous appearance in the cleavage-surface of the latter, especially in massive varieties; from Spardumare by its blow-pipe characters. Felspar is one of the constituents of granite, gneiss, mica-slate, porphyry, and basalt, and often occurs in these rocks in crystals. Dana says St. Lawrence county, New York, affords fine crystals; also Orange county, New York; Haddam and Middletown, Connecticut; South Royalston and Barre, Massachusetts; besides numerous other localities. Green Felspar occurs at Mount Desert, Maine; an Aventurine Felspar at Leyperville, Pennsylvania; *Adularia* at Haddam and Norwich, Connecticut; and Parsonsfield, Maine. A Fetid Felspar (sometimes called *Necronite*) is found at Roger's Rock, Essex county; at Thomson's Quarry, near 196th-street, New York city, and twenty-one miles from Baltimore. Carlshad and Elbrogen in Bohemia; Baveno in Piedmont; St. Gothard; Arendal in Norway; Land's End, England; and the Mourn Mountains, Ireland, are some of the more interesting localities. The name Felspar is a German word, '*feld*' meaning field.

Felspar is used extensively in the manufacture of porcelain. Moonstone and Sunstone are often set in jewellery. They are polished, with a rounded surface, and look somewhat like cat's-eyes, but are much softer.

Kaolin.—This name is applied to the clay that results from the decomposition of Felspar. It is the material used for making porcelain or china-ware. The change the Felspar undergoes in producing Kaolin consists principally in a removal of the alkali-potash, with part of the silica, and the addition of water. Composition of a specimen from Schneeberg (Berthier):—

Silica	43·6
Alumina	37·7
Peroxide of Iron	1·5
Water	12·6

It occurs in extensive beds in granite regions, where it has been derived from the decomposition of this rock. A granite containing talc seems to be the most common source of it. [ROCKS.]

FENESTE'LLA, a beautiful and abundant genus of Fossil *Zoophyta*, allied to *Retepora*, which occurs in the whole Palæozoic series. (Lonsdale, 'Sil. System,' &c.)

FENNEC, the name of a species of *Canis*, the *C. Zerda* of Gmelin.

FENNEL. [FOENICULUM.]

FENUGREEK. [TRIGONELLA.]

FERÆ, the third order of *Mammalia*, according to Linnæus. The following is his character of the order:—Upper incisor teeth (primores) six, rather acute (acutiusculi); canine teeth solitary. The order contains the following genera:—1. *Phoca* (the Seals); 2. *Canis* (the Dogs, Wolves, Foxes, Hyænas, and Jackals); 3. *Felis* (the Cats, Lions, Tigers, Leopards, Lynxes, and smaller cats); 4. *Viverra* (the Ichneumons, Coatis, Skunk (*Putorius*), Civets, and Genets); 5. *Mustela* (the Otters, Glutton, Martens, Pole-Cats, Ferrets, and Weasels, including the Ermine, &c.); 6. *Ursus* (Bears, Badgers, and Racoons); 7. *Didelphis* (the Opossums); 8. *Talpa* (the Moles); 9. *Sorex* (the Shrews); 10. *Erinaceus* (the Hedgehogs). Linnæus places the *Feræ* between the orders *Bruta* and *Glires*.

FERGUSONITE, a crystallised mineral, which is principally a Columbate of Yttria. It has been found only in Greenland, near Cape Farewell, imbedded in quartz.

Its primary form is a square prism. Colour brownish-black. Opaque, except in the splinters. Lustre slightly metallic. Specific gravity 5·838. Hardness 5·5 to 6·0. Streak pale brown. Fracture conchoidal. Before the blow-pipe becomes of a greenish-yellow, and does not fuse, but with a phosphate it dissolves completely. According to Hartwall, this mineral consists of

Oxide of Columbium	47·75	
Yttria	41·91	
Zirconia	3·02	
Oxide of Cerium	4·68	
Oxide of Tin	1·00	
Oxide of Uranium	0·95	
Oxide of Iron	0·34	
		99·65

FERNS, the common name for a group of Cryptogamous Plants. [FILICES; DANÆACEÆ; LYCOPODIACEÆ; POLYPODIACEÆ; MARSILEACEÆ; OPHIOGLOSSACEÆ.]

FERO'NIA, the name of a genus of Plants belonging to the natural order *Aurantiaceæ*. The flowers are often polygamous. The petals are usually 5 in number, occasionally 4 or 6, spreading. The calyx is flat and 5-toothed. Stamens 10; filaments dilated and united at the base; anthers linear-oblong, tetragonal. The ovary is seated on the elevated disc, 5- or occasionally 6-celled; ovules numerous in each cell. It has scarcely any style and an oblong stigma. The fruit is inclosed in a hard rind, 5-celled and many seeded, which seeds are immersed in a fleshy pulp. The leaves are pinnated with from 5 to 7 leaflets nearly or quite sessile, very slightly crenulated, with pellucid dots along the margin, inconspicuously dotted elsewhere: the racemes are axillary, terminal, and few-flowered.

F. Elephantum is the Elephant-Apple or Wood-Apple of the Coromandel coast, where it is very generally eaten. The branches of this tree are armed with small spines. The leaflets, which vary in number from 5 to 7, are small, obovate and smooth; when very young they are thin, and when bruised have a most fragrant smell resembling anise. The native practitioners of India consider them stomachic and carminative. After a certain age however the leaves become tough and almost coriaceous. The fruit is fleshy, and extremely acid before it arrives at maturity; but when ripe, it contains a dark-brown agreeable subacid pulp. In appearance the fruit is large, spheroidal, rugged, and often warted externally: the seeds are in five parcels, and are flat and woolly, adhering to the branched placentæ by means of long cords.

A transparent oily fluid exudes from the trunk of this tree when an incision is made into it, which is used by painters for mixing their colours. A clear white gum may also be obtained from the tree very much resembling gum-arabic. The wood is likewise valuable on account of its durability, whiteness, and hardness.

F. pellucida has leaves full of transparent dots; the common petiole round, pubescent; this tree usually attains a height of 20 feet, and is a native of the East Indies, where the fruit is generally eaten. The flowers are white.

In cultivation these trees thrive well in a mixture of turfy loam and peat: and ripened cuttings will strike root in sand under a glass exposed to heat.

(Lindley, *Flora Medica*; Don, *Dichlamydeous Plants*.)

FERRET. [MUSTELIDÆ.]

FERRO-TANTALITE. [COLUMBITE.]

FE'RULA, a genus of Plants belonging to the natural order *Umbelliferæ*, whose species often yield a powerful stimulating gum-resin employed in medicine. It differs from *Pastinaca* and *Peucedanum* by its fruit having several vittæ in each channel, and from *Opoponax*, which it otherwise resembles, in the margin of the fruit being thin and flat, not thickened and convex. The fruit is in appearance extremely similar to that of a parsnip; it is compressed from the back till it is extremely flat, and it thins away at the edge. There are three approximated filiform dorsal ridges, and the two lateral ones are distant, obsolete, or lost in the edge. In each channel there are three or more vittæ, and on the commissure four, or a great many. The flowers are always yellow, and the stem solid, its cavity being filled with a spongy substance, in which fibres are vaguely dispersed.

The drugs called Sagapenum and Assafœtida were supposed to be produced by species of this genus, but by which in particular it was not known with certainty. Dr. Falconer has shown that Assafœtida at least is produced by another genus, which he calls *Narthex*. [NARTHEX.]

F. Assafœtida is found in only two districts of Persia, namely, the fields and mountains of Herat, the capital of Khorassan, and the range of mountains in the province of Lar (Laristan), extending from the river Cur as far as the town of Congoon, along the coast of the Persian Gulf. Kæmpfer states that even here the plants do not always yield the drug; that it is only those of the desert near Herat and of the mountains round Disguun in Laristan that furnish it; and he figures a plant, with a naked simple stem, clothed with leafless sheaths, umbels without involucre, a coarse woody root rising above the ground, and pinnated leaves with pinnatifid segments and oblong obtuse lobes. This plant is the *Ferula Assafœtida* of Linnæus and De Candolle; what is supposed to be it has since been met with in Beloochistan, and Lieutenant Burnes saw what he calls *Assafœtida* growing in great luxuriance in the mountains of Hindu-Koosh at an elevation of 7000 feet. He states that it is an annual, and grows to the height of 8 or 10 feet, when it withers and decays. The milk which it exudes is first white, and then turns yellow and hardens, in which state it is put in hair bags and exported. Sheep browse upon the tender shoots, which are believed to be highly nutritious. ('Travels,' ii. 243.) It is however by no means certain that this was true Assafœtida. Indeed if it was, as Lieutenant Burnes states, an annual, it must have been some other plant; for Kæmpfer expressly describes the root of Hingisèh, or Assafœtida, as "ad plures annos restibilem, magnam, ponderosam, nudam," and in fact it is from wounds in this root that the gum-resin flows. It is probable that Assafœtida is yielded by different plants. Professor Royle obtained seeds of two kinds from the bazaar of India; and it appears from a communication made to Mr. Macneill from a medical gentleman at Soomeeana in Beloochistan, that in that province a kind of *Ferula* called Hooshee yields a similar product, which however is not collected.

The *F. Assafœtida* is said to arrive at as great an age as man himself, and in consequence its roots sometimes attain a considerable size. It is from wounds in this part that the drug is obtained. The roots are not wounded before they are four years old; the greater their age the better the quality of their produce. There were four operations each year when Kæmpfer visited the country; the first in the middle of April, the second at the latter end of May, the third ten days later, and the fourth in the beginning of July. The gatherers on the first occasion only cleared the hard sandy or stony soil away from the root to the depth of a span or so, pulling off the leaves, replacing the earth about the roots, and then heaping the leaves on them, pressing them down with a stone. On the subsequent occasions they slice the roots transversely, beginning a little below the top, and collecting the juice that flows from the wounds. After every operation they cover the root with the old leaves to screen it from the sun. After the last gathering the screens are thrown away and the roots are left to perish. Dr. Falconer believes his Narthex Assafœtida to be identical with Kæmpfer's plant.

F. Persica, a perennial species with a glaucous stem and supradecompound leaves with linear cut segments, has been reported to yield assafœtida. Dr. Hope entertained this opinion, from which Nees and Ebermaier do not dissent. Treviranus found it yielding a substance extremely like assafœtida in the botanic garden of Breslau; and the same thing has often occurred in the Apothecaries' Garden at Chelsea. Nevertheless, Fée suspects, after Willdenow, that it is rather the origin of sagapenum. Olivier believed it to produce gum ammoniacum; but according to Professor Don that drug is yielded by his *Dorema ammoniacum*.

F. orientalis has also been quoted as the source of gum ammoniacum; and it appears that such a substance is really produced, either by that plant or a nearly allied species, in the empire of Marocco.

F. ferulago has been taken for the plant which furnishes galbanum; but Professor Don states that this drug is really yielded by quite a different genus, called by him *Galbanum officinale*. [ASSAFŒTIDA, in ARTS and SC. DIV.]

FERUSSI'NA, a genus established by M. Grateloup for a Fossil Turbinated Shell from Dax, which seems at first view very near the *Anostomata*, but which M. Grateloup thinks, from the examination of its aperture, approximates more to the *Cyclostomata*, an opinion in which M. Rang concurs, adding that the species, three or four, are all fossil.

Animal unknown. Shell oval, globulous; aperture round, bordered, oblique, simple, toothless, "retournée du côté de la spire;" umbilicus more or less large; operculum (?).

FESCUE-GRASS. [FESTUCA.]

FESTU'CA, a genus of Plants belonging to the natural order of Grasses, containing several species of agricultural importance. It is known among British Grasses by having many-flowered spikelets, the lower paleæ of which are neither awned as in *Bromus*, nor blunt as in *Poa* and its allies, but terminated gradually in a hard sharp point.

F. pratensis, or Meadow Fescue, is about three feet high, with a nearly upright branched 1-sided panicle and broad coarse leaves. It is a native of moist meadows, and forms a portion of most good meadow herbage. Mr. Sinclair states that in point of early produce this grass ranks next to Meadow Fox-Tail (*Alopecurus pratensis*), and is much more productive.

F. ovina, *F. rubra*, and *F. duriuscula* are other agricultural grasses, much smaller than the last, and contributing greatly to the value of pastures. *F. ovina* has a fine succulent foliage, and, according to Linnæus, sheep have no relish for hills on which it does not abound; it is however unproductive. *F. rubra* is more abundant in its produce, but less nutritious; and its creeping root-like stems are said to impoverish the soil very much. *F. duriuscula* is preferrible to both the preceding; it withstands dry weather better than most grasses, and in combination with *F. pratensis* and *Poa trivialis* forms excellent pasturage. It is most prevalent on light rich soils. *F. dumetorum*, another species, will thrive in dry sandy situations, to which property its value is chiefly owing; but its nutritive qualities are slight, and it is altogether an inferior species.

(Babington, *Manual of British Botany*.)

FETTBOLL, a soft hydrous Silicate of Alumina allied to Halloylite. [HALLOYLITE.]

FEUILLEA, a genus of Plants belonging to the natural order *Cucurbitaceæ*, and named in honour of Louis Feuillée, a traveller in Chili, the author of several works on botany. The flowers of this genus are diœcious. The staminiferous flowers have the calyx 5-cleft beyond the middle; 5 petals rather joined at the base; 5 stamens inserted with the petals, and alternating with them; sometimee there are 10 stamens, but when this occurs 5 of them are always sterile. The pistilliferous flowers have the tube of the calyx adnate to the ovarium, with a 15-cleft limb. They have 5 petals, distinct or joined at the base, and oblong; 3 styles. Stigmas broad and bluntly bifid. Fruit globose, fleshy, with a circular scar round the middle and five other scars, 3-celled, with a solid bark, and a large fleshy trigonal central axis. The ovules are numerous, standing erect upon the axis. The seeds oval and compressed. Cotyledons flat and rather fleshy. This genus is a native of the tropical regions of America, and most of the species are frutescent climbing herbs. They have alternate, stalked, cordate, smooth leaves, and small flowers. The tendrils are axillary, spirally twisted, in place of peduncles. The seeds are oily and of a bitter taste; their unctuous matter causes them to be used for burning, and their excessive bitterness renders them good anthelmintics; they are also cathartic.

F. punctata has 3-lobed or ternate leaves, beset with glandular dots on both surfaces along the nerves, but more especially beneath. The lobes of the leaves are lanceolate and rather cut. It is a native of St. Domingo.

F. trilobata has leaves which are rather glandular on both surfaces, 3-parted or trifid, the lower lobes obtuse, the upper ones acute. This species is a native of Brazil. It is the *F. scandens* of some authors, and the celebrated Nhandirhoba or Ghandirhoba of South America, where it is held in great repute as an antidote to various poisons, animal and vegetable. The natives employ it not only against serpent-bites but also to counteract the baneful effects of the Manihot and Manchineel. M. Drapiez, after having made experiments expressly to test its power, states that animals poisoned with hemlock, nux-vomica, *Rhus*, *Toxicodendron*, &c., were restored by the administration of the seeds of this plant. He recommends that the seeds be bruised in a little water, and asserts that it is equally efficacious as an antidote whether taken internally or applied to a poisoned wound. These seeds act with great rapidity as emetics and purgatives. The oil expressed from them is used as an application in pains in the joints.

F. cordifolia has glandless cordate acuminate leaves, somewhat 3-lobed and rather serrated. It is a native of the West Indies, and has likewise a reputation as a preventive of the ill effects of vegetable poisons, and as an emetic and purgative.

F. Javilla has glandless roundish leaves, sinuately cordate, and acuminate. It is a native of New Granada in the woods near Turbaco, where it is known by the name of Javilla. The seeds have winged margins; hence this species agrees with the genus *Zanonia*.

The fruit of the *Feuillea* is as large as an apple, and from a fancied resemblance it is called the Shaving-Box.

A light rich soil is found to suit best the species of *Feuillea*, and cuttings will easily take root in a hot-bed or glass frame exposed to heat. Being creeping plants they are well adapted for training up rafters in stoves.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

FEVERFEW. [MATRICARIA; PYRETHRUM.]

FIBER. [BEAVER.]

FIBRE, ANIMAL. [FIBRIN; FIBROUS TISSUE.]

FIBRE, VEGETABLE, one of the most elementary forms of vegetable tissue. It consists of excessively delicate threads, twisted spirally in the interior of a cell or tube. It is uncertain whether the fibre is solid or hollow, its tenuity being such as to baffle all microscopical observers who have yet examined it. It is this elementary fibre which, being turned spirally round a long delicate tube with its spires in contact, forms the elastic spiral vessel. It occurs in the interior of common cells, when its turns cross each other and produce a netted appearance. It is frequent in the cellular tissue which forms the lining of an anther, and is supposed to have some connection with the opening of that organ. In its naked state, uncombined with membrane, it is supposed to be very rare. On the surface of some seeds, as *Collomia linearis*, it has been observed in this condition in great abundance, in the form of spiral threads of a highly elastic nature.

Vegetable Fibre should not be confounded with the woody fibre of plants, which consists of tough straight tubes either single or adhering in bundles. It is this which forms the thread of hemp, flax, and the like. [TISSUES, VEGETABLE.]

FIBRIN, an organic proximate principle found in both plants and animals. When obtained from wheaten flour it is called Gluten. It has the same properties whether obtained from vegetable or animal sources. In the animal kingdom it is found in the muscles and the blood. [BLOOD.] The fibrin of the blood is best obtained by what is called whipping the blood, that is, by rapidly stirring a quantity of fresh-drawn blood with a spoon or a piece of stick. During this process the blood coagulates, and the coagulum adheres to the spoon or stick. The red particles which are mixed with this coagulum may be removed by washing it in large and repeated portions of water; the substance that remains is Fibrin nearly in a state of purity.

During the state of life the fibrin is contained in solution in the fluid part of the blood, the liquor sanguinis. Professor Müller obtained fibrin in a state of purity from frog's blood by opening one of its large arteries, or by laying bare and incising the heart itself. This blood being received into a watch-glass and the process of coagulation watched, it was observed that previously to the complete coagulation of the blood there formed a small colourless coagulum clear as water. "Having brought a drop of pure blood," says Müller, "under the microscope, and diluted it with serum, so that the blood-corpuscles lay completely scattered about and separated from each other, I observed that in the interval between the blood-corpuscles a coagulum of previously dissolved matter was produced, by which the whole separated blood-globules were connected together. I was then able to remove at the same time all the blood-corpuscles, notwithstanding their wide distribution and the size of the intervals between them, by raising with a needle the fibrous coagulum occupying the intervening spaces. As the blood-corpuscles of the frog are rendered by a microscope uncommonly large, this observation admits of the greatest distinctness, and allows no ambiguity to remain on the subject. There is still however an easier and more convincing method of proving that fibrin is dissolved in frog's blood. As I showed from experiment that the blood-corpuscles of the frog are about four times larger than the blood-corpuscles of men and *Mammalia*, I concluded that perhaps the filter would keep them back, while it allowed the corpuscles of men and *Mammalia* to pass. This is the case. The experiment may be made on a small scale with the blood of a frog alone: a small glass-funnel and a filter of common white filtering-paper, or thick printing-paper, are the only requisites. The paper must previously be moist, and it is well to add an equal quantity of water to the fresh blood of the frog. The liquid which flows through the filter is an almost colourless clear serum diluted with water, with a slight tinge of red, from the colouring matter dissolved by the water. As however the solution of the colouring matter of frog's blood by water requires a considerable time, the filtered fluid can scarcely be termed reddish, and is sometimes quite colourless. If instead of water a solution of sugar in water (one part of sugar to 200 or more of water) be employed, no colouring matter will be dissolved during the filtration, and the filtered liquid is quite colourless and without the slightest trace of mixture. If the filtered serum be examined under the microscope no trace of corpuscles can be detected. In this clear serum in the course of a few minutes a colourless coagulum is formed, so clear and transparent that it is not even detected after its formation until it is raised out of the fluid with a needle. It gradually thickens, and becomes whitish and fibrous; it then assumes gradually the appearance of the coagulum of human lymph. In this way the fibrin of the blood is obtained in the purest state, and this has not hitherto been done."

Pure fibrin is of a whitish colour, inodorous, and insoluble in cold water; it is a solid substance, tough, elastic, and composed of thready fibres.

The relative quantity of fibrin contained in the blood varies greatly, according to the state of the system at the time it is obtained.

Fibrin and Albumen, if not identical, are very closely allied, and appear rather to differ in organisation than in essential chemical character. For an account of the relations of Fibrin and Albumen see PROTEIN.

That variety of fibrin which constitutes muscular fibre is so interwoven with nerves, vessels, and cellular and adipose tissue, that its properties are probably always more or less modified by foreign matters. "To obtain the fibrin of a muscle, it must be finely minced and washed in repeated portions of water at 60° or 70° till all colouring and soluble substances are withdrawn, and till the residue is colourless, insipid, and inodorous; it is then strongly pressed between folds of linen, which renders it semi-transparent and pulverulent. Berzelius observes that in this state it becomes so strongly electro-positive when triturated, that the particles repel each other and adhere to the mortar, and that it still retains fat, which is separable by alcohol or ether. When long boiled in water it shrinks, hardens, and yields a portion of gelatine, derived from the interstitial cellular membrane; the fibrin itself is also modified by the continued action of boiling water, and loses its solubility in acetic acid, which when digested with it in its previous state forms a gelatinous mass, soluble in water, but slightly turbid from the presence of fat and a portion of insoluble membrane, derived apparently from the vessels which pervaded the original muscle. It is soluble in diluted caustic potass, and precipitated by an excess of muriatic acid, the precipitate being a compound of fibrin with excess of muriatic acid, and which when washed with distilled water become gelatinous and soluble, being reduced to the state of a neutral muriate of fibrin.

"When the fibrin of muscle is mixed with its weight of sulphuric acid it swells and dissolves, and when gently heated a little fat rises to the surface, and may be separated: if the mass is then diluted with twice its weight of water, and boiled for nine hours (occasionally replacing the loss by evaporation), ammonia is formed, which combines with the acid; and on saturating it with carbonate of lime, filtering, and evaporating to dryness, a yellow residue remains, consisting of three distinct products: two of these are taken up by digestion in boiling alcohol of the specific gravity of ·845, and are obtained upon evaporation; this residue, treated with alcohol of the specific gravity of ·830, communicates to it (1) a portion of a peculiar extractive matter, and the insoluble remainder (2) is white, soluble in water, and crystallisable, and has been called by Braconnot leucine. It fuses at 212°, exhaling the odour of roasted meat, and partly sublimes: it is difficultly soluble in alcohol. It dissolves in nitric acid, and yields on evaporation a white crystalline compound, the nitro-leucic acid. The portion of the original residue, which is insoluble in alcohol (3), is yellow, and its aqueous solution is precipitated by infusion of galls, subacetate of lead, nitrate of mercury, and persulphate of iron. It appears therefore that the products of the action of sulphuric acid upon the fibrin of muscle are, 1, an extractive matter soluble in alcohol; 2, leucine; and 3, extractive, insoluble in alcohol, but soluble in water." (Brande.)

FIBROFERRITE, a Mineral consisting of Sulphate of Iron. [IRON.]

FIBROLITE, a name for Bucholzite. [BUCHOLZITE.]

FIBROUS TISSUE. The tissue specially called fibrous consists of the membrane that covers the bones and cartilages (the periosteum and perichondrium); the membrane that is spread over or that forms a part of certain muscles, constituting the muscular aponeuroses or fasciæ; the membrane that forms the sheaths in which tendons are included; the outer membrane that envelopes the brain and spinal chord (the dura mater and its continuation down the spinal canal); the firm membrane in which the more delicate muscles and the humours of the eye are contained (the tunica sclerotica); the outer membrane forming the bag that contains the heart (the pericardium); the membranes by which the bones in general are tied together and the joints in particular are secured, called ligaments; and the firm cords in which many muscles terminate and which form their moveable extremities, termed tendons. Though these substances are extensively diffused through the body, and are apparently independent of each other, yet they are closely connected together, and form a peculiar system. The firm and resisting threads which constitute the basis of these different organs are composed of condensed cellular tissue. The peculiar animal substance of which they consist is coagulated albumen and gelatine, intermixed with a small quantity of mucous and saline matter.

All the proper fibrous organs possess, in the language of anatomists, a low organisation; that is, they receive but a comparatively small quantity of blood, and their blood-vessels are so minute in size, that they are generally incapable of admitting the red particles of the blood. They receive few nerves, and these are so small that some anatomists have doubted whether they are supplied with any nerves at all; but their sensibility in certain states of disease proves that they are not absolutely destitute of sentient nerves. In like manner, few absorbents can be traced to them; yet the ravages of disease in the neighbourhood of joints, the sloughing of tendons, and the destruction of the periosteum by the pressure of aneurism, abundantly testify that they are supplied with absorbent vessels. But the office of all the fibrous organs is mechanical; they are adapted either to contain, support, and defend more delicate organs, or they constitute strong and unyielding bands which tie joints firmly together. A high degree of organisation, great vascularity, great sensibility, would have disqualified them for their office. What they principally need is a power of cohesion sufficient to enable them to resist rupture, and to sustain the opposing shocks to which the joints are exposed in the violent movements of the body; the less sensibility they have the better, and accordingly they are so organised that while their physical properties render them by far the strongest parts of the animal frame, they are endowed only with just a sufficient degree of vitality to constitute them integrant parts of the living system. [AREOLAR TISSUE.]

FIBULA. The Fibula (péroné, Fr., περόνη, a bodkin) is a long slender bone swelling out at both ends, by which it is firmly attached to the outer side of the tibia, or main bone of the leg. The lower extremity forms the projection of the outer ancle: it is received into a deep longitudinal groove at the side of the tibia, to which it is connected by a ligamentous union; and is firmly knit to the foot by strong bands of ligament, which spread like the sticks of a fan from the tip of the ancle to the bones of the heel and instep. The upper extremity slants a little backwards, and is articulated with the side of the tibia below the knee, by means of a true joint, having cartilaginous surfaces and a synovial membrane as well as external ligaments. The tendon of the biceps flexor cruris, or muscle of the outer hamstring, is implanted into this part of the fibula, which is called its head, and spreads over the adjoining bony and muscular surfaces, connecting and supporting them in the double capacity of a ligament and an aponeurosis. There is no greater degree of motion between the tibia and fibula than is sufficient to give some elasticity to the play of the ancle-joint, which is secured on the outer side chiefly by the projection of the fibula beyond it. The shaft of the fibula—nearly straight, triangular, hard, a little twisted, and of great strength for its size—is about as thick as the middle finger, and extends like a bowstring across the arch formed by the gradual enlargement of the tibia towards the knee. A strong sheet of fibrous membrane, called the interosseous ligament, tightly stretched from one bone to the other, fills up the greater part of the interval between them, and gives surface for the attachment of muscles and strength to the limb, without adding inconveniently to its bulk or weight. Nine muscles are attached to the fibula. The biceps cruris, already mentioned, bends the leg back towards the thigh; three on the fore part raise and extend the toes, the remaining five unite in raising the heel, and press the toes and the ball of the foot against the ground; at the same time turning the sole outwards by lifting its external border. The muscles chiefly concerned in the last-mentioned action are the peroneus longus and brevis; their tendons pass behind the ancle, lying in a groove of the fibula, which acts as a fixed pully to change the line of their traction, and are inserted into two bones on the outer and inner edge of the sole near the base of the toes. They are very powerful muscles; and when they act with sudden and spasmodic force, in consequence of the foot coming unexpectedly to the ground, are capable of breaking the fibula above the ancle by pressing the foot against its projecting end. This accident happens not unfrequently from the foot slipping unawares over the edge of the curb-stone, and is complicated with various degrees of lateral dislocation, and with severe sprain of the ligaments of the inner ancle. The force may be sufficient to break off the tip of the inner ancle; and if the sharp edge of the broken tibia be driven through the skin, which sometimes happens, the cavity of the joint is exposed, and the injury becomes a compound dislocation of the ancle-joint. These accidents are sometimes secondary, the foot being in the first instance forced by the weight against the inner ancle, with sprain of the external ligaments, and then drawn up with a jerk by the peronei. However produced, the injury is a very serious one, and often requires much good management to prevent permanent lameness or even worse consequences. Minor degrees of it have a general resemblance to simple sprains of the ligaments, and the fracture of the fibula may be overlooked. It may however be easily detected, notwithstanding the swelling, by the unusual position of the foot, and by pressing the bones together higher up the leg; for if the fibula be fractured, this cannot be done without a sense of yielding of the otherwise solidly compacted parts, and increase of pain to the patient from the pressure of the broken end of the bone against the soft parts. From the name of the eminent surgeon who first delineated and described this injury, it is called 'Pott's Fracture.' [FOOT; TIBIA.]

FIBULARIA. [ECHINIDÆ.]

FICARIA, the genus to which *Ranunculus Ficaria*, the Pilewort, has been referred. [RANUNCULUS.]

FICEDULA. [BECCAFICO; SYLVIADÆ.]

FICHTELITE, a form of Fossil Resin found in coal.

FICOIDEÆ. [MESEMBRYACEÆ.]

FICUS, a large genus of Plants belonging to the natural order *Urticaceæ*, having the flowers, both males and females, mixed indiscriminately on the inside of a fleshy receptacle, which is so concave that its edges are drawn together into a narrow opening. This is illustrated by the common eatable Fig, the receptacle of *Ficus Carica*, which, although resembling a fruit as simple as a gooseberry, is in fact a collection of a large number of minute unisexual flowers growing to a succulent base; at its apex will be found the narrow opening where the edges of the receptacle are drawn together, and when its interior is laid bare the flowers are seen closely packed all over its surface, divided from each other by soft colourless bristle-like bracts or scales. What are called the seeds in the ripe fig are the pericarps, each of which contains a single seed. The calyx is variable in the number of its segments, sometimes having only 3, sometimes 7 or 8. The stamens are solitary in many species, 3 in others, and 5 in some. The pistil consists of a single ovary terminated by an awl-shaped style, ending in a 2-lobed stigma.

The number of species of *Ficus* is very considerable, perhaps as great as that of any arborescent genus. They are all either tropical or inhabitants of warm countries. Some are small plants creeping upon the surface of rocks and walls, or clinging to the trunks of trees like ivy; others are among the largest trees of the forest. All travellers in the woods of South America speak of the noble aspect of the fig-trees (meaning species of *Ficus* not of the cultivated sort), of their gigantic dimensions, and of the thick delightful shade cast by their leafy heads. They are especially remarkable for throwing out roots from their branches, which, after they have reached the ground and established themselves there, increase rapidly in diameter, produce other branches, and thus contribute to extend an individual over a considerable space of ground. Frazer speaks thus of what he saw of their habits in the forests at Moreton Bay in Australia:—"I observed several species of *Ficus* upwards of 150 feet high, enclosing immense iron-bark trees, on which originally the seeds of these fig-trees had been deposited by birds. Here they had immediately vegetated, and thrown out their parasitical and rapacious roots, which adhering close to the bark of the iron-tree had followed the course of its stem downwards to the earth, where, once arrived, their progress of growth is truly astonishing. The roots of the *Ficus* then increase rapidly in number, envelop the iron-bark, and send out at the same time such gigantic branches that it is not unusual to see the original tree, at a height of 70 or 80 feet, peeping through the fig, as if itself were the parasite on the real intruder. In the singular angles or walls, as they are here termed, which are formed by the roots of these trees, and of which I observed many 16 feet high, there is room enough to dine half-a-dozen persons. The fruit is eagerly sought by Regent Birds (*Sericulus chrysocephalus*), blue pigeons, and Swamp Pheasants (*Cuculus Phasianus*), and the spreading and massy boughs support a number of superb parasitical plants." Reinwardt assures us ('Ueber den Charakter der Vegetation auf den Inseln des Indischen Archipels') that he observed on the island of Semao a large wood whose trunks all proceeded from one single stem of a *F. Benjamina*, all united with each other by their branches though the trunks were distinct. The well-known *F. Indica*, or Banyan-Tree, is another instance of this peculiar habit.

The species abound in a milky juice containing caoutchouc, and there is every reason to believe that what of this substance comes from Java is exclusively procured by tapping different species of *Ficus*. The best known on the continent of India is yielded by *F. elastica*.

Although the fruit of *F. Carica* and some others is eatable, yet the whole genus abounds in an acrid highly dangerous principle, diffused among the milky secretion. This is perceptible even in the common fig, whose milk produces a burning sensation on the tongue and throat; but when the fruit of that species is ripe, the acridity is destroyed by the chemical elements entering into new combinations. In some species it is so concentrated that they are among the most virulent of poisons. *F. toxicaria*, a Sumatra species, and *F. dæmona*, from Tanjore, derive their names from this circumstance, in which many more equally participate.

Ficus Indica, the Banyan-Tree, is a native of most parts of India, both on the islands and the mainland. Roxburgh states that it is found in its greatest perfection and beauty about the villages on the skirts of the Circar Mountains. The leaves are ovate, heart-shaped, 3-ribbed, and entire; when young, downy on both sides; when old, much smoother; they are from 5 to 6 inches long, and from 3 to 4 inches broad; at the top of the leafstalk on the under side is a broad, smooth, greasy-looking gland. The figs when ripe grow in pairs from the axils of the leaves, are downy, and about the size and colour of a middle-sized red cherry. The wood is light, white, porous, and of no value. The Brahmins use the leaves as plates to eat off; birdlime is manufactured from the tenacious milky juice. If the seeds drop in the axils of the leaves of the Palmyra-Tree (*Borassus flabelliformis*), the roots grow downwards, embracing the trunk in their descent; by degrees they envelop every part except the top, whence in very old specimens the leaves and head of the Palmyra are seen emerging from the trunk of the Banyan-Tree as if they grew from it. The Hindoos regard such cases with reverence, and call them a holy marriage instituted by Providence. The Banyan-Tree, covering with its trunks a sufficient space to shelter a regiment of cavalry, and used as a natural canopy for great public meetings, has been so often described by writers on India as to have become familiar to the reader. The branches spread to a great extent, dropping their roots here and there, which as soon as they reach the ground rapidly increase in size till they become as large as and similar to the parent trunk, by which means the quantity of ground they cover is almost incredible. Roxburgh says that he has seen such trees full 500 yards round the circumference of the branches, and 100 feet high, the principal trunk being more than 25 feet to the branches, and 8 or 9 feet in diameter. Gum lac is obtained from this tree in abundance. The white glutinous juice is applied to the mouth to relieve tooth-ache; it is also considered a valuable application to the soles of the feet when cracked and inflamed. The bark is supposed to be a powerful tonic by the Hindoos. An excellent account of such a tree will be found in the 'Oriental Annual' for 1834; and a graphic description of the mode of growth in Rumf's 'Herbarium Amboinense,' vol. iii. p. 126. See also 'Asiatic Researches,' vol. iv. p. 310. It is called Vuta in Sanscrit, Bur or But in Bengáli, Bagha in Cingalese.

Ficus elastica, the Indian Caoutchouc-Tree, is now a common tree in the hothouses of this country. It has large, shining, oval, pointed, thick leaves, small axillary uneatable fruits the size of an olive, and long pink or red terminal buds, composed of the stipules rolled together. This species inhabits the Pundua and the Juntipoor Mountains, which bound the province of Silhet on the north, where it grows to the size of a European sycamore, and is called Kasmeer. It is chiefly found in the chasms of rocks and over the declivities of mountains among decomposed rocks and vegetable matter. It produces when wounded a great abundance of milk, which yields about one-third of its weight of caoutchouc. It grows with great rapidity; a tree is described as being 25 feet high, with the trunk a foot in diameter when only four years old. The juice of this valuable plant is used by the natives of Silhet to smear over the inside of baskets constructed of split rattan, which are thus rendered water-tight. Old trees yield a richer juice than young ones. The milk is extracted by incisions made across the bark down to the wood, at a distance of about a foot from each other, all round the trunk or branch up to the top of the tree, and the higher the more abundant is the fluid said to be. After one operation the tree requires a fortnight's rest, when it may be again repeated. When the juice is exposed to the air it separates spontaneously into a firm elastic substance, and a fetid whey-coloured liquid. Fifty ounces of pure milky juice taken from the trees in August yielded exactly 15½ ounces of clean-washed caoutchouc. This substance is of the finest quality, and may be obtained in large quantities. It is perfectly soluble in the essential oil of Cajeput. (Roxb., 'Fl. Ind.,' iii. 545.)

F. religiosa, the Pippul-Tree, is a large tree common in every part of India, especially near houses, where it is planted for the sake of its extensive dark grateful shade. It is held in superstitious veneration by the Hindoos, because their deity Vishnoo is fabled to have been born under its branches. The leaves are heart-shaped, long, pointed, wavy at the edge, not unlike those of some poplars; and as the footstalks are long and slender, the leaves actually tremble in the air like those of the Aspen-Tree (*Populus tremula*). Silk-worms prefer the leaves next to those of the Mulberry. The leaves are used for tanning leather by the Arabs, who call the tree Mudáh or Vudáh, and also Uadi Zebid. See 'Asiatic Researches,' iv. 309, for further information concerning this.

F. Sycomorus, the Sycomore-Fig, is a large tree found in Egypt, where it is planted extensively by the road-side, near villages, and on the sea-coast, for the sake of the shelter of its very widely-spreading branches. The Arabs call it Djummeiz. Forskähl states that its head is often forty yards in diameter. The leaves are broadly ovate, repand, or somewhat angular, rather blunt, nearly smooth, heart-shaped at the base. The figs are not produced upon the young branches, but in clustered racemes upon the trunk and the old limbs. They are sweet and delicate, and eaten by the Egyptians. The timber appears to be of little value, for Forskähl excludes it from the lists of carpenters' wood, and places it among the trees which are used for firewood. It can hardly therefore have furnished the wood of which mummy-cases were made, as has been supposed. Professor Don, with greater reason, conjectures that they were made from the timber of *Cordia Myxa*. When old this tree becomes very gnarled and broken, as is shown in a plate in Salt's 'Abyssinia,' where it is figured under the name of Daroo-Tree, but it is so bare of foliage as to be hardly a picturesque object.

F. Carica, the Common Fig, is a small crooked tree or large bush with round green or russet branches, covered with a coarse short down. The leaves are rough on the upper side, coarsely downy beneath, cordate, 3- to 5-lobed or almost entire, coarsely serrated. The fruit is solitary, axillary, more or less pear-shaped, or almost round, succulent, sweet and pleasant to the taste. All the parts abound in an acrid milky juice, which produces a burning disagreeable sensation in the fauces.

FIDDLE-FISH. [SQUALIDÆ.]

FIELDFARE. [TURDUS.]

FIG. [FICUS.]

FIGURE-STONE. [SLATE.]

FIGWORT. [SCROPHULARIA.]

FILA'GO, a genus of Plants belonging to the natural order *Compositæ*, tribe *Senecionideæ*, sub-tribe *Gnaphalieæ*, division *Helichryseæ*. The outer florets are female, filiform in several rows, the outermost ones intermixed with the inner scales of the involucre or paleæ; central florets few, hermaphrodite, tubular. Pappus capillary. The receptacle conical with a scaly margin. Involucre sub-conical, imbricated, the scales lanceolate, and longer than the florets. The species of this genus were formerly referred to *Gnaphalium*.

F. Germanica is a cottony plant with yellow florets, the stem proliferous at the summit from 4 to 12 inches long. It has lanceolate wavy leaves, heads in axillary and terminal globose clusters, the outer involucral scales cuspidate, cottony, with glabrous points. It is a native of Great Britain, as well as the following species:—

F. minima is distinguished by having its stem dichotomously branched, and the outer involucre scales bluntish, cottony, with glabrous points. The florets are yellow with very small heads. Like the other species it is found in dry, sandy, and gravelly places.

F. Gallica has linear, acute, revolute leaves, the heads conical in axillary terminal clusters, shorter than the leaves. This species is very rare.

F. apiculata has a cottony stem proliferous at the summit, the leaves all oblong, blunt, apiculate, the heads prominently 5-angled, half-sunk in tomentum, forming lateral, axillary, and terminal clusters, surrounded and overtopped by one or two blunt leaves. It smells like tansey. The stem is mostly erect, with short branches below. The heads are rather large, 10 to 20 in a cluster.

(Babington, *Manual of British Botany*.)

FILAMENT, in Botany, the part of the stamens which bears the anther. It is sometimes long and slender, hence its name filament. In some plants however it is nearly or altogether absent, and not unfrequently flat and broad. [STAMEN.]

FILARIA. [ENTOZOA.]

FILBERT. [CORYLUS.]

FILE-FISH. [BALISTES.]

FI'LICES, or FILICA'CEÆ, a natural order of Plants, being the highest group of the class *Cryptogamia*, or Acrogens. The species are flowerless plants, consisting of leafy fronds, which are produced from a rhizoma unfolding in a spiral manner, and traversed by veins which form definite parts on the under surface, and produce unilocular, rarely multilocular, cases containing reproductive sporules.

The parts of these plants which require most attention in their study, and on modifications of which modern classifications depend, are the veins and organs of reproduction. The veins are either produced equally from both sides of a midrib, or they radiate from the base or axis of development, or from one side of an eccentric or unilateral costa. They are either simple, or once or repeatedly dichotomously branched, or the primary veins are pinnate; the branches either simple or forked. Their apices are either free or they are combined by various forms of anastomosis. The organs of reproduction consist of a sporangiferous receptacle, which is a thickened point or lengthened portion of the ultimate veuules or veinlets. It is generally superficial, sometimes immersed in the substance of the frond, or considerably elevated, and then globose or columnar. The sporangia, thecæ, or spore-cases, are transparent, globose, oval, or pyriform unilocular cases, each girded by a more or less complete elastic articulated ring, or destitute of a ring; then sometimes oblong, opaque, and multilocular, and usually pedicillate. The sori are collections of sporangia, and have the same form, position, and direction as the receptacles. They are either naked, or each sorus is furnished with a membranaceous covering of various forms which rises from the receptacle. This covering is called an indusium, and is a plane, or vaulted, or cup-shaped membrane, produced from the receptacle of each sorus, and is generally deciduous as it becomes replicate. Often the entire margin (or lobules of the frond) is changed in texture, and forms an accessory indusium. Sometimes the whole of the sori of each segment are included within a universal indusium which is formed by the revolute margin of fertile contracted fronds.

The following account of the reproduction of the Ferns is given in a Report to the British Association in 1851, on the higher Cryptogamous Plants, by Mr. Henfrey. Speaking of the Ferns, Mr. Henfrey says:—

"This class formed for a long time the great stumbling-block to those who sought to demonstrate the existence of sexuality in plants. The young capsules were generally considered to be the analogues of the pistillidia of the Mosses, and the young abortive capsules which frequently occur among the fertile ones were supposed by some authors to represent the antheridia. Mr. Griffith noticed a structure which he was inclined to regard as the analogue of the antheridium in certain of the ramenta upon the petioles.

"In the year 1844 Professor Nägeli published an account of his observations on the germination of certain ferns, and announced the discovery of moving spiral filaments closely resembling those of the *Charæ*, on certain cellular structures developed upon the pro-embryo or cellular body first produced by the spore. It is not worth while to enter into an analysis of his observations, as they have since been clearly shown to have been very imperfect; it is sufficient to state that he only described one kind of organ, and from his description it is evident that he confounded the two kinds since discovered, regarding them as different stages of one structure. The announcement of this discovery seemed to destroy all grounds for the assumption of distinct sexes, not only in Ferns but in the other Cryptogams, since it was argued that the existence of these cellular organs, producing spiral filaments, the so-called spermatozoa, upon the germinating fronds, proved that they were not to be regarded as in any way connected with the reproductive processes.

"But an essay published by the Count Suminski in 1848 totally changed the face of the question, and opened a wide field for speculation and investigation on this subject, just as it was beginning to fall into disfavour. Count Suminski's paper gives a minute history of the course of development of the Ferns, from the germination of the spore to the production of the regular fronds; and he found this development to exhibit phenomena as curious as they were unexpected. The cellular organs seen by Nägeli were shown to be of two perfectly distinct kinds, and moreover to present characters which gave great plausibility to the hypothesis that they represented reproductive organs; moreover, this author expressly stated that he had obtained absolute proof of sexuality by observing an actual process of fertilization to take place in the so-called ovules, through the agency of the spiral filaments or spermatozoa. The main points of his paper may be briefly summed up as follows:—The fern-spore at first produces a filamentary process, in the end of which cell-development goes on until it is converted into a Marchantia-like frond of small size and exceedingly delicate texture, possessing hair-like radicle threads on its under side. On this under side become developed, in variable numbers, certain cellular organs of two distinct kinds. The first, which he terms antheridia, are the more numerous, and consist of somewhat globular cells seated on and arising from single cells of the cellular Marchantia-like frond. The globular cell produces in its interior a number of minute vesicles, in each of which is developed a spiral filament, coiled up in the interior. At a certain epoch the globular cell bursts, and discharges the vesicles, and the spiral filaments moving within the vesicles, at length make their way out of them, and swim about in the water, displaying a spiral or heliacal form, and consisting of a delicate filament with a thickened clavate extremity; this, the so-called head, being said by Count Suminski to be a hollow vesicle, and to be furnished with six or eight cilia, by means of which the apparently voluntary movement of the filament is supposed to be effected.

"The second kind of organ, the so-called 'ovules,' are fewer in number and present different characters in different stages. At first they appear as little round cavities in the cellular tissue of the pro-embryo, lying near its centre, and opening on the under side. In the bottom of the cavity is seen a little globular cell, the so-called 'embryo-sac.' It is stated by Count Suminski that while the ovule is in this state one or more of the spiral filaments make their way into the cavity, coming in contact with the central globular cell. The four cells bounding the mouth of the orifice grow out from the general surface into a blunt cone-like process, formed of four parallel cells arranged in a squarish form, and leaving an intercellular canal leading down to the cavity below. These four cells become divided by cross septa, and grow out until the so-called ovule exhibits externally a cylindrical form composed of four tiers of cells, the uppermost of which gradually converge and close up the orifice of the canal leading down between them. Meanwhile the vesicular head of one of the spiral filaments has penetrated into the globular cellule of the embryo-sac, enlarged in size and undergone multiplication, and in the course of time displays itself as the embryo, producing the first frond and the terminal bud, whence the regular fern-stem is developed. In considering the import of these phenomena, the author assumes the analogy here to be with the process of fertilisation in flowering plants, as described by Schleiden, regarding the production of the embryo from the vesicular head of the spermatozoa as represcuting the production of the phanerogamous embryo, from the end of the pollen tube after it has penetrated into the embryo-sac.

"The promulgation of these statements naturally attracted great attention, and since they appeared we have received several contributions to the history of these remarkable structures, some confirmatory, to a certain degree, of Suminski's views; others altogether opposed to them.

"In the early part of 1849 Dr. Wigand published a series of researches on this subject, in which he subjected the assertions of Suminski to a strict practical criticism; the conclusions he arrived at were altogether opposed to that author's views respecting the supposed formation of the organs, and he never observed the entrance of the spiral filaments into the cavity of the so-called ovule. About the same time M. Thuret published a series of observations on the 'Antheridia of Ferns.' In these he merely confirmed and corrected the statements of Nägeli respecting the antheridia, and did not notice the so-called ovules.

"Towards the close of the same year Hofmeister confirmed part of Suminski's statements, and opposed others. He stated that he had observed distinctly the production of the young plant (or rather the terminal bud for the new axis) in the interior of the so-called ovule; but believed the supposed origin of it from the end of the spiral filament to be a delusion. He regards the globular cell at the base of the canal of the ovule as itself the rudiment of the stem, or embryonal vesicle (the embryo originating from a free cell produced in this), analogous to that produced in the pistillidia of the Mosses. He also describes the development of the ovule differently, saying that the canal and orifice are opened only at a late period by the separation of the contiguous walls of the four rows of cells.

"About the same time appeared an elaborate paper on the same subject by Dr. Hermann Schacht, whose results were almost identical. He found the young terminal bud to be developed in the cavity of one of the so-called ovules, which were developed exactly in the same way as the pistillidia of the Mosses. He stated also that the cavity of the ovule is not open at first, and he declares against the probability of the entrance of a spiral filament into it, never having observed this, much less a conversion of one into an embryo. In the essay of Dr. Mettenius, already referred to, an account of the development of the so-called ovules is given. His observations did not decide whether the canal of the ovule, which he regards as an intercellular space, exists at first, or only subsequently, when it is entirely closed above. Some important points occur in reference to the contents of the canal. The contents of the canal in a mature condition consist of a continuous mass of homogeneous tough substance, in which fine granules, and here and there large corpuscles, are embedded. It reaches down to the globular cell, or embryo-sac, and is in contact with it. This mass either fills the canal or diminishes in diameter from the blind end of the canal down to the embryo-sac; in other cases it possesses the form represented by Suminski, having a clavate enlargement at the blind end of the canal, and passing into a twisted filament below; in this latter shape it may frequently be pressed out of isolated ovules under the microscope, and then a thin transparent membrane-like layer was several times observed on its surface. In other cases the contents consisted of nucleated vesicles, which emerged separately or connected together.

"The embryo-sac consists of a globular cell containing a nucleus, and this author believes that the commencement of the development of the embryo consists in the division of this into two, which go on dividing to produce the cellular structure of the first frond.

"With regard to the contents of the canal the author says, 'Although I can give no information on many points, as in regard to the origin of the contents of the canal of the ovule, yet my observations on the development of the ovule do not allow me to consider them, with Suminski, as spiral filaments in course of solution; just as little have I been able to convince myself of the existence of the process of impregnation described by that author. It rather appears to me that the possibility of the entrance of the spiral filaments and the impregnation cannot exist until the tearing open of the blind end of the canal in the perfectly-formed ovule, as after the opening of the so-called 'canal of the style' in the pistillidia of the Mosses.'

"Another contribution has been furnished by Dr. Mercklin, the original of which I have not seen, but depend on analyses of it published in the 'Botanische Zeitung,' and the 'Flora' for 1851, and further in a letter from Dr. Mercklin to M. Schacht, which appeared in the 'Linnæa' at the close of last year.

"He differs in a few subordinate particulars from M. Schacht, in reference to the development and structure of the prothallium, or pro-embryo, and of the antheridia and spiral filaments; but these do not require especial mention, except in reference to the vesicular end of the spiral filament described by Schacht, which Mercklin regards as a remnant of the parent vesicle, from which the filament had not become quite freed. The observations referring to the so-called ovule, and the supposed process of impregnation, are very important; they are as follows:—

"'1. The spiral filaments swarm round the ovule in numbers, frequently returning to one and the same organ.

"'2. They can penetrate into ovules. This was seen only three times in the course of a whole year, and under different circumstances; twice a spiral filament was seen to enter a still widely open young ovule, then come to a state of rest, and after some time assume the appearance of a shapeless mass of mucilage; the third case of penetration occurred in a fully developed ovule through its canal; it therefore does not seem to afford evidence of the import of the spiral filament, but certainly of the possibility of the penetration.

"'3. In the tubular portion of the ovule, almost in every case, peculiar club-shaped granular mucilaginous filaments occur at a definite epoch; these filaments, like the spiral filaments, acquiring a brown colour with iodine. These mucilaginous bodies sometimes exhibit a twisted aspect, an opaque nucleus, or a membranous layer, peculiarities which seem to indicate the existence of an organisation.

"'4. These club-shaped filaments are swollen at the lower capitate extremity, and have been found in contact with the embryo-sac, or globular cell, which forms the rudiment of the future frond.

"'5. The spiral filaments, which cease to move and fall upon the prothallium, are metamorphosed, become granular, and swell up.'

"Hence the author deduces the following conclusions:—

"'That these clavate filiform masses in the interior of the ovule are transparent spiral filaments, which at an early period, while the ovule was open, have penetrated into it; which leads to the probability that—

"'1. The spiral filaments must regularly penetrate into the ovules; and 2. They probably contribute to the origin or development of the young fruit frond (or embryo). In what way this happens the author knows not, and the details on this point given by Suminski remain unconfirmed facts.'

"An important point in this essay is the view the author takes of the whole process of development in this case. He regards it as not analogous to the impregnation in the *Phanerogamia*, since the essential fact is merely the development of a frond from one cell of the prothallium, which he considers to be merely one of the changes of the individual plant, while all the other authors who have written on the subject, with the exception of Wigand, call the first frond, with its bud and root, an Embryo, and regard it as a new individual; or at all events, even a distinct member of a series of forms, constituting collectively the representatives of the species.

"Finally, Hofmeister, in his notice of this essay in the 'Flora,' declares that the development of the so-called embryo, or first frond, commences not by the subdivision of the globular cell, or embryo-sac, but by the development of a free cell, or embryo vesicle in this, like what occurs in the embryo-sac of the *Phanerogamia;* and he asserts that this is the first stage of development from the globular cell in all the vascular Cryptogams, including that found in the pistillidia of the Mosses."

The position of the Ferns in a natural system of classification has not been a matter of much difference. Their imperfect organs of reproduction have at once led to their being placed by most botanists among *Cryptogamia;* nevertheless Bory St.-Vincent elevates Ferns to the rank of a class intermediate between Monocotyledons and Acotyledons, or *Cryptogamia;* at the same time he rejects the view of Jussieu, who, from the mode of germination of their sporules, placed the Ferns among the Monocotyledons. Their relation with the flowering plants is seen through *Cycadaceæ*, with which order they agree in their gyrate vernation and their pinnate leaves. Their affinity with Cryptogamic Plants is obvious in the *Equisetaceæ* and *Lycopodiaceæ*. The order of Ferns may be divided into the following sub-orders, which Lindley regards as of the rank and value of orders:—

I. Gleicheniaceæ. The thecæ with a transverse or obliquely transverse complete elastic annulus or ring, bursting vertically. The species are tropical, or extra-tropical only in the Southern Hemisphere, of a harsh and rigid texture, simple or generally with copious dichotomous branches and gemmæ in the axils; the ultimate branches pinnatifid. None of the genera of this order, as understood by Hooker, are British. It includes about forty species.

II. Polypodiaceæ, with the sori dorsal, often near or at the margin, various in form, sometimes constituting an uniform linear or spreading mass, naked or furnished with an involucre, the thecæ 1-celled, with a longitudinal or oblique elastic articulated generally incomplete ring, bursting transversely and irregularly. This is a very extensive sub-order: the species inhabit almost every part of the world, from the tropics to the arctic and antarctic regions; they are exceedingly variable in size and appearance, including the largest tree-ferns and the smallest herbaceous species. It contains by far the largest number of genera of any of the sub-orders of Ferns. Many of these are very extensive, and have no British representatives, as *Cyathea*, *Hemitelia*, *Alsophila*, *Dicksonia*, &c.

III. Osmundaceæ has the thecæ with an operculiform ring, or without one, reticulated, striated with rays at the apex, bursting lengthwise, and usually externally. The species of this sub-order are not numerous.

IV. Danæaceæ. The thecæ sessile, without any ring, concrete into multilocular sub-immersed masses, opening at the apex. This is also a small sub-order, with three genera—*Danæa*, *Marattia*, and *Kaulfussia*.

V. Ophioglossaceæ. The thecæ single, roundish, coriaceous, opaque, without ring or cellular reticulation, half 2-valved, with a straight vernation. It embraces the genera *Ophioglossum*, *Helminthostachys*, and *Botrychium*.

The following is an arrangement of the British genera of Ferns:—

Sub-Order *Polypodiaceæ*.

Tribe *Polypodieæ*. The sori nearly circular, without an indusium.
Genera, *Allosorus*, *Polypodium*, *Woodsia*.

Tribe *Aspidieæ*. The sori nearly circular, covered by an indusium.
Genera, *Lastrea*, *Polystichum*, *Cystopteris*.

Tribe *Asplenieæ*. The sori oblong or linear, covered by an indusium opening longitudinally on one side.
Genera, *Athyrium*, *Asplenium*, *Scolopendrium*.

Tribe *Grammitideæ*. The sori elongate, without an indusium.
Genus, *Ceterach*.

Tribe *Adiantariæ*. The thecæ covered by a marginal or sub-marginal elongated part of the frond, or by a separated portion of the cuticle, resembling an indusium.
Genera, *Blechnum*, *Pteris*, *Adiantum*.

Tribe *Hymenophylleæ*. The thecæ opening irregularly; the ring oblique, eccentric, transverse, complete; the receptacle terminating a vein at the margin of the frond.
Genera, *Trichomanes*, *Hymenophyllum*.

Sub-Order *Osmundaceæ*.

Tribe *Osmundeæ*. The vernation circinate; the rachis solid; the thecæ stalked.
Genus, *Osmunda*.

Sub-Order *Ophioglossaceæ*.

Genera, *Ophioglossum*, *Botrychium*.

The Ferns have a wide geographical distribution. The herbaceous and shrubby kind being found towards the north and south poles: whilst the tree-ferns rival the gigantic palms in the forests of tropical climates. It is these last which give a peculiar character to the vegetation of the countries where they grow, as their foliage and stems differ altogether from any that are observed amongst flowering plants. The proportion which they bear to other plants varies much in different parts of the world. In Jamaica they are in the proportion of 1 to 9; in New Guinea as 28 to 122; in New Ireland as 13 to 60; in the Sandwich Islands as 40 to 160; on continents they are less numerous; in equinoctial America 1 to 36; in Australia 1 to 37; in France 1 to 63; in Portugal 1 to 116; in the Greek Archipelago 1 to 227; in Egypt 1 to 971. In the north their proportions are greater; they form in Scotland 1 to 31; in Sweden 1 to 35; in Iceland 1 to 18; in Greenland 1 to 10; and the North Cape 1 to 7.

The properties and uses of the Ferns are not in proportion to their numbers in the vegetable kingdom. Many of them deposit starch in their rhizomata, from which food may be prepared. The roots of

Nephrodium esculentum are eaten in Nopaul; those of *Angiopteris erecta* are used in the same manner in the Sandwich Islands. *Diplazium esculentum*, *Cyathea medullaris*, *Pteris esculenta*, and *Gleichenia dichotoma*, all yield starch, and are employed as food in different countries. [CYATHEA.] The *Adiantum Capillus Veneris* yields astringent and aromatic secretions. [ADIANTUM.] Some of the American polypodiums are said to possess powerful medicinal effects, and are used as anti-rheumatic, anti-venereal, and febrifugal remedies. The *Angiopteris erecta* yields an aromatic oil, which is used in the Sandwich Islands to perfume the fixed oils, as cocoa-nut oil. The stems of many species contain bitter principles, and have hence been used as tonics. Species of *Aspidium* and *Asplenium* have been used in European medicine. [ASPIDIUM; ASPLENIUM.] The Brazilian negroes form tubes for their pipes from the stems of *Mertensia dichotoma*. *Osmunda regalis* had at one time a great reputation in medicine.

(Babington, *Manual of British Botany*; Lindley, *Natural System*; Hooker, *Species Filicum*; J. Smith, *The Genera of Ferns*; *Journal of Botany*, vol. iv.; Newman, *History of British Ferns*; Burnett, *Outlines of Botany*; Meyen, *Pflanzen-Geographie*.)

FIN. [FISH.]

FINCH. [BULLFINCH; CHAFFINCH; COCCOTHRAUSTES; FRINGILLA.]

FINGER. [SKELETON; HAND.]

FINGERLING, the young of the Salmon. [SALMONIDÆ.]

FINSCALE. [LEUCISCUS.]

FIR. [ABIES; PINUS.]

FIRE-FLAIRE. [TRYGON.]

FIRE-FLY. [ELATERIDÆ; LAMPYRIDÆ.]

FIRE-STONE, a local term for the Upper Greensand, as it occurs along the edges of the chalk-hills south of London, as at Mesterham and Petersfield. (Fitton, 'On Greensand,' in 'Geol. Trans.')

FIROLA. [NUCLEOBRANCHIATA.]

FISH (French, Poisson; German, Fisch), a name applied to all the species of a class of animals occupying the lowest station of the four great divisions of the section *Vertebrata*.

A Fish may be defined as a Vertebrate Animal, breathing through the medium of water by means of branchiæ, or gills, having one auricle and one ventricle to the heart, cold red blood, and extremities formed for swimming.

In considering fishes, perhaps the most important thing which offers itself to our attention is the apparatus called the Branchiæ, or Gills. This apparatus is situated on each side of the neck, and consists of numerous laminæ fixed on arches. These laminæ are covered with innumerable blood-vessels, and are so constructed as to present a considerable surface to the water, so that the blood may receive a sufficient portion of the oxygen contained in that element. As the water in contact with the gills becomes deteriorated, it is necessary that a constant current be caused to flow over them. In most fishes this is effected by their taking the water in at the mouth and expelling it from under the gill-covers. The blood, which is constantly sent to the branchiæ from the heart, is distributed by means of the arteries to every part of the body, whence it returns to the heart by means of the veins.

the fore legs constituting what is termed the Pectoral Fins (*fig.* 1, *a*), and the posterior extremities the Ventral (*fig.* 1, *b*); besides these fins ordinary fishes are furnished with one or two Dorsal Fins (*fig.* 1, *c c*), an Anal Fin (*fig.* 1, *d*), and a Caudal Fin, or tail.

All these fins are not always present, nor when present are they always in the same relative positions; and we shall hereafter find that both the absence of certain fins, and the peculiar position of these organs, afford characters in the classification of fishes. The fins consist of a thin elastic membrane supported by rays. The rays are of two kinds—those which consist of a single bony piece, usually hard and pointed, are termed spinous rays; and when the rays are formed of numerous portions of bone united by articulations, and frequently divided longitudinally into several filaments, they are called flexible rays. The principal organ of motion is the tail; the dorsal and ventral fins apparently serve to balance the fish, and the pectorals to arrest its progress when required.

The Bones of fishes are of a less dense and compact nature than in the higher orders of animals, and always remain in an isolated state, similar to that of the embryo of the *Mammalia*. The skeleton may be divided into four chief parts—the vertebral column, the head, the respiratory apparatus, and the limbs. The vertebral column consists of vertebræ which are concave at each end and pierced in the middle; and when joined together the hollow space between each two is occupied by a gelatinous substance, which passes from one space to the next through the hole in each bone. This hole is usually very small, but in some of the Chondropterygians it is so large that the bodies of the vertebræ are mere rings. To the vertebræ are attached the ribs; in fact the ribs are the main support of all the other bones. The head varies more in form than in any other class of vertebrate animals. The same bones as those found in other oviparous animals are almost always traceable. We shall confine our observations to those which are most frequently referred to in technical descriptions.

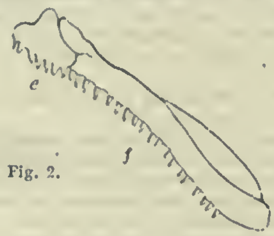


Fig. 2.

Fig. 3.

Fig. 2, upper jaw of a Trout: *e*, intermaxillary bone; *f*, maxillary bone.

Fig. 3, front view of the mouth of a Trout: *l*, the vomer furnished with teeth; *m m*, palatine bones also furnished with teeth; *n*, the tongue with recurved teeth.

The upper jaw consists of maxillary and intermaxillary bones; in the greater number of fishes the intermaxillary bones (*fig.* 1, *e*) con-

Fig. 1.

a, the pectoral fin; *b*, the ventral fin; *c c*, the dorsal fins; *d*, the anal fin; *e*, the intermaxillary bone; *f*, the maxillary bone; *g*, the operculum; *h*, the sub-operculum; *i*, the pre-operculum; *k*, the inter-operculum.

As the breathing apparatus in the fish is suited to aquatic habits, so likewise is every part of its structure. The body is generally of an elongate oval compressed form, covered with scales directed backwards, and furnished with fins; thus being beautifully adapted for swimming. Many fishes moreover have a bladder filled with air situated immediately beneath the spine, by the dilatation or compression of which their specific gravity is said to be varied. The thoracic part of the body is thrown forwards towards the head (so that fishes may be said to have no neck), and thus the hinder part of the body is more free and fitted for motion. The limbs are formed into fins,

stitute the chief portion of the upper jaw, the maxillary bones (*fig.* 1, *f*) being placed behind and parallel to them and articulated to the vomer. (*Fig.* 3, *l*.) In the salmon tribe and some other fishes however the intermaxillary bones (*fig.* 2, *e*) are smaller in proportion, and form a continuous line with the fore-part of the maxillary bones. (*Fig.* 2, *f*.) In the Chondropterygians the maxillary and intermaxillary bones are reduced to mere rudiments, their functions being performed by the bones analogous to the palatines, and sometimes by the vomer.

The lower jaw is generally composed of at least two bones on each side, the dental portion in front, and the articular portion behind.

The Palatines (*fig.* 3, *m m*) are extended longitudinally on each side, and form part of the roof of the mouth; they are often furnished with teeth.

The Opercular Bones.—The chief portion of the sides of the head behind the eye consists of the opercular bones: these are generally four in number, and are termed the operculum (*fig.* 1, *g*), the sub-operculum (*fig.* 1, *h*), the pre-operculum (*fig.* 1, *i*), and the inter-operculum (*fig.* 1, *k*). The first of these covers the gills.

The Branchiostegous Rays (*fig.* 1, *o*), which are often mentioned in descriptions, are situated under the opercular bones.

The Teeth in fishes are almost entirely osseous; they are usually of a simple spine-like form, and recurved at the tip. Teeth are found in almost every bone in the interior of the mouth; in the superior and inferior maxillary, and intermaxillary bones; likewise on the branchial arches, pharangeal bones (which are situated in the throat), and on the tongue. There is considerable variety in their structure, as will be found in the various descriptions of fishes found in other parts of this work.

The Scales are composed of two substances, one resembling horn in its texture, and the other of a harder and bone-like nature; they are generally attached to the skin by their anterior edge, and consist of numerous concentric laminæ (secreted by the skin), the smallest of which is first formed. Certain scales, forming a continuous series, in a slightly waved line from the head to the tail of the fish, are pierced in or near their centre, and furnished with a tube through which a slimy matter is poured, which serves to lubricate the body of the animal. This series of tubes forms a line visible on the sides of the body, and which is termed the lateral line.

The structure, form, and position of the scales of fishes are very variable, and have furnished M. Agassiz ('Recherches sur les Poissons Fossiles') with characters for a new classification of these animals.

As regards the senses, those of taste and touch appear to be but slightly developed in fishes. When we find the tongue thickly covered with teeth (as is often the case), and used as an organ of prehension, and when we consider the quick manner in which the food is swallowed, it would certainly appear that their sense of taste is very slight. The sense of touch is probably most developed in the cirrhi attached to the mouth of those fishes that have them. The long filaments with which the fins of some fishes are furnished also perhaps serve, through the sense of touch, to indicate the vicinity of weeds, or other objects in the water.

The eyes are differently placed in the various species of fishes, in accordance with their habits: for the most part they are placed laterally, and in some (those that live at the bottom of the water) we find them directed upwards. In some of the species of sharks (those of the genus *Zygæna*) they are situated at the end of an elongated lateral process on each side of the head.

The sight in fishes is acute; the range of vision however is probably somewhat limited. The eyes (which are furnished with a spherical lens) are generally large, but in some species they are very small, whilst others appear to be destitute of them.

Although fishes appear not to possess certain portions of the auditory apparatus, observed in animals of a higher grade, they nevertheless possess the sense of hearing.

There are reasons for the belief that the sense of smell in fishes is tolerably acute: their olfactory nerves are of large size, and disposed over a considerable extent of surface.

By far the greater number of fishes are of carnivorous habits; there are some however which feed upon vegetable substances, and we find the stomach modified accordingly as in other animals.

The sexes of fishes, if we except the sharks and rays, offer no very decided external characters by which they may be distinguished: as in the higher animals however, observes Mr. Yarrell, "the respiratory organs occupy more space in the males than in the females; and, on the other hand, the abdomen is larger in the females than in the males: the males may therefore be known from the females by their somewhat sharper or more pointed head, the greater length of the gill-cover, and the body from the dorsal fin downwards being not so deep compared with the whole length of the fish."

The sexual organs of fishes are in the generality of the species of a more simple nature than is observed in the higher orders of the *Vertebrata*, "consisting, as will be found, towards the season of producing their young, of two elongated oval lobes of roe, one on each side of the body, placed between the ribs and the intestinal canal; the lobes in the female, called hard roe, contain a very large number of roundish grains, called ova or eggs, which are inclosed in a delicate membranous tunic or bag, reaching to the side of the anal aperture, where an elongated fissure permits egress at the proper time. In the males, the lobes of roe are smaller than in the females, and have the appearance of two elongated masses of fat, which are called soft roe; they remain however firm till the actual season of spawning, when they become by degrees more and more fluid, and the whole is ultimately voided by small portions at a time under slight abdominal pressure.

"At the season for depositing the spawn, which varies with almost every genus, some species repair to the gravelly shallows of rivers, and others to the sandy bays of the sea. This movement is called by fishermen 'going to hill,' or 'roading;' other species resort to bunches of weeds. In many instances, when ready to deposit her spawn, a female is accompanied by two males, one on each side—a provision of nature which seems intended to secure the impregnation of the largest quantity of ova, and the range of the influence of the male fluid is enormously increased by diffusion in water. The adhesive nature of the surface of each egg supplies the means of attachment to any of the various substances near which it may happen to be left; and the time required for the appearance of the young fish is very variable, depending upon the species, the season, and its temperature. The young fish is first apparent as a line wound round the central vitelline portion of the egg, and ultimately escapes by rupturing the external capsule with its tail."

We now proceed to give an outline of Cuvier's classification of fishes, since it is that which is perhaps most generally adopted: it is nevertheless in many respects very artificial.

Fishes are divided by this author into two series, that of Ordinary Fishes, or *Ossei*, distinguished by having the skeleton bony; the osseous matter being disposed in fibres; the sutures of the cranium distinct; maxillary and intermaxillary bones, either one or both present: and that of the *Cartilaginei*, or *Chondropterygii*, distinguished by having the skeleton cartilaginous; the bones destitute of fibres; sutures of the cranium indistinct; maxillary and intermaxillary bones either wanting or rudimentary, their place being supplied by the palatine or vomer.

These two series are subdivided as follows:—

Series 1. *Ossei.*

Section 1. *Pectinibranchii.*

Order 1. *Acanthopterygii.*

Family *Percidæ.*
Loricati.
Sciænidæ.
Sparidæ.
Mænidæ.
Squamipinnati.
Scombridæ.
Tænioidæ.

Family *Theutyes.*
Pharyngiens labyrinthiformes.
Mugilidæ.
Gobiadæ.
Lophiadæ.
Labridæ.
Centriscidæ.

Order 2. *Malacopterygii.*

1\. *Abdominales.*

Family *Cyprinidæ.*
Esocidæ.
Siluridæ.
Salmonidæ.
Clupeidæ.

2\. *Subbrachiales.*

Family *Gadidæ.*
Pleuronectidæ.
Discoboli.
Echeneididæ.

Order 3. *Apodes.*
Murænidæ.

Section 2. *Plectognathi.*
Gymnodontidæ.
Sclerodermi.

Section 3. *Lophobranchii.*
Syngnathidæ.

Series 2. *Cartilaginei*, or *Chondropterygii.*

Order 1. *Eleutheropomi.*
Sturionidæ.
Chimæridæ.

Order 2. *Plagiostomi.*
Squalidæ.
Raiidæ.

Order 3. *Cyclostomi.*
Pteromyzidæ.

The characters of the two great series or sections into which fishes are divided, it has been shown, are taken from the nature of the skeleton. It remains for us now to make a few observations upon the minor subdivisions.

In the *Ossei*, or bony fishes, there are three sections. Those of the first, the *Pectinibranchii*, possess the following characters:—Branchiæ in continuous pectinated ridges, furnished with an opercular and branchiostegous membrane; jaws complete and free. Section 2, *Plectognathi*:—Branchiæ with the pectinations continuous; opercule and rays concealed beneath the skin; external aperture a simple cleft; jaws incomplete; maxillary firmly attached to the side of the intermaxillary, which alone forms the jaw; palatine arch united to the cranium by suture, and immovable. To this section belong the globe-fishes, file-fishes, &c. Section 3, *Lophobranchii*:—Branchiæ in small tufts; opercule large, confined on all sides by a membrane, with only a small hole for the external aperture; branchiostegous rays rudimentary; jaws complete and free. To this section belong the pipe-fishes, hippocampus, &c.

The two latter sections contain but a limited number of species: the *Pectinibranchii*, on the contrary, contain all the ordinary and typical fishes, and, as is seen in the foregoing list, is subdivided into three orders. The fishes of the first of these orders, the

Acanthopterygii, are distinguished by their having the anterior part of the dorsal, anal, and ventral fins furnished with simple spinous rays. [ACANTHOPTERYGII.] The perches, mullets, gurnards, mackerels, &c., belong to this order. In the second order, the *Malacopterygii*, all the fin-rays are flexible, with the exception sometimes of the first ray of the dorsal and pectoral fins. The three principal divisions of the *Malacopterygii* are founded either upon the position of certain fins or their absence. In the first division, the *Abdominales*, the ventral fins are situated far behind the pectorals; as in the carp, tench, bream, dace, roach, pike, salmon, &c. In the second group, the *Subbrachiales*, the ventral fins are situated immediately beneath the pectorals (or even a little before them); as we find them in the cod-fish, haddock, and whiting. The flat fishes also belong to this group—such as the plaice, flounder, turbot, sole, &c. To the third and last of these greater divisions of the *Malacopterygii* belong the eels, which have received the name *Apodes*, from their possessing no ventral fins.

In illustration of the three orders into which the *Cartilaginei* are divided, the Sturgeon will serve as an example of the first, or the *Eleutheropomi*. The *Plagiostomi* contain the Sharks and Rays; and the Lampreys and Myxines chiefly constitute the *Cyclostomi*.

Mr. M'Leay, to whom Natural History is so largely indebted for methods of classification, has given a new arrangement of fishes. The basis of this method is the quinarian system. He bases his classification on three generally admitted facts, which he holds to be incontestable. The first is the near approach of fishes to Batrachian *Amphibia*, which, with Swainson, he considers to be made by means of *Lophius* and *Malthe*. 2nd. The near approach of fishes to the Cetaceous *Mammalia*, the viviparous sharks constituting the connecting link. 3rd. "As the grand character of fishes as a class is their being the most imperfect of *Vertebrata*, the most typical of fishes ought therefore to be the most imperfect of them, namely, the furthest removed from the type of *Vertebrata*;" a position which many naturalists will be inclined to combat. He regards as examples of such fishes the *Cyclostomi*. Bearing the above 'fundamental facts' in mind, he constitutes the following primary divisions:—

Aberrant Group, *Ctenobranchii*. Gills pectinated.

1. *Plagiostomi*. Cartilaginous Fishes with fixed branchiæ, leading to *Mammalia*.
2. *Sturiones*. Cartilaginous Fishes with free branchiæ.
3. *Ostinopterygii*. Bony Fishes with free branchiæ, leading to *Amphibia*.

Normal Group, *Actenobranchii*. Fish breathing with gills, not pectinated.

4. *Lophobranchii*. Bony Fishes breathing by tufts arranged in pairs along the branchial arches.
5. *Cyclostomi*. Cartilaginous Fishes breathing by a series of cells.

Mr. M'Leay has not presented an analysis of the families and genera included under the above five orders, with the exception of those of the third, *Ostinopterygii*, a term by which he proposes to denominate the osseous fishes having pectinated gills. The following table of his subdivisions of this important order will convey to the naturalist a clear idea of his system.

Ostinopterygii.

A.

Aberrant Group, *Acanthopterygii*. Spines in the first dorsal fin hard.

Tribe 1, *Balistina*. Maxillary bones soldered to the intermaxillaries, and both to the palatine arch; opercula and gills concealed beneath the skin. Includes the families *Balistidæ, Ostraciontidæ, Cephalaspis, Orthagoriscidæ, Diodontidæ.*

Tribe 2, *Percina*. Bones of the jaws free and complete. Operculum distinct. Operculum or pre-operculum generally with dentated edges, or with spines. Includes *Chætodontidæ, Percidæ, Scorpænidæ, Cirrhitidæ, Sparidæ.*

Tribe 3, *Fistularina*. Bones of the jaws free and complete. Operculum distinct. Operculum and pre-operculum generally with smooth edges. *Scombridæ, Fistularidæ, Gobioidæ, Lophiidæ, Labridæ.*

B.

Normal Group, *Malacopterygii*. Spines in the dorsal fins soft.

Tribe 4, *Pleuronectina*. Ventral fins, when existing, inserted under the pectorals, and directly suspended to the bones of the shoulder. *Anguillidæ, Echeneidæ, Cyclopteridæ, Pleuronectidæ, Gadidæ.*

Tribe 5, *Abdominales*. Ventrals suspended behind the pectorals, and not attached to the bones of the shoulders. *Siluridæ, Cyprinidæ, Esocidæ, Clupeidæ, Salmonidæ.*

Geographical Distribution of Fishes.—This branch of ichthyology is beginning to attract the attention and research which the interest of the subject demands. Within the last twenty years the example of Yarrell has been followed in many countries, and valuable local monographs published, with excellent illustrations. In the north of Europe, besides the writings of Nilson and Eckstrom, the fishes of Denmark have been illustrated by Henrik Kroyer. Those of Belgium have been carefully examined by M. de Selys Longchamps. In that naturalist's 'Faune Belge' fifty-three fresh-water fishes and forty-one species inhabiting the sea are enumerated. Of the former, forty-three live only in fresh-water; six in fresh-water, but go to the mouths of rivers in winter; and four live in the sea, but migrate to the rivers in spring or summer. Of the sea-fishes thirty pass up the Scheldt as far as Antwerp. The fresh-water fishes of Central Europe have engaged the attention of Agassiz. Freyer has published an account of those inhabiting Carniola, amounting to thirty-two species. Italian ichthyology has been admirably illustrated by Prince Charles Lucien Bonaparte. In Asia the fishes of the Caspian have been described by Eichwald in his 'Fauna Caspio-Caucasica,' published in 1841. Those inhabiting the rivers of Syria have been enumerated by Heckel (1843) from the collections of Kotschy. Fifty-seven species inhabit the rivers Orontes and Euphrates, of which no fewer than forty-five are *Cyprinidæ*. Indian ichthyology has received valuable contributions from M'Clelland, whose papers have been chiefly published in the 'Calcutta Journal.' In Siebold's 'Fauna Japonica' (1842) are accounts and figures of Japanese fishes by Temminck and Schlegel. The most valuable contribution ever made to our knowledge of the ichthyology of Eastern Asia was communicated to the British Association at Cambridge in 1845, in the form of a report on the 'Ichthyology of China,' by Sir John Richardson. From his researches it would appear that the fishes of that region are not only very numerous as regards species, but also very valuable on account of the extensive fisheries there carried on. His remarks on their distribution are highly interesting. It would appear that chains of islands or coasts having an east and west extension determine the extent of the range of species and groups of species. For example, to take the intertropical zone of the ocean, we find a great number of fishes common to the Red Sea, the coasts of Madagascar, the Mauritius, the Indian Ocean, the south of China, the Philippines, the Malay Archipelago, the northern coast of Australia, and the whole extent of Polynesia, including the Sandwich Islands. As regards the generic forms of the fresh-water fishes, China agrees with the peninsula of India. Were the vast zone in question, embracing more than two-thirds of the circumference of the globe, to be suddenly elevated, we should find the remains of fishes similar everywhere throughout, the species which have a local distribution being few and unimportant. This result of Sir John Richardson's researches is of the highest importance when brought to bear on geological considerations. Sir John Richardson has also been engaged in the special investigation of the ichthyology of Australia, and his many valuable memoirs on that subject may be consulted in the 'Transactions of the Zoological Society,' and in the 'Annals of Natural History.' In Dieffenbach's 'Travels in New Zealand' (1843), the same indefatigable and philosophic zoologist has published, in conjunction with Dr. Gray, a list of the fishes of New Zealand. Ninety-two species are there enumerated. In Smith's 'Illustrations of the Zoology of South Africa,' figures and descriptions are given of the fishes of the Cape of Good Hope. The researches of Dr. Peters on the eastern coast of Africa, have made us acquainted with the ichthyology of that interesting region. With those of the northern part of Western Africa we have had ample information in the valuable memoirs of Lowe on the fishes of Madeira. ('Zoological Transactions and Proceedings.')

The labours of Jenyns on the fishes collected during Captain Fitzroy's voyages have contributed materially to our knowledge of the ichthyology of the southern extremity of South America, whilst that of Guyana has been illustrated by Sir Robert Schomburgk, in the 'Naturalists' Library.' De Kay's 'Zoology of New York' (1842) has made us acquainted in detail with the fishes of the United States. They amount, so far as known, to 440 species, distributed through 156 genera and 32 families. In the State of New York there are 126 *Acanthopterygii*, 115 *Malacopterygii*, 3 *Lophobranchii*, 18 *Plectognathi*, 3 species of sturgeon, and 27 cartilaginous fishes.

The distribution of fishes appears to be determined by the same laws which regulate that of other aquatic animals. Climate, composition of the element in which they live (whether salt, brackish, or fresh), and conformation of the sea or river bed, on which the depth of water depends, are the great regulating influences. The great distinctions of form and colour between fishes of tropical and those of temperate regions, evince the influence of climate; the fact of the fisheries for certain species commonly used for food being invariably conducted in deep water, whilst others can only be maintained among shallows, shows the influence of depth; the fact pointed out by Sir John Richardson that the seas, by ranges of land or reefs extending for great distances under the same climatal parallel, are peopled by the same species of fishes, is an instance of the action of the combined influences of climate and depth. The distinctness as to genera and species of the greater number of river and lake fish from those inhabiting the sea depends on the second of the three great influences enumerated—that of the composition of the element in which they live. Great depths cut off the range of species even when climatal conditions are similar. Hence the fishes of the coast of the United States are for the most part distinct from those on our own side of the Atlantic. Some fishes have very limited ranges in depth compared with others, and, generally speaking, it may be assumed that those having the greatest vertical range (that is, range in depth) have also the widest horizontal extension, a fact depending on the capacity of such species for living under a greater variety of conditions.

Barriers of land, as chains of mountains, determining the courses of rivers, are often the boundaries between two distinct specific assemblages of fresh-water fish, and in like manner a very narrow strip of land may divide two very distinct marine faunas. The distribution of marine vegetables, affecting the distribution of numerous marine *Invertebrata* which feed on those vegetables, and in their turn serve to furnish food for fishes, will materially affect the distribution of many species of the latter. So also will the presence of currents, and even the agency of man, assisting often unintentionally in the conveyance of ova from one country to another. Distant regions, presenting similar conditions, such as the arctic and antarctic seas, are inhabited by species representative but not identical, and presenting a general aspect very similar, depending on characters of form and colour, &c. It is probable also that the fishes inhabiting the greater depths of tropical seas resemble those of temperate climes, and that those of the latter in like manner approach arctic forms.

A brief glance at the range and distribution of the principal genera will best serve to illustrate the above positions.

The lowest and most anomalous of all the species of fishes, the *Branchiostoma*, is generally distributed through the seas of Europe. Only one species is known, yet we cannot but hope that the researches of the many active naturalists now occupied with the study of marine zoology will bring to light forms connecting the Lancelet with other genera. The *Myxine*, or Glutinous Hag, almost equally strange in form and structure, is confined to the most northern and most southern seas, and is replaced in the higher parts of the southern hemisphere by the equally curious and nearly allied genus *Heptatrema*. The Lampreys inhabit the fresh-waters of Europe and North America, but the species in each are quite distinct. *Lepidosiren*, the connecting link between fishes and reptiles, so dubious in organisation that its position is still disputed, is an inhabitant of the west of Africa, and a genus closely allied has been discovered by Dr. Peters on the eastern coast of the same continent.

The Rays and Sharks are universally distributed, but many of the genera and species are very local and apparently regulated in their range by climatal zones. The seas of Europe can boast of the greater number, though fortunately the most formidable of the species are exotics. The largest species, as the great *Silachus maximus*, the Basking Shark, are harmless, and have their favourite habitats in the temperate zone. Size among fishes does not appear to bear any relation to latitude. *Chimaera* is northern and southern, extending from the frigid zone. The *Sclerodermi* are for the most part southern and tropical, especially the curious forms of *Cestracion* and *Astracion*. *Monacanthus* inhabits the American and Chinese seas; *Triodon*, the Indian Ocean; *Tetrodon*, *Diodon*, and *Balistes* have wider ranges. The typical genus of Pipe-Fishes (*Syngnathus*), is cosmopolitan, and has a very wide geographical distribution. Six species are found in the British seas, two on the coast of the United States, and Mr. Jenyns has described new forms from Valparaiso, Tahiti, and Patagonia. *Hippocampus* is of the temperate zones of both hemispheres, and in the tropical seas is replaced by *Solenostoma* and *Pegasus*. The Sturgeons inhabit the Western European seas, the Caspian, the Black Sea, and the Mediterranean. Three species are North American.

Of the Eels, *Anguilla*, *Conger*, and *Muræna* are typical and cosmopolitan. *Gymnarchus* is Egyptian, *Gymnotus* (the Electrical Eel) South American, both inhabitants of fresh-water. The osseous flat fishes are very generally distributed; the largest species are inhabitants of northern seas. The Mediterranean boasts of many species of *Pleuronectes*. Species of Sole are found in both northern and southern hemispheres. The *Gadidæ* are inhabitants of northern and temperate seas, and certain species, as the Tusk, do not range farther southward than Norway and Scotland. *Lepidosteus*, one of the few remaining genera of Sauroid fishes, which appear to have played a most important part in the waters of ancient geological epochs, is confined to the rivers of America, and some allied forms to northern Africa. The herring tribe, *Clupeidæ*, has a wide distribution, and forms of the typical genus *Clupea* are found in the southern as well as in the northern hemisphere. The species however are locally distributed; thus the true Herring is unknown in the Mediterranean, where its place is taken by the Sardine, and the herrings of the South American coasts are quite distinct from those of the north. Even within very limited areas, as in that of the British seas, the species have peculiarities of distribution, as we see in the prevalence of the herring, properly so called, on the coasts of Scotland and in the Irish Sea, while it is replaced by the Pilchard on the south-west coasts of England and south of Ireland: the Whitebait is also a remarkable instance of local distribution. *Mormyra*, *Exocœtus*, and *Esox* are the typical forms of pikes; the first is North African; the flying fishes are oceanic and Mediterranean, and the pikes proper are inhabitants of the temperate zones. The restricted genus *Esox* is confined to fresh water.

The important family of *Salmonidæ* has its most valuable members in northern regions, some with a wide range, the same species of trout occurring in Lapland and in Switzerland. In North America the Trouts are represented by very similar but distinct species. M'Clelland has described a true salmon from India inhabiting the tributaries of the Oxus. This instance however does not affect the essentially temperate and subarctic character of the distribution of the *Salmonidæ*, for this Indian species was found at an elevation of 11,000 feet, where we must expect to find temperate forms prevail. Jenyns has made known a peculiar genus of *Salmonidæ*, which he has named *Aplochiton*, inhabiting the seas of the Falkland Islands and Tierra del Fuego. *Bajore* is a genus constituted by De Kay, and confined to the United States. The Argentines are Mediterranean, and *Sternoptyx* is oceanic.

Among the most characteristic fishes of the fresh waters of tropical countries are the *Siluridæ*, which abound in the regions of Central Asia, where almost all the species of the typical genus *Silurus* occur. A single offset finds its way to Europe. *Pimelodus* and *Callichthys* are American genera of this family; the electrical *Malapterurus*, North African; *Loricaria*, South American. Equally interesting and well marked in distribution is the fresh-water family *Cyprinidæ*. The true Carps are characteristic of the Old World; *Catastoma* and *Anableps* of the New World.

Of the Acanthopterygious Fishes the genera *Centriscus* and *Fistularia* are, with the exception of a single Mediterranean species, tropical. The genera of *Labridæ* have well-marked provinces. Thus the numerous species of *Scarus* are grouped together in tropical seas, being replaced in temperate regions by *Labrus* and *Crenilabrus*. There are offsets however of each. The frog-fishes *Lophius* and *Chironectes* are chiefly represented in Africa and South America. A single *Lophius* is a native of European seas. De Kay enumerates seven *Lophiadæ* as inhabitants of the United States, and Richardson has described some Australian species. The Goby tribe prevails in Europe and Asia. Some of the species of *Gobius* are remarkable for the depth at which they live. The Blennies are truly European, with very few exceptions. The Gunnels are mostly of northern seas. Some species of the Goby tribe inhabit fresh water, as the genus *Tænioides*, which is found in marshes in India. *Comepturus* lives in Lake Baïkal, and one or two species of *Gobius* proper live in rivers.

The *Mugiloidæ* are very generally extended. They have been said to be absent from North America, but this is incorrect, four species of Mugil inhabiting the United States. *Atherina* is also a cosmopolitan genus.

The Labyrinthiform Pharyngeans are essentially tropical, being all natives of the eastern regions of Asia. Their organisation is peculiarly adapted to their climatal range. The *Teuthyes* are fishes of warm climates, and many species inhabit the Australasian seas. The Mackerel tribe includes a number of genera, which have very various areas of distribution. Among them the Dolphins (*Coryphæna*) are Mediterranean and oceanic; the Dories (*Zeus*) mostly European; *Vomer*, exotic; *Notacanthus*, arctic; *Lichia*, Mediterranean. *Scomber* and the allied typical genera of the tribe are mostly cosmopolitan. The Chetodons are essentially equatorial.

The family of *Sparoideæ* gives the most prominent feature to the ichthyology of the Mediterranean and seas of Southern Europe. *Pagrus* has a wide range, but chiefly through warm regions. The *Sciænoideæ*, very numerous in species, are mostly equatorial. The important family of *Triglidæ*, of which the Gurnard is the type, has a very extensive distribution. The true Gurnards are mostly European; *Scorpæna* ranges from Europe to Australia. *Platycephalus* is peculiarly Indian. *Sebastes* is a genus of the Old World, with one or two exceptions.

The *Percidæ*, chief of the Acanthopterygious families, is partly composed of marine and partly of fresh-water genera. The genus *Perca* is characteristic of the northern temperate zone. *Mesoprion*, *Diacope*, *Plectropomus*, and *Serranus* are cosmopolitan. *Mullus* and *Paralepis* are European genera. *Holocentris*, *Myripristis*, *Priacanthus*, and *Dules* are represented in both hemispheres. *Ambassis* is an Indian fresh-water genus. *Percophis*, *Pinguipes*, *Centrarchus*, and *Pomotis* are American. *Beryx*, *Trachichtes*, *Helotes*, *Pelotes*, and *Chironema* are Australian.

Fossil Fishes.—In the study of extinct fishes the structure of the scales is of first importance, and according to their particular characters the whole of the fossil species have been divided. M. Agassiz makes four orders, each of which contains fishes having a cartilaginous skeleton; in each there are genera the species of which have spinous rays in the dorsal fin, and other genera where all the rays of the dorsal fin are soft. There are likewise in each order both apodal and abdominal genera; and in two of the orders there are in addition certain species in which the ventral fins are thoracic, and others in which they are jugular. These four orders are named by M. Agassiz *Placoides*, *Ganoides*, *Ctenoides*, and *Cycloides*.

The name *Placoides* (from πλαξ, a plate or slab) was applied to the first of these orders on account of the irregularity which the solid tegumentary parts present. They consist of masses of enamel, which are often of considerable size, and sometimes minute. To this family belong the *Cestracionites*, of which there is but one existing genus (the genus *Cestracion*), the *Squalidæ*, *Raidæ*, and *Cyclostomi*.

The second order, *Ganoides* (from γανὸς, splendour), are distinguished by the angular form of the scales; these are composed of layers of corneous or osseous substances, disposed one upon the other and covered by a thick coat of enamel, and consequently resemble teeth in their structure. This order contains the following families:—*Lepidoides*, all the species of which are fossil; the *Sauroides*, which are also fossil, with the exception of two genera, *Lepisosteus* and *Polypterus;* the *Pycnodontes*, likewise fossil; the *Sclerodermi*, *Gymnodontes*, *Lophobranchii*, *Goniodontes*, *Siluridæ*, and *Sturiones*.

In the third order, *Ctenoides* (from κτένος, a comb), the scales consist of laminæ whose posterior and free margin is pectinated. A structure very evident in the Chætodons and Flat-Fishes (*Pleuronectidæ*), which M. Agassiz thinks ought to be placed close together. In this order are also arranged the *Percidæ*, *Polyacanthes*, *Sciænidæ*, *Sparidæ*, *Scorpænidæ*, and *Aulostomes*.

Order four, *Cycloides* (from κύκλος, a circle). The families which belong to this order have the scales formed of simple laminæ, with the posterior margin smooth. The scales of the lateral line are formed like the others, but instead of flat laminæ they consist of ducts placed one within the other, of which the retiring portion, which is applied against the disc of the scale, forms the tube through which flows the mucous secretion which covers the fish. This tube is sometimes bifurcate, or even ramified. The *Labridæ*, *Mugilidæ*, *Atherinæ*, *Scombridæ*, *Gadidæ*, *Gobiadæ*, *Murænidæ*, *Lucioides*, *Salmonidæ*, *Clupeidæ*, and *Cyprinidæ* belong to this tribe.

In his work entitled 'Recherches sur les Poissons Fossiles' M. Agassiz has employed this arrangement in his description of Fossil Fishes. At the request of the British Association for the Advancement of Science, M. Agassiz has drawn up a list of fishes occurring in the British strata, and we subjoin an abstract of this report. The geological classification is that developed in the articles PALÆOZOIC SERIES and SALIFEROUS SYSTEM.

TABLE I.—*General Distribution of the Orders of Fossil Fishes.*

	Placoid.	Ganoid.	Ctenoid.	Cycloid.
Cainozoic Strata	•	•	•	•
Mesozoic Strata	•	•	•	•
Palæozoic Strata	•	•		

Hence it appears that the two orders of Ctenoid and Cycloid Fishes, which are the most abundant in existing nature, have no representatives yet discovered in the Palæozoic Strata.

If we divide the two groups of Mesozoic and Palæozoic Strata into their constituent parts we shall have additional results.

TABLE II.—*Distribution of the Orders of Fossil Fishes in Mesozoic and Palæozoic Strata.*

	Placoid.	Ganoid.	Ctenoid.	Cycloid.
MESOZOIC:				
Upper	•	•	•	•
Middle	•	•		
Lower	•	•		
PALÆOZOIC:				
Upper	•	•		
Middle	•	•		
Lower	•			

Hence it would appear that the Placoid Fishes (*Onchus*, &c.) are, geologically speaking, the most ancient of the finny races; that the Ganoid Fishes, *Holoptychius*, &c., begin in the middle Palæozoic series, and the Ctenoid and Cycloid only in the upper Mesozoic (Cretaceous) group. It is however very possible that this last statement may be modified by further research in the Oolites. At present the distribution of Ctenoid and Cycloid Fishes in the Chalk is thought to favour the notion of the almost Cainozoic character of that deposit.

In the next four tables (Tables III., IV., V., and VI.) we give the geological distribution of the several families (some are merely provisional) under which M. Agassiz has ranged the British Fossil Placoid Fishes.

TABLE III.—*Distribution of the Families of Placoid Fishes.*

	Ichthyodorulites.	Cestraciontes.	Hybodontes.	Squalides.	Raies.	Chimerides.	
CAINOZOIC:							
Upper . .	•	—	—	•	•	—	
Middle . .	—	—	—	—	—	—	
Lower . .	•	—	—	•	•	•	Period of greatest abundance.
MESOZOIC:							
Upper . . .	•	•	—	•	—	•	
Middle . .	•	•	•	•	•	•	
Lower . .	•	—	—	—	—	—	
PALÆOZOIC:							
Upper . .	•	•	•	•	—	—	
Middle . .	•	•	—	—	—	—	
Lower . .	•	—	—	—	—	—	

Hence the most prolific periods for Placoid Fishes seem to be the upper Palæozoic, the middle and upper Mesozoic, and the lower Cainozoic strata.

TABLE IV.—*Distribution of the Families of Ganoid Fishes.*

	Lepidioides.	Sauroides.	Cœlacanthes.	Pycnodontes.	Acipenserides.	Sclerodermes.	
CAINOZOIC:							
Upper . .	—	—	—	—	—	—	
Middle . .	—	—	—	—	—	—	
Lower . .	—	—	—	•	•	—	
MESOZOIC:							
Upper . .	•	•	•	•	—	•	Period of abundance.
Middle . .	•	•	•	•	•	—	
Lower . .	•	•					
PALÆOZOIC:							
Upper . .	•	•	•	—	—	—	
Middle . .	•	•	•	—	—	—	
Lower . .	—	—	—	—	—	—	

The Ganoid Fishes (singular forms however) begin to abound in the middle Palæozoic series, and become rare above the lower Cainozoic series. They are also rare in existing nature. M. Agassiz once included the *Glyptocephalus* of Sheppey among the Ganoids, but in his later catalogue he has joined it to the Cycloids.

TABLE V.—*Distribution of the Families of Ctenoid Fishes.*

	Percoides.	Sparoides.	Teuthies.	Chetodontes.
CAINOZOIC:				
Upper	—	—	—	•
Middle	—	—	—	—
Lower	•	•	•	—
MESOZOIC:				
Upper	•	—	—	—
Middle	—	—	—	—
Lower	—	—	—	—
PALÆOZOIC:				
Upper	—	—	—	—
Middle	—	—	—	—
Lower	—	—	—	—

The account of the Ctenoid Fishes in the lower Cainozoic Strata is from the report of M. Agassiz to the British Association in 1844.

TABLE VI.—*Distribution of the Families of Cycloid Fishes.*

	Acanthopterygians.					Malacopterygians.						
	Scomberoides.	Xiphioides.	Sphyrænoides.	Labroides.	Blennioid	Scomberesoces.	Clupeides.	Characins.	Gadoides.	Anguilliformes.	Doubtful.	Undetermined.
CAINOZOIC:												
Upper . .	—	—	—	—	—	—	—	—	—	—	—	—

To complete this view of the geological distribution of Fossil Fishes we append an abstract of the catalogues of M. Agassiz, which have been already referred to.

Silurian System.

PLACOID FISHES.

Ichthyodorulites.

Onchus, 2 species.

Family unknown.

Thelodus, 1 species.
Sclerodus, 1 species.
Plectrodus, 2 species.
Sphagodus, 1 species.
Pterygotus, 1 species. (This is probably a Crustacean.)

Devonian System.

PLACOID FISHES.

Ichthyodorulites.

Onchus, 2 species.
Parexus, 1 species.
Ctenacanthus, 1 species.
Ptychacanthus, 1 specie
Clematius, 1 species

Cestraciontes.

Ctenoptychius, 1 species.

GANOID FISHES.

Lepidoides.

Dipterus, 1 species.
Osteolepis, 4 species.
Acanthodes, 1 species.
Diplacanthus, 4 species.
Cheiracanthus, 3 species.
Cheirolepis, 3 species.
Cephalaspis, 4 species.
Pterichthys, 8 species.
Coccosteus, 3 species.
Chelonichthys, 2 species.

Sauroides.

Diplopterus, 3 species.
Platygnathus, 3 species.
Dendrodus, 3 species.
Lamnodus, 2 species.
Cricodus, 1 species.
Megalichthys, 1 species.

Cœlacanthes.

Holoptychius, 5 species.
Glyptosteus, 2 species.
Phyllolepis, 1 species.
Glyptolepis, 2 species.

Carboniferous System.

PLACOID FISHES.

Ichthyodorulites.

Onchus, 6 species.
Ctenacanthus, 6 species.
Ptychacanthus, 1 species.
Sphenacanthus, 1 species.
Asteroptychius, 2 species.
Physonemus, 1 species.
Gyracanthus, 4 species.
Oracanthus, 4 species.
Leptacanthus, 2 species.
Tristychius, 1 species.
Cladacanthus, 1 species.
Cricacanthus, 1 species.
Orthacanthus, 1 species.
Pleuracanthus, 3 species.

Cestraciontes.

Orodus, 2 species.
Helodus, 9 species.
Chomatodus, 3 species.

GANOID FISHES.

Lepidoides.

Acanthodes, 1 species.
Amblypterus, 3 species.
Palæoniscus, 6 species.
Eurynotus, 2 species.
Platysomus, 1 species.
Plectrolepis, 1 species.

Sauroides.

Megalichthys, 2 species.
Diplopterus, 2 species.
Pygopterus, 3 species.
Acrolepis, 1 species.
Orognathus, 1 species.
Graptolepis, 1 species.
Pododus, 1 species.

Cœlacanthes.

Cœlacanthus, 2 species.
Holoptychius, 8 species.
Hoplopygus, 1 species.
Uronemus, 1 species.
Phyllolepis, 1 species.

Permian System.

PLACOID FISHES.

Ichthyodorulites.

Gyropristis, 1 species.

GANOID FISHES.

Lepidoides.

Palæoniscus, 5 species.
Platysomus, 3 species.

Sauroides.

Acrolepis, 1 species.
Pygopterus, 2 species.

Cœlacanthes.

Cœlacanthus, 1 species.

Triassic System.

PLACOID FISHES.

Ichthyodorulites.

Hybodus, 1 species.
Nemacanthus, 2 species.
Leiacanthus, 1 species.

Cestraciontes.

Acrodus, 1 species.
Ceratodus, 10 species.

Hybodontes.

Hybodus, 1 species.

GANOID FISHES.

Lepidoides.

Gyrolepis, 3 species.
Palæoniscus, 1 species.

Sauroides.

Saurichthys, 3 species.
(N.B. Agassiz includes the Bone-bed at the base of the Lias in the Triassic System.)

Oolitic System.

PLACOID FISHES.

Ichthyodorulites.

Leptacanthus, 3 species.
Nemacanthus, 1 species.
Myriacanthus, 3 species.
Asteracanthus, 5 species.
Hybodus, 13 species.
Pristacanthus, 1 species.
Cochliodus, 5 species.
Psammodus, 4 species.
Pœcilodus, 6 species.
Pleurodus, 2 species.
Ctenoptychius, 8 species.
Ctenodus, 3 species.
Petalodus, 8 species.

Hybodontes.

Cladodus, 8 species.
Diplodus, 2 species.

Squalides.

Carcharopsis, 1 species.
Cyclarthrus, 1 species.
Squaloraia, 1 species.

Chimerides.

Chimæra, 11 species. (This includes several generic groups of Egerton.)

GANOID FISHES.

Lepidoides.

Dapedius, 7 species.
Tetragonolepis, 14 species.
Centrolepis, 1 species.
Amblyurus, 1 species.
Semionotus, 1 species.
Lepidotus, 13 species.
Pholidophorus, 12 species.
Nothosomus, 1 species.
Ophiopsis, 2 species.

Sauroides.

Eugnathus, 13 species.
Ptycholepis, 1 species.
Conodus, 1 species.
Pachycormus, 9 species.
Caturus, 3 species.
Thrissonotus, 1 species.
Amblysemius, 1 species.
Sauropsis, 2 species.
Leptolepis, 4 species.
Saurostomus, 1 species.
Aspidorhynchus, 2 species.
Belonostomus, 3 species.
Macrosemius, 1 species.

Cœlacanthes.

Ctenolepis, 1 species.
Gyrosteus, 1 species.

Pycnodontes.

Gyrodus, 6 species.
Sphærodus, 3 species.
Gyronchus, 1 species.
Microdon, 2 species.
Periodus, 1 species.
Pycnodus, 13 species.

Acipenserides.

Chondrosteus, 1 species.

Cretaceous System.

PLACOID FISHES.

Ichthyodorulites.

Ptychodus, 5 species.
Hybodus, 1 species.
Chimæra, 1 species.
Spinax, 1 species.

Cestraciontes.

Ptychodus, 5 species.
Acrodus, 1 species.
Strophodus, 2 species.

Squalides.

Scylliodus, 1 species.
Notidanus, 2 species.
Corax, 1 species.
Otodus, 1 species.
Oxyrhina, 1 species.
Lamna, 3 species.

Chimerides.

Chimæra, 5 species.

GANOID FISHES.

Lepidoides.

Lepidotus, 1 species.

Sauroides.

Caturus, 1 species.

Cœlacanthes.

Macropoma, 2 species.

Pycnodontes.

Acrotemnus, 1 species.
Gyrodus, 4 species.
Pycnodus, 5 species.
Sphærodus, 1 species.

Sclerodermes.

Dercetis, 1 species.

Cestraciontes.

Acrodus, 8 species.
Ceratodus, 1 species.
Strophodus, 6 species.

Hybodontes.

Hybodus, 10 species.
Sphenonchus, 3 species.

Squalides.

Thyellina, 1 species.
Oxyrhina, 1 species.

Raies.

Arthropterus, 1 species.

CTENOID FISHES.

Percoides.

Beryx, 3 species.

CYCLOID FISHES.

Hypsodon, 1 species.
Enchodus, 1 species.
Saurocephalus, 2 species.
Saurodon, 1 species.
Tetrapterus, 1 species.
Acrognathus, 1 species.
Aulolepis, 1 species.
Osmeroides, 2 species.

Tertiary System.

PLACOID FISHES.

Raies.

Myliobates, 16 species.
Zygobates, 1 species (Crag.).
Aetobates, 2 species.
Pristis, 3 species.
Raia, 1 species.

Squalides.

Notidanus, 1 species.
Glyphis, 1 species.
Carcharodon, 2 species.
Otodus, 2 species.
Lamna, 1 species (Crag.).

Chimerides.

Elasmodus, 1 species.
Edaphodon, 3 species.
Passalodon, 1 species.
Psaliodus, 1 species.

GANOID FISHES.

Pycnodontes.

Pycnodus, 1 species.
Periodus, 1 species.
Gyrodus, 1 species.
Phyllodus, 6 species.
Pisodus, 1 species.

Acipenserides.

Acipenser, 1 species.

CTENOID FISHES.

Percoides.

Myripristis, 1 species.
Cœloperca, 1 species.
Eurygnathus, 1 species.
Podocephalus, 1 species.
Synophrys, 1 species.
Brachygnathus, 1 species.
Percostoma, 1 species.

Sparoides.

Sciænurus, 2 species.

Teuthies.

Ptychocephalus, 1 species.
Pomaphractus, 1 species.
Calopomus, 1 species.

CYCLOID (ACANTHOPTERYGIOUS) FISHES.

Scomberoides.

Cybium, 1 species.
Cœlopoma, 2 species.
Bothrosteus, 3 species.
Phalacrus, 1 species.
Rhonchus, 1 species.
Echenus, 1 species.
Scombrinus, 1 species.
Cœlocephalus, 1 species.
Naupygus, 1 species.

Xiphioides.

Tetrapterus, 1 species.
Cœlorhynchus, 2 species.
Phasganus, 1 species.
Acestrus, 1 species.

Sphyrænoides.

Sphyrænodus, 2 species.

Labroides.

Auchenilabrus, 1 species.

Blennioides.

Laparus, 1 species.

CYCLOID (MALACOPTERYGIOUS) FISHES.

Scomberesoces.

Hypsodon, 2 species.
Labrophagus, 1 species.

Clupeides.

Halecopsis, 1 species.
Megalops, 1 species.

Characins.

Brychetus, 1 species.

Gadoides.

Rhinocephalus, 1 species.
Merlinus, 1 species.
Ampheristus, 1 species.
Goniognathus, 1 species.

Anguilliformes.

Rhynchorhinus, 1 species.

(Doubtful Family.)

Pachycephalus, 1 species.
Rhipidolepis, 1 species.
Glyptocephalus, 1 species.
Gadopsis, 1 species.
Loxostomus, 1 species.

Note.—In the preceding Lists the French titles of the families are retained, as given by Agassiz.

The following description of some of these fishes, from Professor Ansted's picturesque 'Sketches of Creation,' will give the general reader an idea of the forms assumed by some of the extinct fishes of our own Island:—

"The tribe of existing Placoid Fishes most resembling those whose remains are found fossil, is that of which the Sharks are the well-known representatives. These powerful and rapacious animals, which are at this day the tyrants of the deep, seem to have been, when first introduced, of small size, and were accompanied by some few species of the next or Ganoid order. Only nine species of these Shark-like monsters have yet been determined with certainty from the Silurian and Devonian rocks, and of these two only are from the former. It is chiefly the Ganoid Fishes whose remains are handed down to us in the Old Red-Sandstone and other rocks of that period. Sixty distinct species of these fishes have been mentioned; and almost all of them are known from British specimens. Most of them are remarkable for exhibiting strange peculiarities of shape, approximating them in some instances to the structure of the lower orders of animals, combined with some apparent affinities to the class of reptiles. The most remarkable group of these fishes contains several genera, three of which will require special notice: they are the *Cephalaspis*, or Buckler-Headed; the *Pterichthys*, or Wing-Fish; and the *Coccosteus*, so called from the berry-like tubercles with which its bony scales are covered.

"The most extraordinary part of the first of these fishes, the Buckler-Headed, is the head, from which its name is taken. This has been compared to the crescent-shaped blade of a saddler's cutting-knife, the body forming the handle. It is extremely broad and flat, extending on each side considerably beyond the body, and the bones appear to have been firmly soldered together, so as to form one shield, the whole head being thus apparently covered by a single plate of enamelled bone, and when seen detached from the body, hardly to be distinguished from the head of a trilobite. The body, compared with this singular head, appears extremely diminutive; the back is arched, and gradually recedes in elevation towards the tail, which is of moderate length; the fins are few in number, and not very powerful, but appear to have possessed a bony ray in front, the rest of the fin being more fibrous. The whole body was covered with scales, which varied in shape in different parts, and seem to have been disposed in series. This fish never seems to have attained a large size, the best preserved specimen having only a length of seven inches, with a breadth of three inches between the points of the crescent-shaped buckler. It has been supposed by Professor Agassiz that the singular shape of the head served as a defence to this animal in case of attack; and one can readily imagine that the soft substance of the Orthoceratites, probably the largest and most formidable of its enemies, would be injured by any attempt to swallow so singular and knife-like an animal as the one before us. Like many and indeed most of the species belonging to the Ganoid order of fishes, and common in the older rocks, the bones of the head and the scales of this strange monster were composed internally of a comparatively soft bone, but each was coated with a thick and solid plate of enamel of extreme hardness, and almost incapable of injury by any ordinary amount of violence. The detached scales, the buckler head, and sometimes the complete outline of the animal have thus been able to resist destruction, and are found in sandy rocks composed of such coarse fragments that their accumulation would seem to have been accompanied with violence sufficient to have crushed to powder almost any remains of organised matter, and from which indeed we never obtain any fragments of shells or other easily-injured substances. The remains of this fish have been found in Herefordshire and many parts of Wales, as well as in Scotland, and lately also in Russia; but the animal was strictly confined to the period of the Old Red-Sandstone, though it is not easy to guess what may have been its habits, in what depth of water it preferred to live, or in what way it obtained its food.

"The *Pterichthys* is even more strikingly different from any existing species of animal than the singular monster we have just been describing. Reverting to the graphic description of Mr. Miller, we find it compared to the figure of a man rudely drawn, the head cut off by the shoulders; the arms spread out at full length as in the attitude of swimming; the body rather long than otherwise, and narrowing from the chest downwards; one of the legs cut away at the hip-joint, and the other, as if to preserve the balance, placed directly under the centre of the figure, which it seems to support. Something of this appearance is indeed presented in the fossil remains of these creatures, once the tenants of the sea in our own latitude; but we are now able to describe with more minuteness, if not so vividly, the real nature of the animal. It was of small size, not more than a few inches or a foot in length; its head and body were defended by strong plates of bone, coated with enamel; and its shape and proportions were singularly unlike those of ordinary fishes, the head being small, and the body much flattened but swelling out immediately at the junction of the head and neck, and gradually tapering thence towards the tail. From the junction of the head and body there extended that pair of singular paddles, or wings, from which the genus has been named, and which have been supposed to answer the same purpose as the horns of the crescent-shaped shield of the *Cephalaspis*, and to defend the animal from the attacks of its soft-mouthed enemies. Besides those paddles, which were hard and pointed, and nearly as long as the body, at least some species of *Pterichthys* seem to have been provided with another smaller pair extending from the part where the body is attached to the tail; and it is thought that this second pair of wings may be the remains of anal fins, the other pair representing the pectoral fins. The body, like the head, was certainly covered on the upper side by hard plates, accurately fitting one another, but the lower part both of the head and body was probably defended by tough skin, capable of distension, and enabling the creature to swallow prey of large size. The position of the mouth is not known with certainty, but it may have been formed by a transverse slit, covered by thick fleshy lips, situated round the edge of the plate which defended the head; this position, and the absence of teeth, readily accounting for the difficulty there is in discovering remains of it in imperfect specimens. The eyes and the apertures of the nostrils were probably extremely small, and placed on the edge of the broad plate, the only indication of the head hitherto met with. The tail was not long, but seems to have been thick and conical, and covered with scales overlapping each other like the tiles on the roof of a house.

"The departure from the general form of most fishes in this animal is so remarkable, that, when first discovered, it was looked upon by some naturalists as an insect, by others as a crustacean, and by others again it was thought to be connected with reptiles, owing to the singular resemblance of one small species to the shell of a tortoise. Strange as it undoubtedly is however in all respects, this genus forms one of an extinct family of fishes, and it is allied to the other genera of its class by the genus *Coccosteus*, which at one time was thought still more anomalous. The *Coccosteus* is entirely without the wing-like projections which characterise the *Pterichthys*, and while when seen, as in ordinary specimens, lying on its back and crushed, it appears to bear no resemblance to any fish or other animal, either recent or extinct; it was not in reality much unlike many well-known fishes in its general outline, although so oddly coated with large broad plates, which were studded with enamel instead of scales.

"The head of the *Coccosteus* was large, broad, and high, nearly circular in shape, covered by several plates, and attached to the body by a very small articulating surface, resembling in this the insects, and departing widely from the fishes. The jaws are large in proportion, and armed with very strong pointed teeth; the mouth opened as in the cod and other well-known fishes, and no doubt rendered the animal sufficiently formidable; and the lower part of the head seems to have been covered with a tough membrane capable of distension, and enabling the animal to swallow very large bodies; the upper part of the body was chiefly covered by one large plate, and the lower part by four plates of rather curious shape. The tail was large, and much longer than the body, and was provided with two small fins. The detached plates, more especially those which covered the body, are frequently found fossil in certain localities of the Old Red-Sandstone. The fishes just described form together one of several groups characteristic of the period we are now considering. But another group also, containing four genera, is worthy of notice, as contrasting strongly with the *Cephalaspides* (as the former are called), and instead of being clothed with large plates, these are recognised by the extremely minute scales with which the fish belonging to it are covered. These scales give to the skin an appearance very strikingly resembling shagreen.

"The size of the fishes thus brought together is generally small, and their shape is squat and awkward, the head being large, and the body dwindling away to a very small tail. They have however large teeth, and must have been powerful if not very rapid fishes. Their fins offer some peculiarities, being formed of a multitude of delicate-jointed rays, generally terminated by one very powerful ray or spine, sometimes simply planted in the flesh, sometimes articulated to bone. Both this group and the former are entirely confined to the first epoch, and almost entirely to the particular period of the Old Red-Sandstone.

"Another group of these ancient fishes (Dipterians) is remarkable for the great magnitude to which the fins were developed, and the fact that in all of them the fins on the back and below the tail are double. The jaws of these animals were provided with sharp pointed teeth; the head inclosed as if in a box of cartilage coated with enamel, and the scales of the body are in some species so large as not to have required more than half a dozen to reach from head to tail. This however was by no means a general character; and the presence of prominent spines supporting and defending the fins is probably more essential. It is probable that almost, if not all, the fishes of this family of Dipterians were more rapid swimmers and more voracious than those of the former two families. They are all however of small size. Besides these there is another family, chiefly developed in the latter part of the period, and attaining a larger size. One of the members of this group has been named *Holoptychius*, and is confined to the Devonian period. Its head was small compared with the size of the body, whose proportions were so robust, and its covering of large, rounded, deeply-wrinkled scales, on so grand a scale as almost to deserve being called gigantic. The actual measurement of the body in one complete specimen is 30 inches by upwards of 12 inches. The jaws were of bone coated with naked enamel; a row of thickly-set pointed teeth fringed the lips, and within this row another, whose bulk was at least twenty times as great. The other genus, *Megalichthys*, was perhaps more strikingly characteristic of the next succeeding period, during which the Carboniferous Limestone and Coal were being deposited; and it may therefore be as well to postpone for the present any description of it."

(Owen, *Lectures on Comparative Anatomy*, vol. ii.; Yarrell, *British Fishes;* Agassiz, *Recherches sur les Poissons Fossiles;* Agassiz, *Report on the Fossil Fish of the Devonian System; Transactions of British Association*, 1842; Richardson, *Report on the present State of the Ichthyology of New Zealand*, ib.; Agassiz, *Synoptical Table of British Fossil Fishes*, ib. 1843; Agassiz, *Sur les Poissons Fossiles de l'Argile de Londres*, ib. 1844.)

FISH-LICE. [CALIGUS.]

FISHES, FOSSIL. [FISH.]

FISHING-FROG. [LOPHIUS.]

FISSIROSTRES, the Swallow Tribe of Birds, distinguished by a very broad bill with a very wide gape, and small and feeble feet. They belong to the order *Insessores*, or Perchers, and take their food on the wing. [HIRUNDINIDÆ; INSESSORES.]

FISSURELLIDÆ, a family of Prosobranchiate Gasteropodous *Mollusca*. This family constitutes a very natural transition from the Limpets [PATELLIDÆ], to the completely spiral univalve shells. All the species of this family are remarkable for some solution of continuity in the shell, either a perforation or a slit in the region of the vent. The form of their shells is more or less conical, with indications of a rudimentary spire at the apex, which often disappears with increasing age. The animals have well-developed heads, with short muzzles and subulate tentacles, at the external bases of which are the eyes placed on rudimentary pedicles.

This family embraces the genera *Fissurella, Emarginula, Puncturella, Parmophorus*, and *Rimula*.

The *Fissurellæ*, which Cuvier places among the Scutibranches, his seventh order of Gasteropods, have a large fleshy disc or foot beneath the belly, like the *Patellæ*, and a conical shell fixed upon the middle of the back, but not always entirely covering it, for this shell is pierced at its summit with a small aperture, generally oval, which, according to Cuvier, serves at the same time as a passage for the water necessary to respiration and as an outlet for the excrements. This aperture penetrates into the cavity of the branchiæ situated on the fore part of the back, and in the bottom of which the vent discharges itself. This cavity is, besides, widely opened above the head. There is on each side, symmetrically disposed, a pectinated branchia or gill. The tentacula are conical, at the external bases of which the eyes are situated. The sides of the foot are fringed with filaments. Dr. Gray says, "In the young state of the *Fissurellæ*, the hole by which the fæces pass out of the shell is placed a little in front of its recurved and spiral apex; in this state it has been formed into a genus under the names of *Rimula* and *Puncturella*. But as the animal grows, the hole enlarges in size backwards, and the true apex being absorbed, the hole appears in the adult shell to be placed on the tip, and in some species even to extend behind it."

The muscular impression is in the form of a horse-shoe, with the opening in front.

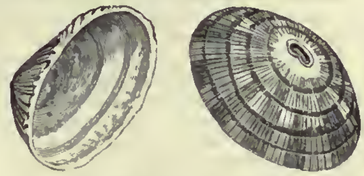
Animal of *Fissurella*.

Shell of *Fissurella*.

De Blainville thus arranges the genus:—

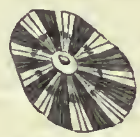
α. Species which have the middle part of the borders of the opening excavated as it were, so that when placed upon a flat surface, they only touch it at their extremities. Ex. *Fissurella nimbosa*.

Deshayes observes that the synonymy of this species has been very faulty from the time of Linnæus downwards; and he remarks that three species are confounded under *Patella nimbosa* in the 12th edition of the 'Systema Naturæ.' Deshayes adds that the species was named in Lamarck's collection, and that he has seen it, and therefore knows what Lamarck meant by his *Fissurella nimbosa*. The figure from which our cut is taken, that of Martini I. t. xi. f. 91-92, is one of those references which Deshayes would leave untouched as indicating the species.



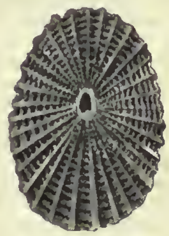
Fissurella nimbosa.

β. Species more depressed, &c., so that when placed upon a flat surface, the extremities are raised, forming a kind of canal. Ex. *Fissurella rosea*. Locality, Guyana, &c.



Fissurella rosea.

γ. Conical species with horizontal borders. Ex. *Fissurella Græca*. Locality, Mediterranean and Atlantic.



Fissurella Græca.

The distribution and habits of the *Fissurellidæ* are the same as those of *Patella*. Like that genus, *Fissurella* is littoral, and has been found at depths ranging from the surface to 25 fathoms.

The following species are described as British by Messrs. Forbes and Hanley: *Fissurella reticulata, Puncturella Noachina, Emarginula reticulata, E. rosea, E. crassa*.

Genera, *Emarginula* and *Parmophorus*.—Cuvier observes that the *Emarginulæ* have exactly the same structure as the *Fissurellæ*, with this exception, that the former, instead of the aperture at the apex of the shell, have in their mantle and shell a small slit or notch at their anterior border, which opens into the branchial cavity. The borders of the mantle envelop and cover a great portion of those of the shell.

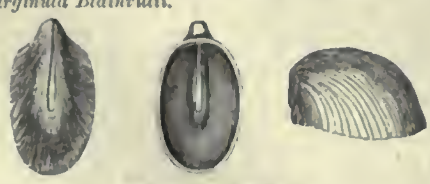
The eyes are situated upon a tubercle at the external bases of the conical tentacula. The edges of the foot are furnished with a row of filaments. G. B. Sowerby observes that "the animal of the *Fissurella* is very nearly related to that of *Emarginula*, as the shell is to the *Emarginula* itself; the fissure in the anterior margin of the latter serving for the same purposes as the perforation in the vertex of the former. One difference however is peculiarly observable, which is that in *Emarginula* the vertex is directed posteriorly, contrariwise to that of *Fissurella;* for Lamarck is mistaken in speaking of the notch or fissure in the edge of *Emarginula* as posterior." Of *Parmophorus* Cuvier says that, like the *Emarginulæ*, its shell is covered for a considerable portion by the turned-up edges of the mantle; this shell he describes as oblong, slightly conical, and without hole or notch. The branchiæ and the rest of the organs are the same as they are in the two preceding genera. G. B. Sowerby thus writes upon this point ('Genera of Shells'):—"*Emarginula* is more nearly related to *Fissurella* than to *Patella*, inasmuch as its branchiæ are not external, and the little fissure or notch in the anterior edge is only the termination of a narrow canal, that serves the same purpose in this shell as the perforation in the summit of *Fissurella*. It is observable that Lamarck has placed *Emarginula* next to *Parmophorus*, without seeming to have remarked the very great resemblance of the animals to each other; we have thought ourselves justified, both by the characters of the shells and of the animals, in uniting them; this may be objected to perhaps on account of the great difference in general form; but we answer that there are some species of Lamarckian *Emarginulæ*, one of which we have figured, which approach very nearly to Blainville's *Parmophorus* in shape. Another objection may raise from the apparent want of the anterior fissure in *Parmophorus* but it will be seen that the anterior edge of the shell is always somewhat emarginate, while in the situation of the branchiæ, the anterior fissure in the mantle of the animal, and in the position of the vertex in the shell, they exactly resemble each other; we therefore consider the *Parmophori* of Blainville and Lamarck as elongated and compressed *Emarginulæ*." Deshayes, in his edition of Lamarck (1836), thus expresses his opinion :—"Cuvier was the first who gave anatomical details of the genus *Emarginula*, and he made it appear how much analogy existed between it and *Fissurella*. There exists, nevertheless, between these two genera sufficient differences to warrant their continuance in systematic arrangement. But it is not so with regard to *Parmophorus*. M. de Blainville, to whom we owe this last genus, and who was the first to make the animal known, had judiciously preconceived the necessity of its junction with *Emarginula*. In fact, not only have the animals of the two genera a perfect analogy, and not only can they be with difficulty distinguished in some cases and in some species, but the shells themselves, as might have been supposed à priori, offer some passages from the one genus to the other, the number of which will be augmented by new researches. When we have before us a fairly complete series of living and fossil species belonging to the two genera the following observations occur :—The two fossil species of *Parmophorus* have no trace of a marginal notch; *Parmophorus Australis* has the anterior border a little depressed in the middle, and within the shell is to be seen, corresponding with this depression, a small crest indicating the separation of the mantle. Among the species of *Emarginulæ* brought home by Messrs. Quoy and Gaimard there is one which they name *Parmophoïda*, and which would seem to be entirely deprived of a marginal notch. In the *Subemarginulæ* of M. de Blainville the shells have no longer this notch, but they have within a deep ridge (sillon) in the place of it. In other species, as in *Emarginula rubra* of Lamarck and *E. elegans* of M. Defrance, the small interior ridge is terminated on the border by a very short notch; and from this commencement to the termination of the series of species we see this notch become deeper and deeper, and change at last into a deep slit occupying one half of the height of the shell." After dwelling upon the differences of the shells in other points of external form, M. Deshayes observes that the general aspect of the shells leads the zoologist to separate the genera, while the structure of the animals tends to fuse them into one, and thus concludes :—"M. Sowerby has come, as we have before said, to this conclusion, and in his 'Genera of Shells' has united the *Parmophori* to the *Emarginulæ*. This example will without doubt be followed by other zoologists."

We entirely agree in this conclusion, and consider the following arrangement of *Emarginulæ* by De Blainville as merely arbitrary, and calculated to assist the conchologist and fossil zoologist in his subdivision of this molluscous form.

Animal of *Emarginula*.

Shell of *Emarginula* (*E. conica*).

α. Species whose notch is in the middle of the back of the shell, and far from reaching the edge. (*Rimula?* or *Rimulaire?* of Defrance.) Ex. *Emarginula Blainvillii*.



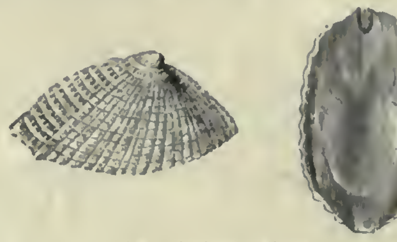
Emarginula Blainvillii.

β. Compressed species, whose anterior border is deeply notched, and the summit strongly marked. (Les Entailles.) Ex. *Emarginula fissura*.

γ. Species still more compressed, whose anterior border is only bent into a gutter, and whose summit is still evident. (*Subemarginulæ*.) Ex. *Emarginula emarginata*.

Emarginula fissura.

a, natural size; *b*, magnified; *c*, magnified, the shell turned up, showing the animal in situ.



Emarginula emarginata.

δ. Species very much depressed; the summit very little developed and præmedian, with a small notch. Ex. *Emarginula depressa*.

Emarginula depressa.

Parmophorus (*Scutum* of De Montfort).—Ex. *P. Australis*, syn. *elongatus* (*Patella ambigua*, Linn.)

Localities, seas of Australia and New Zealand.

Parmophorus Australis.

Emarginula and *Parmophorus* are littoral shells like *Patella*, and their habits are similar to those of the last-named genus. *Emarginula* has been found at depths ranging from the surface to 11 fathoms.

Fossil Fissurellidæ.—G. B. Sowerby says that a few fossil species are found in the truly marine formations above the Chalk. Deshayes, in his Tables, enumerates 33 living species and 8 fossil (tertiary). Of these, *F. Græca*, *F. costaria*, and *F. neglecta*, he states to be both living (the two former in the European and Indian oceans, and the latter in the Mediterranean) and fossil, in the pliocene (all three) and miocene (the two latter) periods of Lyell (Sicily, Italy in the sub-Apennine beds, English Crag, and Touraine). He mentions three Sicilian species, three Italian (sub-Apennine beds), one in the English Crag, two at Dax, two in Touraine, two at Angers, and four at Paris. The *Fissurella Noachina* of Deshayes, *Patella Noachina* of Lyell, is living in the northern seas, and found fossil in Sweden and Norway. It appears to be between a *Fissurella* and an *Emarginula*, and it is not impossible that it may be a *Fissurella* in a young state.

G. B. Sowerby ('Genera of Recent and Fossil Shells') observes that the fossil *Emarginulæ* are scarce. "They occur," adds that author, "in the calcaire grossier and its contemporary strata; in the crag of Suffolk, Essex, and Norfolk; and in the Bath oolite. They are very elegant little fossils, particularly Lamarck's *E. clypeata*. We cannot consider his *P. elongatus* as a species of this genus, for its vertex is anterior, as its muscular impression demonstrates; consequently we find in it no mark of a canal at either end; it must therefore be classed with *Patella*."

Deshayes, in his Tables, gives 7 living species of *Emarginula*, and 11 fossil (tertiary), one, *E. fissura*, an inhabitant of the European and

Mediterranean seas, fossil in the Crag at Bordeaux and Dax, and at Paris (Pliocene, Miocene, and Eocene periods of Lyell). De la Bèche enumerates two in the Blue Marls of the south of France, namely, one closely approaching *E. fissura* of Lamarck and *E. reticulata* of Sowerby. In the Cretaceous group he gives two, *E. Sanctæ Catherinæ* and *E. pelagica*, both from Rouen. In the Oolitic group he records one species, *E. scalaris*, Sowerby, from the great oolite at Ancliff, Wilts. Deshayes, in his edition of Lamarck (1836), enumerates 11 living species, and 5 found only in the fossil state, namely *E. costata* and *E. clypeata*, Lamarck, from Grignon; *E. radiola*, Lamarck, from Parnes; and *E. elegans* and *E. clathrata*, Deshayes, the first from Paris and Valognes, and the other, a rare species, from Parnes.

Deshayes, in his Tables, gives 2 living and 2 fossil species of *Parmophorus* (tertiary), one from Touraine (Miocene period of Lyell); and he enumerates 2 from the Crag, 3 from Touraine, 3 from Angers, 5 from Paris, and 2 from Valognes. In his edition of Lamarck he notes 2 species only as fossil, one, *P. elongatus*, Lamarck, with a variety, from Grignon, and the other, *P. angustus*, Deshayes, from Paris.

Woodward in his 'Manual of the Mollusca,' gives the following numbers of the fossil species of *Fissurellidæ*:—

Fissurella, 25 species. Great Britain and France.

Puncturella, 2 species. In the Glacial Formations of North Britain.

Emarginula, 40 species. Triassic, Britain and France.

Parmophorus, 3 species. Paris Basin.

FISTULA'RIA, a genus of Acanthopterygious Fishes, remarkable for the extreme elongation of the anterior part of the head, forming a tube, at the extremity of which is the mouth. The *Fistularia tabacaria* of the Antilles is the type. It lives on little fishes and *Crustacea*, which it draws out from the interstices of stones and holes in rocks by means of its long trunk or beak. Two other species are known, the *F. serrata* and the *F. immaculata*. They are all small fishes, not reaching two feet in length, slender, and eel-shaped.

FLABELLA'RIA, a genus of Fossil Plants. *F. borassifolia* is found in the Coal Formation. (Sternberg.)

FLACOURTIA, the type of the order *Flacourtiaceæ*, was named in honour of Etienne de Flacourt, a director of the French East India Company, and the commander of an expedition to Madagascar in 1648, of which he gave an account. This genus is diœcious; the staminiferous flowers have their stamens densely crowded, a hemispherical receptacle, and are glandless at the base; the pistilliferous flowers have the calyx 4-5-cleft, deciduous; the stigmas 4-9, each furnished with a longitudinal furrow above; the seeds long. The species are thorny shrubs, with whitish sepals and yellow stamens.

F. Ramontchi has roundish ovate acute crenated leaves. This shrub attains a height of 8 feet, and is a native of the island of Madagascar, where it is called Ramontchi. The fruit, which is edible, is about the size of a small plumb, is red when ripe, at length becoming violet-coloured. It has a sweet and acid taste. There is a small island off the coast of Madagascar which is covered with these trees. This island is called by English sailors Plum-Tree Island; by the French, Isle aux Prunes.

F. sapida has elliptical leaves, serrated, bluntish at both extremities. It is a native of the mountainous districts of the East Indies. The fruit is about the size of a common currant, and of a red colour. The fruit is eaten by the natives, and the tree is called by the Telingese Pedda Caurew.

F. inermis has elliptical crenato-serrated leaves, with short axillary racemes of hermaphrodite flowers. It is an unarmed tree, attaining a height of 30 feet. It has reddish-purple berries of a pleasant acid taste. It is a native of the Moluccas, where it is also extensively cultivated for the sake of its fruit. There are several other species of *Flacourtia*, all of them yielding edible fruits. The young shoots and leaves of *F. cataphracta*, which have the taste but not the bitterness of rhubarb, are considered astringent and stomachic, and are prescribed in the Circars accordingly. Tho infusion of *F. sepiaria* is thought to be useful as a remedy for the bites of snakes.

FLACOURTIA'CEÆ, or FLACOURTIA'NEÆ, *Bixads*, a natural order of Plants belonging to Lindley's parietose group of Polypetalous Exogens. It has from 4-7 definite sepals cohering slightly at the base; the petals equal in number with the sepals, and alternate with them, sometimes wanting; the stamens hypogynous, equalling the petals, or twice as many or some multiple of them, and sometimes appearing as scales forming a nectary; the ovary roundish, distinct, sessile, or slightly stalked; the style absent or filiform; the stigmas equal in number to the valves of the ovary, more or less distinct from each other; the fruit 1-celled, sometimes indehiscent and fleshy, sometimes capsular, 4-5-valved, filled with a fine pulp inside; the seeds few, thick, usually enveloped in a pellicle formed by the withered pulp, the albumen fleshy, somewhat oily, the embryo straight in the axis, with the radicle turned to the hilum, and therefore usually superior; the cotyledons flat, foliaceous. This order consists of shrubs and small trees, with alternate simple coriaceous leaves on short stalks, and axillary many-flowered peduncles.

The affinities of this order are with *Samydaceæ*, *Lacistemaceæ*, *Pangiaceæ*, and *Tiliaceæ*. They may be distinguished from all other plants by their unilocular fruit having their inside wholly covered with the placentæ. About 31 genera and 85 species are referred to this order.

These plants are natives of the hottest parts of the East and West Indies and Africa. Three of the genera—*Flacourtia*, *Hydnocarpus*, and *Chaulmoogra*—yield plants used by man; few, if any, are cultivated for ornament.

Hydnocarpus (from ὕδνον, a tuber, and κάρπος, a fruit) has diœcious flowers, the staminiferous ones with 5 stamens, 5 sepals, the two outer ones being ovate, 5 petals with villous margins furnished with a scale on the inside; the berry is spherical, terminated by four reflexed tubercles. There is only one species of this genus, which is a tree about 30 feet in height, the *H. venenata* of Gærtner, and *H. inebrians* of Vahl. It is a native of Ceylon. The fruit when eaten produces sickness, giddiness, and a dangerous form of intoxication. It is greedily devoured by fishes, which become stupified, but when taken in this way they produce poisonous effects as food.

Chaulmoogra (*Gynocardia*) is a diœcious genus; the staminiferous flowers with a 4-5-lobed calyx, 5 petals with a scale at the base of each; the pistilliferous the same, except the stamens, the ovary superior, 1-celled, with numerous ovules, and 5 parietal placentæ, 5 styles; the fruit succulent, dry, 1-celled, many-seeded.

C. odorata has short-stalked, alternate, bifarious, drooping, lanceolate, entire, acuminate, smooth, exstipulate leaves, 6 to 10 inches long, 1½ to 2½ inches broad. It is a native of Silhet. The seeds are employed extensively by the natives of India as a remedy for cutaneous diseases. In those cases they are applied externally; the testa being removed from the seed, the perisperm is beaten up with clarified butter into a soft mass, and applied to the part affected three times a day. The Indian names of this plant are Chaulmoogra and Petarkura. [PANGIACEÆ.]

Other genera belonging to this order are—*Ryanæa*, named by Vahl after John Ryan, who collected plants in Guyana; *Patrisia*, named after M. Patris, who collected plants in Guyana; *Roumea*, after Philippe Rose Roume de St. Laurent, an agent of the French government at St. Domingo, who was of great service to Poiteau, who travelled there; *Kiggelaria*, after Francis Kiggelar, a Dutch botanist of the 17th century; *Stigmarota*, *Melicytus*, *Erythrospermum*, *Pangium*, and *Vareca*.

(Don, *Dichlamydeous Plants*; Lindley, *Natural System*; Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

FLAG. [IRIS.]

FLAGSTONE. A variety of Sandstone in which the laminated structure prevails is thus termed. Other laminated or thin-bodied rocks, as certain limestones and some argillaceous beds of the Silurian series, receive the same title. The laminations of flagstone arise from peculiarity of deposition; the laminations of slate (properly so called) arise from a new structure superadded to that of deposition, and possessing a certain symmetry and relations to lines and axes, which are at least analogous to crystalline arrangements.

FLAMINGO. [DUCKS.]

FLAX. [LINUM.]

FLEA. [PULEX.]

FLEABANE. [CONYZA.]

FLEXUOSI. [AMMONITES.]

FLINDERSIA. [CEDRELACEÆ.]

FLINT, a mineral substance composed principally of Silica. [SILICA.] It is found mostly in the Chalk Formation. The true origin of this mineral substance—as it occurs in the Chalk of Europe especially—has been, and still is, the subject of much discussion among microscopists and geologists. Mr. Bowerbank believes generally in the origin of flints (and some allied minerals) from sponges. In confirmation of this view spicula, such as characterise the Siliceous Sponges (*Halispongia*), are found in flint, and on the surfaces of flints peculiar marks of organisation referrible to spongeous texture. Ehrenberg, finding in some flints abundance of Infusorial *Animalcula*, suggests the origin of flint from aggregations of these siliceous-shielded *Microzoaria*. Mr. Charlesworth has recently found flint occupying the closed pulp cavity of a tooth of *Mososaurus*, and regards this fact as opposed to both speculations.

There can be little doubt that, whatever substances are found in the flint, or it may be found in connection with, it has been deposited from solution in water. Not only is flint found in connection with sponges and *Infusoria*, but also with *Echinodermata* and other animal remains of the Chalk. The substance called Chert has the general characters of Flint, and frequently contains in its interior loose particles of sand. [AGATE.] From this circumstance there can be little doubt that the chert has been formed from the deposit of silica upon rolled masses of sand. In the same manner it appears probable the siliceous matter has been deposited in the cavities left by sponges and other animals after they had been covered up by the chalk at the bottom of the ocean. It has been supposed, in the case of sponges, that this process goes on at the bottom of the sea, but this is highly improbable, and it is much more likely that the flint is formed by a process of percolation long after the animal remains with which it is found in contact have been buried up by the chalk. That silex is readily made to assume this form is seen in the cases of silicified wood, in its deposit in vegetable structures, in its existence around the locality of geysers, and in the very ready manner in which it is precipitated in an insoluble form from its solutions.

FLINTY-SLATE, or SILICEOUS SCHISTUS, is a substance which is found chiefly in beds in transition mountains. It occurs in Saxony, the Harz, Bohemia, &c. It occurs also in Scotland, in the Pentland and Muirfoot Hills, in the Isle of Skye, &c.

The substance is of various colours, gray, bluish-gray, and red; its structure is rather slaty; on the edges it is translucent; it is dull, or only glimmering; hard, and broken with difficulty.

It contains about 75 per cent. of silica, the remainder being lime, magnesia, and oxide of iron.

The Basanite, or Lydian Stone, is considered to be a variety of flinty-slate; it has not however a slaty structure, and is not so hard as flinty-slate. It occurs in Bohemia and Hungary, but was first brought from Lydia in Asia Minor, whence its name. It is employed when polished for trying gold by a comparison of colours, and has thence obtained the name of Touchstone.

FLIXWEED. [SISYMBRIUM.]

FLOAT-STONE, a variety of Quartz found in the Chalk Formations of Menil Montant, near Paris. It consists of fibres or filaments aggregated in a spongy form, and so light as to float in water.

FLOOK, or FLUKE. [PLEURONECTIDÆ.]

FLORA. The collective vegetation of a country is called its Flora, in the same manner as the animals are called its Fauna. Thus we speak of the Flora of Great Britain, the Flora of Europe, meaning thereby all the plants growing in those parts of the world. The term is also applied to books, or lists, descriptive of the plants of a country.

FLOS FERRI. [ARRAGONITE.]

FLOUNDER. [PLEURONECTIDÆ.]

FLOWER, that part of a plant in which the organs of reproduction are placed. The flower originates from a bud, and is nothing more than a particular modification in the perfecting of the parts contained in the bud; namely, the several foliar organs and internodes. Only two essential processes of development can exist, and from those only two essential organs, as fundamental organs, can be formed in the plant; namely, the Axis and the Leaf. All the several parts of the flower must therefore be referrible to these fundamental organs, and be traced back to them. Since Göthe's time this tracing back has been termed the Metamorphosis of Plants. Originally this mode of considering the flower rested solely on Comparative Morphology, and the observation of cases in which the interruption of the usual processes of development, in some or all parts of the flower, caused those parts to reassume forms in which it was not difficult to recognise the nature of the fundamental organ from which they had been produced. This latter has been termed Retrogressive Metamorphosis. As examples of it, we may mention the different monstrosities, the doubling of a flower through the transition of the stamens into petals, the transition of the petals and sepals into the common leaves of the plant, &c. This mode of establishing the foundations of the doctrine of metamorphosis has however two essential faults: since, in the first place, it seeks to obtain individual facts by means of hypotheses and comparisons; while, secondly, its progress depends entirely upon favourable circumstances. The only correct and sure ground on which to rest this doctrine is the history of development.

In Phanerogamic Flowers the following parts are distinguished, proceeding from without inwards:—1. The Floral Envelopes, as the External Calyx (Epicalyx), of which the parts are Leaves (Phylla); the Calyx, the parts of which are Sepals; the Corolla, the separate portions of which are Petals; or, instead of these three, the Perianth (Perianthium), whose separate parts are Leaves (Phylla): 2. The Stamens (Stamina), around and within which some stunted accessory foliar organs appear under very various names: and lastly, 3, in the centre of the flower, the Pistil (Pistillum), the separate foliar organs of which are Carpels (Carpella). In the stamens the lower thread-like portion, which is termed the Filament (Filamentum), is distinguished from the upper thick and hollow part, containing the Dust (Pollen), called the Anther (Anthera). In the pistil, the lower part surrounding the Ovules or Seed-Buds (Gemmulæ) is called the Germen; the upper free part, which is usually covered with papillæ, is termed the Stigma, and between these two frequently a stalk-like elongation of the germen occurs, called the Style.

The flower of *Phanerogamia* is the only physiologically determinate organ of the plant, since it contains the apparatus for the regular propagation. But to this only two parts contribute—namely, the stamens, as generators and receptacles of the pollen; and the seed-bud or ovule, as the place in which the pollen is developed into the embryo. All the remaining parts of the flower—namely, the envelopes of the whole perianth, the calyx and corolla, the receptacles containing the seed-bud (the germens, styles, and stigma), are not, in a physiological sense, essential, and they may be absent, without the flower losing its correspondence to the character by which a flower is defined.

In the correct (morphological) view of the flower, there is no distinction between essential and inessential forms, and therefore it is necessarily more proper to divide it into axial and foliar organs. The following relations should be borne in mind:—The axis and its modifications are the basis of the flower, because to them the foliar organs are attached. Attached to the outer part of the axis of the flower occur several forms of true foliar organs, the floral envelopes, accessory leaflets, and stamens. The innermost part is occupied by organs which are formed from true axial organs, or an intimate blending of these with foliar organs, which are termed the female apparatus, or better, the rudiment of the fruit. At the same time the parts of the flower are usually grouped together and treated generally, according to the relations of number and position, as well as of duration. Thus we obtain this plan for our following investigations:—

A. The Axial Organs of the flower.

B. The number, relative position, and duration of the parts of the flower.

C. The true Foliar Organs of the flower.
- *a.* The Floral Envelopes.
- *b.* The Stamens.
- *c.* The Accessory Foliar Organs.

D. The Rudimentary Fruit.
- *a.* The Pistil.
- *b.* The Spermophore.
- *c.* The Seed-Buds.

The Anthers have been called the male organs of a plant (with the superfluous collective term Andrœceum); the Seed-Buds and their receptacle the Pistil, the female parts (together the Gynœceum). A flower that contains both parts is termed Hermaphrodite (Flos Hermaphroditus). Flowers that contain only one of those kinds of organs are termed Unisexual Flowers (Flores Unisexuales, Diclini). When, in the last case, male and female flowers (mas et femina) appear on the same individual plant, such plant is termed Monœcious (Planta Monoica); when they appear on separate individuals the plant is termed Diœcious (Planta Dioica). An Inflorescence which contains both male and female flowers, also is termed Inflorescentia Androgyna. Here again it must be distinguished whether the male and female blossoms are formed upon different plans, as in the *Cupuliferæ* (Diclines); or whether, through the suppression of one or other part, a pseudo-diclinous condition appears in a flower formed on the plan of a hermaphrodite. This latter condition, which is never found to run through all the examples of any species of plant, brings monœcious and diœcious species into hermaphrodite genera, and suggested to Linnæus the establishment of his 23rd class, *Polygamia*, where in one and the same species male, female, and hermaphrodite flowers are present.

There are very few flowers of so simple a structure that they consist only of one simple essential part, so that no formation of internodes is possible within the flower; and the extremity of the pedicels immediately supports the floral parts existing. This is the case in the male flower of the *Euphorbiæ*, where the end of a pedicel bears one single stamen; also in the male flower of the *Abietineæ*, where one single foliar organ, converted into a stamen, constitutes the entire flower. It is also the case in the female flower of *Taxus*, where the small pedicel, clothed with bracts, terminates immediately in the naked seed-bud. In the generality of flowers however several parts are united which do not stand at equal heights on the axis, and thus more or fewer undeveloped internodes take part in the structure of the flower. The original condition of the internodes, is here also most frequently permanent; and the pedicel, after the detachment of all the parts of the flower, frequently ends in a small slightly thickened knot, which represents the collective internodes of the flower in an undeveloped condition,—the simple base or receptacle of the flower (Torus). Examples in which individual internodes become elongated are rather rare. In some families they are elongated between the inner floral envelopes and the stamens (Androphorum), and between the stamens and the germen (Gynophorum). The latter is generally termed Germen Stipitatum. There are examples of both in the *Passifloraceæ* and the *Capparidaceæ*.

A considerably longer part, without elongation of the individual internodes, frequently occurs as a gynophore in flowers which contain many germens (as in the *Rosaceæ*, the *Ranunculaceæ*, *Magnoliaceæ*, &c.) Again, the gynophore is often presented as a hemispherical or cushion-like part, as in some other *Rosaceæ* and *Ranunculaceæ*. A very rare form of it is that of a reversed cone, which bears the germens upon a base turned upward, as in *Nelumbium*. In the rarest instances, with the exception of this case, the axis of the flower is elongated within the floral parts even without ending as a germen; but this does sometimes occur, as in the male flowers of some Palms and other plants; for example *Chamædorea*, where the points of the petals unite with the apex of the axis of the flower which passes up through them.

In very crowded inflorescences, the torus of an axillary bud developes obliquely, and rises up on one side, especially beneath the germen, so as to appear as a part of its side-wall; this happens with most of the Grasses. A similar circumstance, arising from a similar cause, happens when many single germens are present in one flower, by the division of the torus, which forms the basis of each of those germens, and thus assumes the appearance of forming a part of the wall of the germen (as in *Potamogeton* and *Dryadaceæ*).

But the developement of the internodes into a Disc, or in a hollow cup, is far more frequent in the flower. If the collective internodes of the flower form a hollow body, or even a cylindrical elongated tube, which incloses only seed-buds, and bears all the floral parts upon its upper edge, all this is the so-called Inferior Germen or Ovary (Germen Inferum).

Every other similar expansion of the internodes of the flowers which does not immediately bear seed-buds, is called the Disc (Discus). This may be situated beneath the rudiment of the fruit (Discus Hypogynus), and then may be flat, as in *Potentilla* and *Fragaria;* or cup-shaped, as in *Rosa*, *Populus* (*mas*), &c. This latter may be free (*Rosa*), or may be blended with the germen situated inside it (*Pyrus*); or it may pass off from the middle of the (half-inferior) germen (Discus Perigynus), as in many *Myrtaceæ;* or, lastly, it may rise above the (inferior) germen, and stand upon it (Discus Epigynus). Here it is very rarely (or never?) flat, but funnel-shaped, as in *Godetia;* in the form of a long tube, as in *Œnothera;* or resembling a style, as in the *Orchidaceæ* and *Aristolochiaceæ*. In all these cases, the foliar organs of the flower may be situated in very different places. Usually, indeed, they collectively form a zone around the edge of the flat or concave discs; then the discs may be said to correspond to as many discs lying one above another as there are internodes implied by the number of foliar organs. Frequently the true foliar organs stand around the edge of the disc; and upon its inner or upper surface the germens are arranged in one or more circles (as in *Rosa*, *Punica*, *Onagraceæ*). More rarely the floral envelopes alone stand on the border, while the stamens are then at a distance from them, upon an internal prolongation of the disc, as in the *Orchidaceæ*.

The disc is by no means always regularly developed, but sometimes enlarged at one side only, whereby the whole flower appears oblique, thus in *Reseda*. The most remarkable structure is in *Pelargonium*, where the disc forms a cavity to one side of the peduncle, and in *Tropæolum*, where the spur is formed solely by the disc.

There are but few special observations to be made respecting the structure of the internodes of the flower; it is in general like that of annual stems; but it should be remarked that they often possess fewer vascular bundles, and these of simpler development. The internodes (as also some of the foliar organs) within the flower, frequently do not have the epidermis developed, but, instead of this, a delicate soft cellular tissue, somewhat yellowish in colour, and often containing a saccharine secretion, forms the investment of the surface (Nectarium).

It is very rarely that a flower consists of one part only, as in the male flowers of *Euphorbia*, *Lemna*, and *Wolffia*, which are formed of one foliar organ, the anther; or the female flower of *Taxus*, which is formed of one axial organ, the seed-bud. Usually more parts unite to form a flower: thus the female flower of most of the *Araceæ* consists of one or more seed-buds, and a carpel surrounding them. The male flower of the *Salicaceæ* consists of a scale-like disc and several stamens. In the generality of cases, male and female organs are both present in the same flower: they are seldom naked, as in *Hippuris*, but usually surrounded by floral envelopes.

In axillary flowers, those parts which are turned towards the peduncle are termed the upper, and those turned towards the bract, where it is present, the lower. Some plants exhibit the peculiarity that the pedicel, until the time of the blooming, makes a half turn (analogously to the twining stem), and it may be the true pedicel, as in *Calceolaria* and some *Orchidaceæ;* or the inferior germ, as in most of the *Orchidaceæ*. By this curve, the upper parts of such a flower (in those plants the lip) become apparently the under; and such flowers are termed Flores Resupinati. The term is sometimes falsely applied to those *Orchidaceæ* in which no such twisting takes place, but in which the lip stands regularly as the upper part of the flower, as, for example, in *Epipogium*.

The individual organs of the flower taken generally, according to the common view, and known by collective names, may originally consist either of one piece or of more than one: in the first case they are partes monomeræ; in the second case partes di-, tri-, or polymeræ. In the latter case the parts may be entirely separated and independent of one another, or they may be grown together in various ways. These coherent sets were formerly also called partes monomeræ. De Candolle better termed them partes gamomeræ; as, for example, *Hemerocallis* = perianthium gamo- (mono-) phyllum, hexamerum; *Salvia*, corolla gamo- (mono-) petala, pentamera; *Rosa*, coralla pentapetala, &c.

The coherence occurs here in the same manner as in the stem-leaves, but on account of the crowded position in the flower-bud, much more frequently. It happens either that a single foliar organ grows together by its edges into a tubular or cup-like organ, as for example occurs frequently in the so-called monomerous floral envelope (Bracteole); or that several foliar organs grow together by their edges: this commonly affects all the edges of a circle of leaves, but sometimes two edges remain ununited, as with the calyx of *Gentiana lutea*. So, again, this process is usually simultaneous in development at all the edges of a circle; but it sometimes happens very much later—*a*, on two uppermost leaf-edges, whereby the single-lipped forms arise, as in the corolla of *Teucrium* and the flores ligulati of the *Compositæ;* or, *b*, with each pair of leaf-edges at the side of the leaf-circle, whereby the two-lipped forms (partes bilabiatæ) of descriptive botany arise. Another kind of blending also occurs in the flower, of which no example occurs in the stem-leaves, and only one in the bracts and bracteoles, namely, the cupula of the *Cupuliferæ;* this is, the blending together of two or more circles, as in the two circles of the floral envelopes of many *Liliaceæ;* or in these and the two circles of stamens, in the circle of petals and stamens, in the *Labiatæ*, &c.; and in general in all flowers to which are ascribed stamina perianthio vel corollæ (not calyci) inserta.

The coherence of the stamens of one or more circles has been well termed, since Linnæus's time, fraternity (Adelphia); and, according to the number of brotherhoods in a flower, Monadelphia, Diadelphia, Polyadelphia. When the foliar organs of the flower are coherent, the blended part is termed the Tube (Tubus Perianthii, Calycis, Corollæ, &c.); the free parts, the Limb (Limbus); and the boundary of the two, the Throat (Faux). One of the most striking examples of coherence, which also has no analogue in the stem-leaves, is found in the blending of the foliar organs of the flower at the point only, the union never extending farther; so that the foliar organs are connected above, but free below, as in the corolla of the male flowers of *Chamædorea*, *Casuarina*, and in the androphore of *Symphyonema montanum* (?).

Abortion in the flower means that some part present in the rudimentary condition is arrested during the development and gradual perfecting of the flower, and thus at last retires from observation. There is no other kind of abortion. So soon as the individual parts of a flower become distinct members, the foliar organs appear arranged around an ideal and real axis of the flower (the axial organs of the flower), and in the rudimentary condition always regularly. Through subsequent unequal development of the single parts, the flower frequently becomes unsymmetrical, or, as it is called, irregular. This irregularity is always such that the upper part of a flower becomes developed differently from the under. Such irregularity very seldom affects the germen, which almost universally remains regular even in unsymmetrical flowers; yet there are cases in which this is the only symmetrical part, as in many of the *Scrophularaceæ*, *Acanthaceæ*, and *Cryptocoryne spiralis*. If the unsymmetrical flower, with or without coherence of its parts, is divided into two halves, an upper and under, developed in different ways, they are generally termed bilabiate; but if only one single foliar organ is developed in an aberrant form, that leaf acquires the name of Labellum, or Lip. Rare indeed are the cases where the entire flower is unsymmetrical, as in *Goodyera discolor*.

It is not possible to state in general terms the number of parts which may unite to form a flower. We find of foliar organs alone sometimes as many as fifty or sixty united in one flower. Certain combinations, on the contrary, are rarely met with: no monomerous flower possesses double floral envelopes. When the various parts of the flower are present in large numbers, these arise universally in one or more circles (Whorls) at the same height on the axis, and at the same time. When circles containing members of equal number follow in succession, the members of the one circle usually stand opposite the interspaces between the members of the preceding circle (the circles and their members alternating); they seldom stand precisely before them (the circles and their members opposite). But it by no means is to be assumed that the members of each circle are always of equal number in a flower. The number of members often increases up to the stamens, and thence diminishes; it is rare for the circle of the carpel to contain the greatest number, as in the *Malopeæ* and *Malvaceæ*. The generality of monocotyledonous plants with perfect individual flowers have regular homomerous circles through the entire flower: in dicotyledonous plants this is relatively rarer; the outermost and innermost circles have usually fewer members. Again, respecting the number of circles which follow one another, no general statement of importance can be given. Seven different forms of foliar organs may possibly exist in the same flower, namely, the epicalyx, calyx, corolla, accessory corolla, the stamens, accessory stamens, and the carpels; but there is no flower in which all occur in conjunction. All these foliar organs may be present in one or more circles, with the exception of the epicalyx, in which there is no example of a double circle. Perianth, calyx, corolla, accessory corolla, and carpels occur in one, or more rarely in two circles. Stamens may be present in one, two, three, or possibly even four circles; more circles than this are not exhibited in the normal condition of the flower. If the number is increased, which seldom happens except in stamens and carpels, as in *Ranunculaceæ* and *Dryadaceæ*, the *Magnoliaceæ*, &c., they stand no longer in circles but in a spiral. In monocotyledonous plants with perfect individualised flowers, with the single exception of some *Scitaminaceæ*, five trimerous circles of foliar organs of the flower appear to be formed in those where a second circle of petals exists. The greatest multiplicity of forms occurs in the dicotyledonous plants. *Lavatera*, for example, has an epicalyx, calyx, corolla, stamens, and carpels in five circles, with increasing numbers of members; those of the calyx and corolla alone are equal. *Gnidia virescens* has perianth, stamens, accessory stamens, and carpels, but in eight circles, which are throughout composed of two members each. It is by no means necessary that all the parts of a circle of floral foliar organs should be ultimately developed in the same manner; and many floral structures which have hitherto been apparently inexplicable may probably, by keeping this truth in mind and following out the history of the development, be readily traced back to the original type.

The duration of the individual parts of the flower is very various; the axial organs, so far as they support the rudiment of the fruit or aid in its formation, persist naturally at least until the ripening of the seed, then fall away with it; or if it becomes disengaged from them, die away with the remainder of the plant. When axes bear only male organs or flowers their duration is different; sometimes they are cast off at a true articulation, sometimes they remain upon the parent plant, and gradually die away. The foliar organs of the flower are equally various in their duration. Perianth, corolla, and accessory corolla commonly perish soon after the perfecting of the flower; either they are cast off by true disarticulation, or they wither upon the parent plant. The epicalyx and calyx frequently share the fate of the axial organs supporting the rudiments of the fruit; the carpels almost invariably. The carpels are rarely destroyed before the perfecting of the seed, as in *Leontice*, and according to Robert Brown in *Peliosanthes Theta*. The stamens die away almost immediately after the dispersion of the pollen; either they are cast off, or they dry up and die away within the flower.

The terminology in use is as follows:—Those parts which fall away immediately, when their perfect formation is but scarcely completed, are termed caducous or fugacious (partes caducæ); those which endure somewhat longer are termed, if they are cast off by disarticulation, deciduous (partes deciduæ); if they retain their position, and die by gradual withering and drying up, marcescent (partes marcescentes); those parts which remain long, still vegetating, are termed persistent (partes persistentes); if they change their forms by further growth they are termed excrescent (partes excrescentes).

As among the floral envelopes are usually reckoned the perianth, the calyx, and the corolla, we may also include here the epicalyx. Under the term perianth, in its narrowest sense, only those foliar organs fall which, at least two in number, are applied closely to the flower and upon one level; so that all individual foliar organs on the axis of the flower, which only inclose stamens or germens, may be termed bracts. All these bracts have this in common, that they are merely foliar organs peculiarly modified; and consequently all the peculiarities of form which occur in the latter naturally appear in the former also. It is not often that the leaves of the floral envelopes have great thickness; they are almost always more or less flat. But the forms analogous to the pitchers or pouches are here frequent, much more so than is the case with the stem-leaves; and these are termed, according to their various resemblances to objects, cup-shaped, as in the lower petal of *Polygala*; hood-like, as in the upper leaf of the perianth of *Aconitum*; and so on. If a long sac-like appendage is formed at the basis of a perianthial leaf expanded above, it is called a spur (calcar), as in *Orchis*, *Delphinium*, *Fumaria*, &c. The formation of the spur is frequently conjoined with the formation of a symmetrical flower, where one upper or lower foliar organ forms a spur. The flattened expanded form, which is connected with the axis by a linear prolongation, frequently occurs in the sepals (?). This expanded surface is termed the limb or blade of the leaf (lamina); the narrowed base is not termed petiole but claw (unguis). True articulation is frequent between the floral envelopes and the axis, but it never occurs in the continuity of these leaves (?); therefore there are no true compound perianthial leaves, though a simply divided limb is frequent, as the petala palmatifida in *Reseda*, the petala pinnatifida in *Schizopetalum*, &c. An indication of true articulation may probably be afforded in the separation of the upper part of the tube of the flower in *Mirabilis*, of the calyx of the *Datura* from the lower, and in some similar cases.

True stipules are not met with in the floral envelopes, but appendages analogous to the ligula appear, to which indeed a part of the structure described as the corona belongs. As in the *Narcissus* and the *Lychnis*, the scales of the throat of the *Boraginaceæ* also belong here. These parts are formed in very various fashions on the floral envelopes, and such appendages are sometimes exhibited standing upon the surface of the foliar organ, in three or more rows, one above another. Almost all parts recognised as corona and accessory corolla (paracorolla) belong here, in particular a part of those elegant forms exhibited in the *Stapeliaceæ* and the *Passifloraceæ*; so also does a portion of the so-termed nectaria, as, for example in the petals of *Ranunculus*. All these are mere dependent appendages of the foliar organs, which are developed originally simple and flat, all these parts being produced from them subsequently. Here also occurs the one-sided development of a foliar organ: this is seen frequently in the petals of the *Apocynaceæ* (*Vinca*, *Nerium*, and *Cerbera*).

The collective form of one or more circles, whether coherent with each other or not, is more accurately designated according to further peculiarities, as tubular (tubulosum), bell-shaped (campanulatum), funnel-shaped (infundibuliforme), salver-shaped (hypocrateriforme), rotate (rotatum), &c.

Five kinds of floral envelopes are easy to be distinguished. When all the foliar organs are similarly or nearly similarly developed in a circle of one evident form, colour, and structure, they are described under the general name of perianth, the single organs of which are called perianthial leaves. If in the floral envelopes of one flower we can distinguish two circles differing in form, colour, and structure, the outer is named the calyx, its component organs being sepals; while the inner is termed the corolla, its single parts petals. Then if three circles of forms are distinguishable the outermost is called the epicalyx, the leaves of which may be denominated phylla. When between the simple or manifold floral envelopes and the stamens other independent foliar organs occur which exhibit a structure very imperfect and abnormal compared with the true envelopes, these are called a paracorolla, of which it will be necessary to speak further on, among the accessory parts of the flower.

The Perianth consists, according to the preceding considerations, of one or more circles of leaves, which are developed so as to be similar in colour, form, and structure. The following series of its forms may be more minutely characterised:—

The individual foliar organs are always expanded in a flattened form, seldom divided into limb and claw, and, at least when they are not coherent, usually oval or lanceolate. They may be green, as in the male flower of *Urticaceæ*, or of various colours, as in *Thymeliaceæ*; they may be firm and solid, and that especially when green, as in *Elæagnaceæ*; or of delicate texture, as in *Aristolochiaceæ*; or they may be developed as delicate sapless scales (paleæ), or bristles and hair, as in the *Typhaceæ* and *Cyperaceæ*. The perianth is almost universally regular, rarely (in some *Ranunculaceæ* and *Orchidaceæ*) symmetrical; in these cases never (?) 2-lipped, but often with one lip, as in the *Orchidaceæ*. This is then not unfrequently developed, hollow (cucullatum in *Aconitum*, calcaratum in *Orchidaceæ*), and it is commonly the uppermost leaf of the perianth. Its foliaceous portions may be free, as in *Juncaceæ*; or coherent, as in *Funkia*, *Hemerocallis*, &c.; they may consist of one circle, as in *Urticaceæ*; or of more, as in *Liliaceæ*. The parts are frequently blended with the stamens: in the coherent perianth the tube is sometimes straight, as in *Narcissus*; sometimes curved, as in *Aristolochia*. The mouth is mostly naked; sometimes, but seldom, as is the case in *Narcissus*, furnished with appendages which form a corona, which however are rare in the perianth, and in free foliar organs only (?) occur on the lip: the inner circle often has a beard.

The structure of Perianthial Leaves, is on the whole, that of very simple leaves, which exhibit no specal peculiarities, particularly if they are green. The ramifications of the vascular bundles are therefore simple; the separation into an upper and under parenchyma layer is seldom exhibited; but the epidermis usually. In the coloured and delicate parts the cells of the parenchyma contain colouring matter. In general the parenchyma is very loose and almost spongy, with homogeneous transparent fluid contents, and large intercellular cavities filled with air; hence the white colour. The epidermis is less developed in coloured leaves, and more resembles the structure of epithelium; stomates are sometimes present, especially upon the under surface, but the epidermal cells of the upper surface are often raised in shorter or longer papillæ, which give the upper surface a peculiar velvet-like appearance. It is very frequent here to find the secreted layer of the epidermis (cuticle) regularly and delicately striated (aciculatus), which certainly contributes to heighten the brilliancy of the colour, and perhaps, by its effect upon the rays of light, to the production and modification of the peculiar tints.

Occasionally, especially at the base of hollow parts, no epidermis is produced at certain points, and the parenchyma assumes a peculiar structure, to perform the function of secretion of a juice containing much sugar; as, for instance, the nectary at the base of the perianthial leaves of *Fritillaria*, very various parts on the labellum of the *Orchidaceæ*, &c. In rare cases the texture is hard and almost woody from the interspersion of many thickened porous parenchymatous cells, as in the species of *Banksia* and *Dryandra* (?). In paleaceous perianths the spiral and other vessels are not found in the usually simple vascular bundles, and in hair-like perianths even the vascular bundles themselves are wanting.

The Calyx only exists when a corolla occurs with it; it therefore can never be confounded with it. It is always the external of two dissimilar sets of envelopes. Its series of forms very much resembles those of the perianth; perhaps it is not so frequently delicate in structure and colour, as in the *Scitaminaceæ*, *Musaceæ*, *Butomaceæ*, *Ranunculus*, *Tropæolum*, &c. Usually it consists of one circle of sepals, more rarely of two (as in the *Berberidaceæ*). These sepals are always very simple, oval, or lanceolate, seldom pinnatifid, very frequently broad at the base and tapering to a point, or very small (dentes calycis obsoloti); sometimes they appear only as dry scales, or as tufts of hair (the pappus of the *Compositæ*). Appendages seldom occur upon the sepals, but they are frequently of hollow or concave form. The number of the sepals in each circle is in Monocotyledons frequently three, more rarely four or two; in the Dicotyledons it is most frequently five, but also two, three, or four, and perhaps sometimes more. Coherence of the sepals with one another may occur in every way, but never with the corolla and stamens, nor with the germens; that which is so called being quite another condition. Both in free and in coherent sepals, regularity and symmetry are met with; the latter often exhibit the bilabiate structures.

That which has been said of the structure of the perianth applies also to the calyx, only that here green foliaceous sepals are the more frequent.

The Corolla, which only exists as the inner set of floral envelopes accompanying a calyx, may be compared to a very delicate and coloured perianth. No true corolla occurs perfectly green and resembling the leaves; its series of forms is greater than that of any other of the floral envelopes. In the Monocotyledons it presents in general only simple, round, oval, or lanceolate leaves, very seldom having claws. In the Dicotyledons the forms are infinite, as are also the variety and splendour of the colour. The following are the main points in the structure of this organ:—

The individual petal exhibits, on a reduced scale and in a delicate condition, almost every variety of form of the leaf, with the exception of the truly compound. Concave forms are here frequent, such as the hood-shaped, pitcher-shaped, or spurred petals, &c.; these latter very often on individual petals of an otherwise regular corolla as in *Fumaria*. Fringed and feathered forms, as well as variously lobed petals, are also hy no mcans rare. The limb and the claw are often clearly to be distinguished. Parts analogous to the ligule, and every imaginable form of appendage, with the exception only of the stipules, occur frequently, and characterise genera and families.

On this account it is indispensable to distinguish the simple appendages of the petals from the independent foliar organs. To the former belong tho scales (fornices) of the *Boraginaceæ*, the scales of the corona of the *Silenaceæ*, the formations generally described as coronæ in the *Stapeliaceæ* and some other *Asclepiadaceæ*, the uectaria of *Ranunculus*, *Parnassia*, &c.

The corolla consists of one circle, rarely of two (three series in *Berberis*), or more (four series in *Nymphæa*). In Monocotyledons the number of members is equal to those of the calyx; in Dicotyledons the number of five in a circle predominates, though it is sometimes composed of two, of four, or of a greater number in *Dryas*. The number of members is equal to that of the calyx, or greater; very rarely indeed it is smaller; this last case occurs with *Hibiscus*. Suppression is not infrequent, and sometimes involves all the foliar organs of a corolla at once, as in the summer flowers of many species of *Viola*, in *Lepidium ruderale*, and in some species of *Acer*. The coherence of organs in every way is still more frequent; never indeed with the calyx or the germens, hut frequently with the stameus.

The corolla, whether with free or with coherent petals, may he regular or only symmetrical. In tho latter the hilabiate formation is tho most frequent, especially in five-membered circles, in such a way that, according as the odd petal is on the upper or the under side of the flower, the upper lip consists of three or of two petals. In the latter case these two are very often little or not at all coherent, as in *Teucrium*, the so-called radiated flowers of tho *Compositæ* (florihus ligulatis vel radiatis). Peculiar forms of symmetrical flowers are, for iustance—the personate flowers (corolla personata), in which the upper petals of a coherent corolla are so curved inward that they close the entrance of tho tube (as in *Antirrhinum*), the incurved portion is termed the palate (palatum); the true hilabiate or mouth-like corolla (corolla ringens), in the *Labiatæ*, in which the two petals forming the upper lip often present a concave form overhanging the lower lip, termed galea; the so-called papilionaceous flowers of tho *Leguminosæ*, in which the uppermost leaf, which is broad and large, surpassing the others, is termed the standard (vexillum), whilst the lateral petals, as wings (alæ), are usually dissimilarly developed, and the two undermost, very frequently coherent, also developed unequally at the two sides, approach each other in a concave form, so as to form tho keel (carina). Sometimes all the petals of the papilionaceous flowers become coherent at the lower part, and form a tube, as in *Trifolium*; or individual petals are abortive, &c. The most irregular of all the forms have hitherto received no names; such as appear for instance in the *Polygalaceæ*, the *Balsaminaceæ*, *Tropæolaceæ*, &c.

All that was said respecting the structure of the perianth holds also for the structure of the corolla, rememhering only that this is more delicate. The contents of the cells vary much in colouring matter, and their distrihution in groups is sometimes very remarkable. Very dense texture, in consequeuce of the presence of much-thickened porous cells, as in the *Amarantaceæ*, is infrequent. The structure of the epidermis, and its development into papillæ, hairs, &c. is very manifold. Development into surfaces secreting nectar, both at the hottom of concave forms and upon tho appendages, is especially common. The petals also occasionally secrete a viscous substance, in consequence of which they adhere together, as happens at the points of the inner petals of the *Fumariaceæ*.

The Epicalyx is seen where three separate series of foliar organs are distinguishable in the floral envelopes, and it is the outermost of these. There are not many plants which exhibit an epicalyx. In form and structure it much resembles the calyx. It occurs with free leaves (as in *Passiflora*), and coherent leaves (as in *Lavatera*). Its leaves are seldom delicate, such as are seen in the corolla, but are often dry and membranous (as in *Scabiosa*), but generally green and leafy (as in the *Malvaceæ*).

For an account of the other organs of tho flower, see STAMEN; FRUIT; PISTIL; SEED. For the functions of the flower, see REPRODUCTION IN PLANTS.

(Schleiden, *Principles of Scientific Botany*.)

FLOWERING-FERN. [OSMUNDA.]

FLOWERING-RUSH. [BUTOMACEÆ.]

FLUCERINE, the name given to tho native Deutofluate of Cerium, which occurs at Finbo and Broddbo, near Fahlun, in Sweden. It occurs both massive and crystallised. The crystals are either six-sided plates or prisms; they have a yellow or reddish colour; fracture uneven; dull; translucent, in very thin fragments: when heated by the blow-pipe on charcoal it hecomes slightly hrown, hut does not fuse; in the reducing flame it becomes colourless, and in the oxidating flame, with borax and a phosphate, it yields an orange-coloured globule: when heated iu a tube with an acid, the glass is corroded.

FLUELLITE, a compound of Fluoric Acid and Alumina, which occurs at Stenna-Gwyn, in Cornwall, iu octahedral crystals, the primary form being a rhombic prism: the crystals are colourless and transparent, with a vitreous lustre. It is extremely rare.

FLUKE. [PLEURONECTIDÆ.]

FLUKE-WORM. [ENTOZOA.]

FLUOR. [FLUOR-SPAR.]

FLUOR-SPAR, Fluor, Fluate of Lime, Derbyshire Spar, is a well-known mineral, which occurs in many parts of the earth, but especially and in great plenty in Cornwall, Derbyshire, and Durham. It occurs both crystallised and massive. The primary form of the crystal is a cube, the cleavage is parallel to the planes of the regular octahedron, distinct, but seldom with perfect surfaces: it assumes a vast number of secondary forms, as the octahedron, rhombic dodecahedrou. The late W. Phillips mentious his possessing at least 70 heautiful varieties of foru, and he has figured a fragment of a crystal from Devonshire which, if it were perfect, would exhibit 322 planes. It occurs colourless, and of almost every colour, as gray, purple, black, brown, red, yellow, green, aud blue: in Derbyshire the last is the prevailing tint, and the massive Fluor of that county is termed by the miners 'Blue John.' It is frequently transparent, but more commonly ouly translucent; its lustre is vitreous. Specific gravity 3·14. Hardness 4·0. Streak white, or slightly coloured. Fracture conchoidal. When powdered and thrown on a hot coal, Fluor-Spar exhibits a phosphorescent light, which is blue, green, purple, or yellow; when thrown in mass into the fire, it decrepitates. The massive varieties are nodular or amorphous: the structure of the former is large fibrous, or columuar, with divergent fibres: tho structure of tbe amorphous variety is crystalline, granular, earthy, compact, and occasionally straight or curved laminar. The crystallised varieties are more common in Cornwall and the west of England; tho massive varieties in Derbyshire and tho north of England. It occurs in many places on the Continent also. In the United States of America a variety called *Chlorophane* is found at Huutington, Connecticut.

Fluorido of Calcium is found iu the teeth, in bones, and in the ashes of plants. It is used for obtaining Fluoric Acid, which is employed in etching. [FLUORIC ACID, in ARTS AND SC. DIV.]

Fluor-Spar is, strictly speaking, to ho considered as a Fluoride of Calcium, composed of—

One Equivalent of Fluorine	18
One Equivalent of Calcium . . .	20
Equivalent . . .	38

Tho blue and variegated Fluor-Spar of Derbyshire is turned into various ornamental forms, candlesticks, &c.; that of Cornwall is used as a flux in the reduction of copper-ore.

FLUSTRA. [CELLARIÆA.]

FLY, a name applied almost indiscriminately to all insects possessiug wings; by many however restricted to the various species of Dipterous Insects, an account of which is given under the head DIPTERA.

FLY-TRAP, VENUS'S. [DIONÆA.]

FLYING consists in the power which many animals possess of raising themselves in the air, and in moving through it in various directions, supported by tho atmosphere alone.

In the article SWIMMING it is shown that man and many of the lower animals are very nearly equal in weight to an equal hulk of river water; consequeutly a man's weight is very nearly or quite supported when he is immersed in water. But the case is widely different wheu he is in the air, as the density of this is to that of water very nearly as $1\frac{3}{8}$ to 1000; hence it follows that a man should he $\frac{1\frac{3}{8}}{1000}$ less in weight than he is at present, in order that he might he supported in the air with as little effort as he is in water. The physical constitution of the air is also very different from that of water, and presents other obstacles to the efforts of a man to raise himself in that medium.

The air is compressible, and consequently much heavier near tho surface of the earth than it is in the elevated regions of the atmosphere; and it appears from numerous experiments that as the height increases iu an arithmetical, the density decreases in a geometrical progression. Thus, supposing an animal to ascend in the air $3\frac{1}{2}$, 7, 14 miles, the density at the surface, being unity, would decrease iu the ratio of the numbers $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{16}$; so that if the animal were as light as the air itself at the surface of the earth it would continually increase in weight with respect to it as it ascended, and could not be supported unless a force equal to the difference between the weight of the animal and its owu bulk of air were properly applied for that purpose.

It appears from an elahorate investigation of M. Chabrier that tho quantity of force expended, if the weight of the body be called W, is proportioned to $\sqrt{W^3}$ directly, and inversely as the square root of the density of the air.

There are various methods of ascertaining that the air diminishes in weight as we ascend in it. We know that the barometer falls when taken to the top of an elevated hill; and it is owing to this circumstance that the barometer is used to measure the heights of mountains. The difference between the specific gravity of air and that of most animals is so great that there are but a few species amongst the whole range of the *Mammalia* that are capable of flying, and these possess very modified organs for that office.

Attempts have been made to construct mechanism that would enable man to propel himself in the air, and fly by means of his muscular movements. This however is not likely ever to be effected, in consequence of the great weight of his body with respect to that of the air which it displaces. We know that when adventurous persons have descended from the car of a balloon by means of a parachute the surface of the latter which is presented to the wind must be very great to prevent too rapid a descent. The unfortunate termination of the life of Mr. Cocking arose from his not having estimated more accurately the quantity of surface, and consequently the strength of material that was necessary to prevent his falling with too great velocity. Indeed we may dismiss the subject of a man attempting to fly by the application of his muscular force to any machinery at present known; but seeing how extremely difficult it is for any heavy body to be supported in the air, much more to fly, it must be a matter of curiosity at least to inquire into the means employed by animals which are naturally endowed with the power of flight.

Amongst the higher orders of *Mammalia* we find the Bats possessing the greatest power of flight. The figure of the Bat resembles in some degree that of a bird. In order to render it fit for aërial progression the body is small, and the bones of the skeleton are extremely light. The arms are long, and peculiarly constructed: the fore arm has its motion restricted to flexion and extension, and cannot rotate upon its long axis like that of a man. This gives the arm a much greater degree of firmness during flight. The hand moves outwards and inwards horizontally, in the same manner as that of birds, and cannot move upwards and downwards on the fore arm, which would weaken the force of the wing in flight.

Fig. 1.—Kalong Bat.

The wing of the bat instead of being clothed, and having its surface increased with feathers, is composed of a membranous expansion, passing from the neck to the tail. In order to increase the surface of the wing the bones of the fingers are very long; the thumb is not inclosed in the membrane, but lies in front of the wing, and terminates by a strong hook for prehension. In the Bat the area of the wings with respect to the weight of the body is very considerable. Indeed the surface exceeds that of many birds. The muscles which move the wings are extremely powerful, and these animals are enabled to keep on the wing during a period of many hours. They appear also to be endowed with an extraordinary and peculiar sensibility, and can fly through an intricate labyrinth even when deprived of sight. The velocity of some species of the Bat tribe is very great. They chase and capture the insects on which they prey whilst on the wing.

There are some other species of *Mammalia* said to be capable of flying, such as the *Galeopithecus*, or Flying Cat, and the *Pteromys Alpinus*, or Flying Squirrel, but the notion is entirely without foundation. They are certainly provided on each side with an expanded membrane, as seen in *fig.* 2, but these membranes have by no means the surface requisite to enable them to fly; neither are they capable of moving like the wings of birds. They may be useful as parachutes, to break their velocity of descent in falling or leaping from trees, but could never raise the body again from the ground into the air.

Fig. 2.—Flying Squirrel (*Pteromys Alpinus*).

Most Birds are capable of flight, but their facility of flying varies in different orders; and some, as the ostrich and cassowary, are devoid of the power of flight altogether; but this defect is compensated by their great speed in running. [RUNNING.]

In the Ostrich and Cassowary the wings are very small and the body extremely heavy, both which circumstances are unfavourable to flight; but in birds which are endowed with great velocity the converse of this is found, the body being very light and the surface of the wings large.

In order to adapt birds for flight the most refined mechanism has been bestowed upon them. The skeleton is extremely light, and the bones hollow and filled with air: the body is traversed by air-cavities. The figure of a bird is such as to present a very small amount of surface to the wind in the direction of its motion, so that during its flight the animal is retarded as little as possible by the resistance of the air. In birds of passage, such as woodcocks, &c., which are known to cross the sea 500 miles at one flight, Sir George Cayley found the length of the wing to be three and a half times that of its greatest transverse section. The feathers keep the body warm and tend to increase its surface without adding materially to its weight. The muscles which move the wings are very large and endowed with great power. In some birds they are capable of continued action during many successive days. The figure of the wing is nearly triangular, and the surface decreases as the distance increases from the shoulder joint, which is the axis on which the wing moves. (*Fig.* 3.) This figure of the wings is of great importance for rapid flight, as it enables the muscles to move them with greater velocity than they could do if the surface increased with the distance from the body of the bird. The wing is also concave below and convex above, so that the down stroke is much more effectual than the up stroke. The bones of the fore arm and fingers which support the wing are jointed, so that the wing unfolds itself outwards horizontally after it has been raised in the air, as in the Bats; and by these means the wing is prevented from yielding, both in the up and down stroke, to the resistance of the wind. The tail of the bird performs the office of a rudder, and tends by its elevation or depression to elevate or depress the head. The elevation of the tail raises the head, and vice versâ.

The mechanical effects of the tail have been demonstrated by Borelli, and also by Mr. Bishop in the 'Cyclopædia of Anatomy and Physiology,' article 'Motion.' The tail is also turned obliquely to alter the course of the bird, but the effects of this organ are not very powerful in directing its path to the right or left.

The number of flappings which any bird must make in order to fly depends on the weight of the bird, the surface of the wings, and the specific gravity of the atmosphere, the earth's gravity being supposed constant at all heights to which any bird ascends. In most of the smaller orders the wings move with very great rapidity, indeed far too great to enable us to count them by the eye. The wings of the diminutive and beautiful Humming-Bird oscillate with sufficient rapidity to emit a humming sound; hence its name. If we can be satisfied that it is the number of flappings of the wings which determines the pitch of the sound produced, we have a ready method of ascertaining the number made in a given time, because we can easily find in any work on acoustics how many oscillations are necessary to produce the required tone.

Fig. 3.—The Great Ibijau.

The velocity with which any bird moves depends on the number of flappings made by the wing in a unit of time, each flapping being supposed to constitute one elevation and one depression of the wing. It is estimated by M. Chabrier that the swallow expends as much force merely to sustain itself in the air as would be sufficient to raise its own weight 27·5 feet per second, and that its number of flappings is about 15 per second. This estimate of the number of flappings is however obviously greater than the bird employs; and notwithstanding all the care and attention which M. Chabrier has bestowed on the subject it is found that birds fly with much less expenditure of muscular force than would appear to be necessary by mathematical analysis.*

Fig. 4.—Humming-Bird.

The velocity of some birds is very considerable. It has been said that the Eider-Duck can fly 90 miles in an hour, and the Hawk 150 miles in the same time: there is however reason to suspect the accuracy of these accounts. With regard to the Pigeon the case is different. It is well known that these birds are trained to transmit intelligence on special occasions in which great speed is required; and their velocity has in consequence been more accurately taken. Some years ago two trained pigeons were started from Brighton at the same time: one arrived in London in 70 minutes, the other in 78 minutes. Now, if we estimate the distance traversed by the birds in question at 49 miles, it follows, by the rule of three, that the bird which accomplished the journey in 70 minutes travelled at the rate of 42 miles per hour, and the other at that of 38 miles; and it is probable that the former is about the maximum velocity of the Pigeon. It appears that in general pigeons make about 23 flappings of the wing in 5 seconds. The Rook, which has a large surface of wings, makes from about 10 to 15 effective strokes in a second.

Some birds, the Lark for instance, ascend vertically in a right line into the air to such heights as to become quite invisible, during which movement they pour out their well-known joyous song, so pleasing to the ear in consequence of its peculiar melody and purity of tone. The warbling of this bird is distinctly heard even when the little songster itself appears in the zenith (owing to its great altitude) as a mere speck.

"Hark! hark! the lark at Heaven's gate sings!"—*Cymbeline.*

When birds poise themselves in one position in the air, their wings oscillate in very small arcs compared with the arc through which they sweep when in rapid motion.

Many of the small, and indeed some of the larger birds, such for example as the Woodpecker, move from one place to another by a series of jerks, produced by three or four strokes of the wings made in rapid succession; immediately after which they close their wings, whilst the body is forced forwards like a projectile, in the path of a parabolic curve. Of all known birds the Great Condor of South America appears to have the greatest power on the wing. It is said to be capable of elevating sheep and other animals into the air, and of carrying them to the mountains to feed upon them at leisure. The greatest weight it is capable of supporting in the air is not accurately known, but it is doubtless very considerable.

Fishes being adapted by their structure to move and respire in the dense fluid of seas and rivers, are not constituted for flying. There appear to be only two species of fish endowed with the power of suspending themselves above the surface of the water; namely, the *Dactylopterus*, and the *Exocetus*, or Flying-Fish.

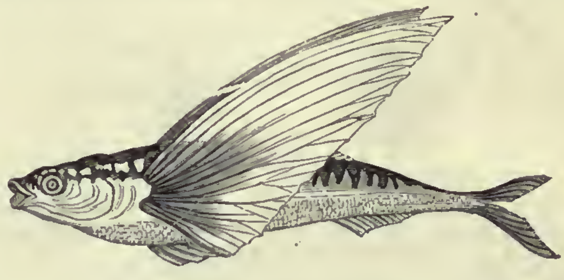


Fig. 5.—Flying-Fish (*Exocetus*).

In the *Exocetus* we observe that the pectoral fins assimilate very nearly in figure, situation, and dimensions to the wings of birds; and if, with the velocity and inclination of the latter, they possessed the power of oscillation, there seems to be no reason why they should not keep in the air as long as they could respire in that medium. But this does not appear to be the case. Their motions have been observed by Mr. Bennett, who states that he never saw them sustain themselves in the air for a longer period than about 30 seconds, and that they made no vibratory movements of the fins. According to Captain Basil Hall, their longest flight is about 200 yards; and they have been known to raise themselves as high as 20 feet above the surface of the water. From these statements an estimate may be made of the amount of force required to project the body into the air to such an amazing height and distance. At least it must be concluded that the muscular force employed is very great.

Amongst the numerous tribes of Insects, there are vast multitudes endowed with the power of flight. Now, although the mechanical principles on which this power depends are the same as those in birds, yet there is a considerable difference in the mechanism employed to effect their aërial progression.

The bodies of insects are traversed by air-tubes, which render them light and buoyant. The jointed structure of their frame enables the animal to curve, shorten, or elongate the body on itself. The wings present various forms (*fig.* 6, *a*, *b*, *c*, *d*, *e*, *f*), which exert a material influence on the velocity and mode of their flight. It is well known that some insects are provided with one pair of wings, and others with two. If we examine the surface of the wings, we perceive cords, which are composed of hollow tubes passing across the disc; these are called neuræ, and when filled with fluid, confer

* Sir George Cayley has estimated that a force equivalent to one-horse power (raising 550 lbs. one foot high in a second), if applied to appropriate machinery, would sustain 115 lbs. in the air. This however he considers only an approximate value, but perhaps not far from the truth.

on the wing strength and resistance, in the same manner as the cordage strengthens the sails of a ship. The wings are elevated and depressed by means of the expansion and contraction of the thorax, and are connected with the respiratory movements of the animal.

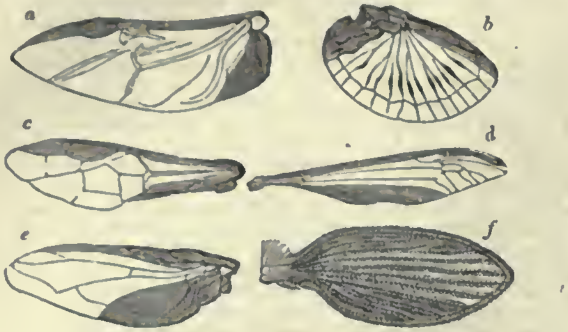

Fig. 6.—Wings of Insects.

a, wing of Beetle; *b*, wing of Earwig; *c*, wing of Saw-Fly; *d*, wing of Crane-Fly; *e*, wing of Common Fly; *f*, wing of Midge.

The *Diptera* have one pair of wings, which are elliptical in form, and connected with the mesothorax. Amongst the *Diptera*, we are familiar with the House-Fly, and the Blue-Bottle Fly. The former of these, it is well known, almost swarm in our houses, wherever sugar or ripe fruits are to be found. If an attempt be made to capture them by the hand, it is necessary that the movements should be made with the greatest rapidity in order to effect the object, as they are very watchful and agile.

The wings of the *Diptera* move far too rapidly to render it possible to count the number of strokes effected by them during flight. The House-Fly moves with considerable velocity; it is frequently observed to play round the ears of horses, when travelling at the rate of 10 or 12 miles an hour. The sound by which the flight of insects is accompanied does not arise, as is generally supposed, from the oscillations of the wing: if such were the case, there would be no difficulty in ascertaining the number of strokes.

The weight of the large Blue-Bottle Fly is less than one grain, and it has an area of wing amounting to about one-twelfth of a square inch, which is a much greater surface than is to be found in most other insects.

Fig. 7.—Humble-Bee.

Fig. 8.—Syrphus.

The *Diptera* are provided with two poisers, which are small bodies occupying the situation of the posterior wings of four-winged insects, and exert a considerable influence on their flight. It is said that if one poiser be cut off, the insect flies but a short distance with great difficulty, and then (one side being rendered lighter than the other) loses its balance, and falls to the ground. If both poisers be removed, it flies very unsteadily. The Crane-Fly makes use of its long legs to direct its movements in flight; the two anterior legs being directed forwards, and the posterior legs backwards. Mr. Kirby considers the former to represent the prow, and the latter the stern of a ship.

In those insects which are provided with four wings, the anterior pair are attached to the mesothorax, and the posterior pair to the metathorax. In the *Coleoptera*, the elytrum, or sheath must be elevated before the wings can be unfolded. The sheath adds weight to the insect, without contributing to aid its suspension in the air; indeed, in flying against the wind, the progress of the animal is rather retarded than accelerated by the sheath; but by the inclination of its surface the head is elevated so as to render the axis of the body nearly vertical during flight.

In the Stag-Beetle, the weight of the body is very great compared with the area of the wing, being about 40 grains to 1·25 square inch. In consequence of this disproportion, and the additional impediment of the elytra, the *Coleoptera* are unable to fly against a strong wind. Some entomologists maintain that none of the *Coleoptera* can fly against the wind, but Mr. Kirby confutes this opinion, and mentions a species (*Melolontha Hoplia*) which, he says, can fly in all directions.

The *Dermaptera*, such as the Earwigs, expand their wings like a fan. They take their flight generally towards the evening. The *Gryllus domesticus*, or House-Cricket, flies with an undulatory motion like the woodpecker.

The Diurnal *Lepidoptera*, or Butterflies, fly with a peculiar undulatory movement of the body, and have an enormous surface of wing compared with their weight. In the down stroke the two wings on each side lock together, producing by their combined action a greater effect. These wings spread out like a fan, and their surface rather increases than decreases as the distance from the axis on which the wings move increases. (*Fig.* 9). It is this form of wing and extent of motion, which produce the undulating flight to which allusion has already been made.

Fig. 9.—Butterflies (*Lepidoptera*).

Although in the Diurnal *Lepidoptera* the surface of the wings is so great with respect to the weight of the body, these insects do not fly with proportionate velocity; but are, nevertheless, endowed with sufficient speed to outstrip the schoolboy, when engaged in the chace of these beautiful insects.

The Nocturnal *Lepidoptera*, the Moths, possess considerable power of flight. The areas of their wings, instead of increasing with the distance from the axis of motion, decrease, as seen in *fig.* 10. They more nearly resemble the triangular figure of the wings of birds. The anterior wing is much larger than the posterior, but they act in unison with each other. The volume of the trunk of the Moths is usually much greater than that of the Diurnal *Lepidoptera*, and they fly with greater precision and velocity. Some species, the Silkworm-Moth for instance, is said to travel upwards of 100 miles a day.

Fig. 10.—Moths (*Lepidoptera*).

The Dragon-Fly affords a good example of the locomotive organs of the *Neuroptera*. They are furnished with four wings of a peculiarly delicate texture, the neura resembling net-work. (*Fig.* 11.) Unlike the *Lepidoptera*, the two wings on either side, being provided with a distinct set of muscles, act independently of each other, and are detached. The anterior and posterior wing are nearly equal in size, and the surface of the four wings, compared with the weight of the body, is greater than in *Coleoptera* and *Hymenoptera*. The velocity of the Dragon-Fly is very great, and necessary on account of its predaceous habits. They chase and capture the insect on which they feed with great ease, and the beauty and rapidity of their evolutions in the chace are worthy of attentive consideration. Leuwenhoek observed one of this tribe in a menagerie 200 feet in length, chased by a swallow. The insect flew with such velocity, and turned to the right and left in all directions so instantaneously, that the swallow, with all its powers of flight and tact in the chace, was unable to capture it ,the insect always keeping about 6 feet in advance of the bird. The wings are attached to the upper part of the body, about the centre of gravity, by which the animal is kept steady during flight.

Fig. 11.—Dragon Fly.

In the *Hymenoptera* (*fig.* 12), the ratio of the area of the four wings to the weight of the body is less than in the Dragon-Fly; and they are consequently obliged to make a far greater number of strokes in the same interval of time; because, both in birds and insects, when all other things remain the same, the number of strokes made by the wings will vary as the square root of the weight directly, and as the area of the wings inversely.

The area of the anterior and upper wings (*fig.* 7, *a*) is much greater than that of the posterior. The Humble-Bee has about 1-12th of a square inch of surface of wing to each grain weight of its body.

Fig. 12.—Bees and Snapdragon.

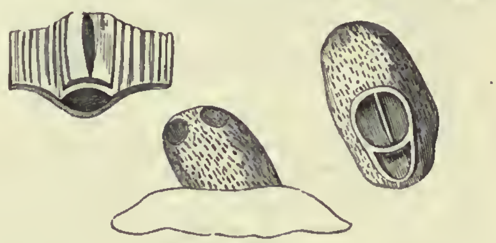
Bees are celebrated, not only for the geometric instinct which they display in the structure of their hexagonal cells so as to provide themselves with the greatest amount of room in the hive, whilst occupying the least possible space, but they are also known to fly between two distant points by the shortest road—that is, by the straight line. In consequence of the small amount of the surface of wing in the *Hymenoptera*, the Humble-Bee, Wasp, and Hornet, cannot fly with much speed against a strong wind; and in that direction the fleet schoolboy is enabled with ease to outstrip them. The *Ichneumoneæ* are provided with a larger surface of wing, as compared to the weight of the body, than the Bees.

The mechanism of the locomotive organs of birds and insects provides us with all the data necessary for the study of aërial progression. It affords ample proof that to render a man whose weight is 150 lbs., capable of supporting himself in the air by means of a pair of artificial wings, with the same facility as birds and insects, would require an extent of surface far beyond the control of his muscular force; and hence we conclude that the art of flying by means of muscular exertion, however applied, is denied to man.

FLYING-DRAGON, or FLYING-LIZARD. [DRACONINA.]

FLYING-FISH. [DACTYLOPTERUS; EXOCETUS.]

FO'DIA, a genus of *Mollusca* established by Bosc, and generally arranged by zoologists at the end of the simple Ascidians, and next to *Bipapillaria;* It is not better known than the last-named genus.



Fodia rubescens.

It has the following characters:—Animal oval, mammillated, divided throughout its length by a vertical partition, which contains the stomach, into two unequal tubes, opening at each extremity by an orifice, the upper one being a little sunk, and irregularly dentated, and the lower edged by a circular border forming a kind of sucker (ventouse), and serving to fix the animal.

Bosc founded the genus from a mollusk found on the coasts of North America.

FŒNI'CULUM, a genus of Exogenous Plants belonging to the natural order *Umbelliferæ*, to which the common herb called Fennel belongs. It was formerly considered a species of *Anethum*, but since the remodelling of the natural order *Apiaceæ* by Koch, it has been universally looked upon as a distinct genus. *Anethum* in fact belongs to the sub-division *Peucedaneæ*, with thin flat fruit, while *Fœniculum* forms part of *Seselineæ*, the fruit of which is tapering or very little compressed, and by no means flat.

F. vulgare, is a biennial plant with leaves cut into hair-like segments, yellow flowers, and glaucous stems. The fruit is ovate, not quite two lines long, pale bright-brown, smooth, the ridges sharp with but little space between each, the lateral ones rather the broadest, terminated by a permanent conical disc. Common on chalky cliffs in the southern parts of England, and everywhere cultivated for the sake of the agreeable aromatic quality of its leaves. Oil of fennel is obtained from the fruit.

F. dulce, the Finocchio Dolce of the Italians, is an annual sort which is cultivated in Italy as celery with us; and its blanched stems are said to be an excellent vegetable, resembling celery, but more tender and delicate, with a slight flavour of common fennel. The summers of England are not warm enough to render it possible to cultivate this successfully.

F. piperitum is a wild Fennel, occurring on dry elevated hills in Sicily, where it is called Finocchio d'Asino. It is known from Common Fennel by its long slender stem, short rigid leaves, and very hot biting fruit.

F. Panmorium is cultivated in various parts of Bengal, under the name of Panmuhuree, or Mudhoorika in Sanscrit. Its fruit has a warmish very sweet taste, and aromatic smell, and is much used by the natives with their betel and in their curries. The root is white, nearly fusiform, and almost simple; the stem is erect, branched from the base to the top, from 2 to 4 feet high, the branches erect, round, and smooth, with a uniform pale-glaucous tinge and not striated. The umbels are terminal, rather concave, but not regular; the flowers small, bright deep-yellow, the petals long, ovate, with their points rolled in. The stamens longer than the petals. The fruit is used medicinally in India as a warm aromatic and carminative.

F. Capense is a species little known, with a thick esculent aromatic root, found in the interior of the Cape of Good Hope.

F. tingetana is a native of Africa, in the province of Tangiers. It has a taper branched stem; the leaves are supra-decompound and shining; the segments oblong lanceolate, cut and toothed; the upper petioles large and sheathing. The umbel is terminal on a short stalk; the lateral flowers are few, the male on longer stalks. Sprengel considers this the

Silphion of the ancients, from which the *Laser Cyrenaicum*, or *Asa dulcis* was procured, but Viviani asserts that *F. tingetana* does not grow in the country of Cyrene, but only occurs more to the westward.

FŒTUS. [REPRODUCTION IN ANIMALS.]

FOOD. The materials taken into the system of organised beings, and by which their functions are maintained, and out of which their bodies are formed, are called Food. Food in its widest sense is the raw material out of which plants and animals are manufactured. We shall confine ourselves here to the consideration of the food of animals, and of man in particular.

The great cause of the necessity of a constant supply of new matter or food to the body is the waste of the materials of which the blood and organs are composed, during the performance of their functions. The result of this waste is seen in the form of the various excretions which are thrown off from the body by the skin, liver, kidneys, and bowels. We shall find, then, that the food, the blood, and the excretions, represent each other, that they contain substances of the same nature, and are all composed of the same ultimate elements.

If we take a portion of human flesh or blood, and seek for its ultimate elements, we shall find that, on accurate analysis, they will yield the following elements:—

Carbon.	Potassium.	Aluminum.
Hydrogen.	Sodium.	Copper.
Nitrogen.	Calcium.	Chlorine.
Oxygen.	Magnesium.	Fluorine.
Sulphur.	Iron.	Silicon.
Phosphorus.	Manganese.	

Few or none of these elements occur in the human body in their pure form, but are combined variously with one another, forming compounds having very different physical properties and chemical relations. These elements may be divided, for physiological purposes, into two classes; the first four, carbon, hydrogen, oxygen, and nitrogen, being called Organic, whilst the remainder are called Inorganic elements. The first are called organic elements because they are found universally present in plants and animals, and because no animal cell and no vegetable cell can grow unless the whole of these elements exist. Hence, as they lie at the foundation of all organic existence, they are properly designated by this term.

The inorganic elements, though very generally present in large classes of animals and plants, are not universal. Man requires phosphorus and calcium in the form of phosphate of lime for his bones; but many of the lower animals contain no phosphate of lime. Sea-animals and plants will not live without chlorine and sodium in the form of common salt; but fresh-water plants, and plants away from the sea-shore, do not require this constituent. The term inorganic, then, is applied to these elements to express their different relation to plants and animals, and will also point out their frequent occurrence in the mineral world. The elements of man's body however are all derived from the mineral world, and are identical with the same bodies in inorganic substances. The carbon found in the human body is identical with that which forms, in its pure state, the diamond —which enters into the composition of graphite and various kinds of coal, and is found in limestone and chalk, forming a part of the carbonic acid of the carbonate of lime, of which these rocks are composed. The hydrogen of the human body is the same as the gas which, united with oxygen, forms water, and when combined with nitrogen produces ammonia. The oxygen of the animal is identical with the gas which, with nitrogen, forms a fifth part of the atmosphere, and which, combined with the metals, forms oxides, of which the greater portion of the earth's surface is composed. The nitrogen of the organic world is identical with that which constitutes so large a portion of the atmosphere. Nor are these elements alone identical in and out of the human body; but we find that they possess the same chemical properties, and that their agency in the human body depends on these properties. Thus, carbon and hydrogen are inflammable bodies, and have a great affinity for oxygen, with which they unite, forming carbonic acid and water, giving out heat during the process of union. This very process goes on in the animal body, and constitutes one of the most important functions of the body. The characteristic features of the functions and properties of animal and vegetable bodies depend on the chemical relations of the four organic elements.

These elements never enter the system in their pure form. Carbon, however needed in the animal frame, cannot be appropriated pure; and a man would starve with the Koh-i-noor diamond in his mouth, were he not allowed to exchange it for more digestible forms of carbon. The gases hydrogen, oxygen, and nitrogen, would, any one of them in their pure state, destroy human life; and even when the two last are mixed with the atmosphere, they will not support life in that form. Again, we may mix them in various ways, and not be more successful. Carbon combines with oxygen to form carbonic acid, and hydrogen combines with nitrogen to form ammonia, and these two compounds unite together to form common smelling-salts, or carbonate of ammonia. But smelling-salts, though they contain all the organic elements, will not serve for human food. Nevertheless what is not food for man is nutriment for plants. Carbonic acid and ammonia supply plants with materials of growth. It is from these two bodies that the vegetable kingdom elaborates all the secretions which give to plants elegance of form, beauty of colour, deliciousness of scent, deadliness as poisons, and nutritiousness as food. The plant stands between the mineral and animal kingdoms, preparing the former for the service of the latter. Without plants there could be no animals. In the whole range of natural history we are presented with no instance of an animal existing directly on mineral matter. It is true that many animals are carnivorous, and live on the flesh of lower animals. The lion and the tiger prey upon the deer and the antelope; but if we go one step further we still arrive at the vegetable kingdom as the source of animal nutrition. The deer and the antelope are herbivorous creatures, and the flesh of their body is formed directly from the plants they eat. So with the animals eaten by man; they are all grain or herb-eating animals, and supply to man the materials they have obtained from the vegetable kingdom. At the same time the best standard we can take of food is milk, which is derived from the animal. When human milk is examined, it gives the following results in every 1000 parts:—

Water	870
Butter	52
Sugar	63
Casein	10
Salts	5
	——1000

These five constituents of milk may be regarded as typical of all kinds of food, whether obtained from the animal or vegetable kingdom. Hence, we may class alimentary substances according as they are represented by one or other of these constituents of milk.

1. *Aqueous.* Water is required not only as the medium of conveying the other substances into the body, but it forms a prominent constituent of the body itself. Blood contains 790 parts of water to 210 parts of solid matter in every 1000. Muscles contain 770 parts of water to 230 parts of solid ingredients. The brain and nerves contain about 800 parts of water in 1000. If food does not contain water naturally, it is taken into the system in the form of tea, coffee, beer, and also in its pure state. The quantity of water taken with the food should be about in the proportion of four to one, as we find it in milk. We cannot however judge of the quantity contained in solid food till we know its composition. Thus many substances which appear solid contain large quantities of water. In potatoes, for instance, there are 75 parts of water in every 100.

2. *Oleaginous.* The butter of the milk represents oily and fatty matters in general, which seem to enter into the composition of all healthy food. They are taken by the inhabitants of tropical countries in the seed of the cocoa-nut, as well as by those of the polar regions from the fat of the seal and many kinds of fish. They are obtained from both the animal and vegetable kingdoms, being known by the name of suets, fats, and lards, from the former source; and oils and butter from the latter.

3. *Saccharine.* The sugar of the milk represents several substances obtained from plants and used as food. Sugar itself varies in its composition according to its sources; hence we have cane-sugar, grape-sugar, maple-sugar, &c. Sugar has also a composition nearly approaching that of starch, and this substance is very generally found in the vegetable diet of man; pure in the form of arrow-root, tapioca, and sago; combined in the flour of wheat and other cereal grasses. Of all the animal products used as food, sugar is found alone in milk.

4. *Proteinaceous.* The casein of the milk, which, when separated, is known by the name of cheese, has, in common with two other vegetable and animal substances, called fibrine and albumen, a principle for their basis named protein. [PROTEIN.] These substances form the chief part of the fabric of the body, and in their capacity of food perform a very different function in the body to the butter and sugar before mentioned.

5. *Inorganic.* The salts of milk are the saline substances which, entering into the composition of various parts of the human body, are necessary to its integrity and health. The importance of the presence of those substances is frequently overlooked in food, and many diseases of the human frame arise from their absence. They are conveyed into the system in both animal and vegetable food; but in common salt we have an instance of a substance belonging to this class taken directly from the mineral kingdom as food without the intervention of an organic body.

In addition to these forms of dietetic substances found in milk, the food of the adult human being constantly contains certain principles which do not appear to be represented in the milk. Thus, the substances called condiments, as the various spices, contain volatile oils, which, although not essential to the diet of man, seem to exert a very beneficial influence when taken into the system. In tea and coffee there is a principle called theine, which seems to be the active ingredient of these substances. In the fruit of plants also, we have acids, as the citric, tartaric, malic, and oxalic acids, which seem to act very beneficially in certain states of the system. As these substances seem to act medicinally rather than dietetically, they may be properly called, as a class, the medicinal constituents of food. The following classification will give an idea of the kinds of food:—

Class I. *Alimentary Substances.*

Group A. *Aqueous*, containing water as a principal ingredient. Examples:—Tea, coffee, beer, wine.

Group B. *Carbonaceous*, containing carbon as a distinguishing ingredient.
1. *Saccharine.* Examples:—Sugar, starch, cellulose.
2. *Oleaginous.* Examples:—Oil, butter, fat.

Group C. *Nitrogenous*, containing nitrogen as a distinguishing feature.
1. *Vegetable.* Examples:—Flour, oatmeal, maize.
2. *Animal.* Examples:—Butcher's meat, cheese.

Group D. *Inorganic.*
1. From organic sources. Examples:—Potash in fresh vegetables, phosphate of lime in flour and flesh.
2. From the mineral kingdom. Example:—Common salt.

Class II. *Medicinal Substances.*

Group A. *Acids.* Examples:—Citric acid in oranges, tartaric acid in grapes, oxalic acids in rhubarb-leaves.

Group B. *Volatile Oils.* Examples:—Mustard, pepper, nutmeg, cloves.

Group C. *Alkaloids.* Examples:—Theine in tea and coffee, theobromine in chocolate.

We shall here make a few general remarks on the nature of the substances in the groups indicated, referring for special information on the plants and animals yielding food to the various articles devoted to these subjects throughout the 'English Cyclopædia.'

Under the head of WATERS, MINERAL, will be found an account of Water and the substances it usually holds in solution. In taking it as an article of diet, the following general remarks should be borne in mind:—

First, It may be taken in too large quantities to be carried off by the other emunctories, and then it remains in the system to impoverish the blood, and to reduce the amount of solid matter that is necessary for the performance of the functions of the tissues of the body. This is one of the results that take place from what is called the 'water cure.' Unless persons have sufficient vigour to take the exercise necessary to throw off by the skin the water that is taken into the stomach, serious ill effects must necessarily arise. The good that is effected by this system of the treatment of disease must be attributed more to the exercise it renders necessary than to the unnatural quantities of water taken into the system.

Secondly, Water may not be taken in sufficient quantities to carry on the healthy functions of the system. If the food is taken too dry, it is only imperfectly digested, and many important constituents, such as the salts, are not taken into the body in sufficient quantity. A deficient quantity of water in the blood will also prevent the healthy process of nutrition, and wasting and degeneration of the solid parts of the body will occur. It would be difficult, perhaps, to lay down any law with regard to the quantity of water individuals should take, and perhaps it is safer to rely on the instincts of the body, which seem to point out how much we ought to take by the feeling of satiety that comes on after enough has been taken. We may however get at something like an approximation of the proportion of solids and fluids required by the system in food, by examining the composition of milk, in which we find the proportion of water to solid parts is as 870 to 130 in 1000 parts, or about as seven to one.

Thirdly, The good effects of water may be destroyed by the substances with which it is taken. Although the stomach has the power of separating water from the food in which it exists, it yet often happens that the fluid articles of diet are injurious. Water itself may contain so large a quantity of saline matters, or of organic matters in a state of decomposition, as to cause serious disease. The taking habitually water in the form of fermented liquors, as beer and wine, as also the admixture of distilled spirits, may cause irritation and congestion of the mucous membranes, and derangement of the nervous system.

We now proceed to speak of the Carbonaceous Group. This class of substances is sometimes called Respiratory and Combustible. They are called respiratory because it is through the function of respiration that they become useful in the system. They are called combustible because it is through the process of combustion that their effects upon the system are developed. This class of foods does not, in fact, contribute directly to the nutrition of the body, but they are consumed in maintaining the animal heat. The temperature of the human body is always a fixed one; and if we place a thermometer upon the tongue, or under the arm, or in any other unexposed part of the body, we shall find that it stands at the point in the index of Fahrenheit's thermometer marked 98°. [HEAT, ANIMAL.] This heat the human body maintains equally at the poles and under the tropics. No external temperature alters it, and we have thus conclusive evidence that it is produced from within. The cause of this heat is the combustion of the carbon and hydrogen contained in the carbonaceous group of foods. Starch, sugar, and oil are conveyed from the stomach into the blood, and whilst in the blood they are brought in contact with oxygen gas, which is taken in during respiration, and the consequence of this contact is the union of the carbon and the hydrogen with the oxygen, the formation of carbonic acid gas and water, and the giving out of heat.

The human body is preserved at the same temperature by the regulating action of the skin. When large quantities of heat are generated in the body, by exercise or other causes, then the extra heat is carried off by the perspiration from the skin; but when the body is exposed to a low temperature, and its heat is rapidly conducted away by surrounding cold, the heat is maintained by increased supplies of food belonging to the carbonaceous group. The animal heat of the lower animals varies according to the circumstances of the creature. Those performing great muscular exertions, and living in cold climates, have a higher temperature than man; whilst those which are not active in their habits, and live in hot climates, have a temperature lower than that of man.

The substances belonging to this group which enter into the food of man are cellulose, starch, sugar, and oil.

Cellulose forming the external membrane of the cells of all plants is found in all food derived from the vegetable kingdom. It has a composition almost identical with starch, but differs in being insoluble and indiffusible in water. There can be little doubt however that it is taken up extensively into the system in the food of the lower animals, especially of the *Herbivora.* When cells are very thick with cellulose they are indigestible, and this will account for many articles of food as carrots, turnips, radishes, uncooked vegetables, &c., not being readily digested. Cellulose is converted into starch by the addition of sulphuric acid, and it is not improbable that some change of this sort may take place when it is taken into the stomach. It is however seldom taken by human beings alone, although recommended by no less an authority than Benjamin Franklin, who showed by example that saw-dust puddings might be used as an article of diet.

Starch enters very largely into the diet of man, and of the lower animals. It is distinguished from cellulose by its ready diffusibility in water. [SECRETIONS, VEGETABLE.] On this account it appears to be much more readily absorbed from the stomach or converted into the forms in which food is taken up into the system. Its property of uniting with water and forming with it at a high temperature a gelatinous mass, explains the change which takes place in boiling the flour of the grains in which it is contained.

Starch is found in some plants in greater quantities than in others; it is however very generally found in perennial roots and rootstocks, in the stems and in the seeds of plants. There are few or no vegetables or parts of plants that are eaten that do not contain starch. It is found in turnips, carrots, potatoes, cabbages, parsnips, beans, peas, wheat, barley, oats, and the rest of the *Cerealia;* in chestnuts, walnuts, hazel-nuts, and all other seeds; in the apple, the pear, the plum, and cherry, and all other fruits. In many of these things however it is not the distinguishing alimentary ingredient, but it is often separated, and is used pure as an article of diet. The substances in which it occurs pure are arrow-root, sago, and tapioca.

What is sold under the name of arrow-root in the shops, is a form of starch procured from the rootstocks of various species of plants belonging to the family *Marantaceæ.* There are three kinds of arrow-root known in the shops, the West Indian and the East Indian arrow-roots, and Tous les Mois. [MARANTA.]

Although there is much difference in the price of arrow-root, its composition is always the same. Even the substances used to adulterate arrow-root, as potato and sago starch, are of the same composition; and though the appearance and flavour of the arrow-root may be impaired, its ultimate dietetical action is the same.

Although arrow-root, sago, tapioca, and potato starch, are all composed of the same constituent, their flavour is very different; hence the preference given to arrow-root as an article of diet. This flavour depends on some peculiar principle which is produced in the plant from which the starch is obtained, and by very careful preparing can be entirely got rid of. Arrow-root is used for making cakes, puddings, and a thick gelatinous fluid in great request in the sick room. It is a property of starch to combine with water at a temperature of 180°, and form a gelatinous compound. This property of starch renders it very useful in cookery, and seems to increase the digestibility of the starch itself.

Arrow-root is frequently regarded as nutritious; but it will be seen that it is not nutritious in the proper sense of that word. Those foods can alone be called nutritious that contribute to the building up of the fabric of the body by adding those materials to the tissues which are being constantly removed by the wear of the body. Now starch does not perform this function, and is entirely consumed in the body in maintaining its animal heat. Arrow-root however and the other forms of starch, are frequently mixed with nutritious matters, such as milk and bread; and in this way the food into which they enter becomes nutritious.

Another form of starch is Sago. It is starch obtained from the inside of the trunks of palms, and other trees. Many plants yield starch in their stems, which, on being prepared, is called sago by Europeans. The sago which is sold in the shops of England is principally imported from the islands of the Indian Archipelago, and is the produce of a palm called the true Sago-Palm, or *Sagus lævis.* There is however another palm belonging to the same genus, the *S. Rumphii* (the Prickly Sago-Palm), which yields the sago that is consumed by the natives of India.

Sago is not generally so carefully prepared as arrow-root, and it is a much cheaper article of diet. Its ultimate action is perfectly the same as arrow-root. It is now often employed by starch-makers to procure the finer kinds of starch used by manufacturers. When thus prepared, it is used to adulterate arrow-root.

Tapioca is another form of starch. It is brought to Europe from South America, and is the produce of a plant known to botanists by the name of *Denipha Manihot*. It is a poisonous plant, and the Indians in the countries where it grows extract a poison from it, which they use to poison their arrows, before they obtain the starch. Cassava, which is eaten by the natives, is procured from the same plant, but is prepared in a different way from tapioca. The starch of tapioca does not differ in chemical composition from that of sago and arrow-root, and it is used in the same way, and for the same purposes.

An Indian family preparing Tapioca. The woman is poisoning an arrow with the juice which exudes from the bag containing the Tapioca.

There are many other well-known plants which owe their dietetical properties to the starch they contain; amongst these we may mention the potato, the carrot, the turnip, the parsnip, the cabbage, the Jerusalem artichoke. From any of these starch might be prepared. The roots of *Arum maculatum*, though acrid, contain much starch. When cooked, the acridity of the plant is got rid of, and they are eaten with impunity. These roots are employed in making the substance called Portland sago, which is the starch separated from the rest of the matter of the plant. This sago is used for the same purposes as the other kinds of sago.

The roots of *Orchis mascula*, which is a common plant of our meadows, form the substance called salep. When it is boiled, it forms an agreeable article of diet, which, before the introduction of tea and coffee, was very generally used in this country. It is now almost entirely disused in Great Britain.

Starch differs in some of its chemical and physical properties according to the plants whence it is obtained. In this way chemists have distinguished several kinds of starch. Inuline is a form of starch obtained from the *Inula Helenium*, a plant not uncommon in our own fields. [INULA.] Lichen-starch is another form, which is found in almost all kinds of *Algæ* as well as Lichens. This starch has the same power of thickening water at a high temperature as arrow-root and tapioca; and hence, when any of these plants are boiled in water, they form a thick mucilaginous decoction. The thickness of the fluid thus obtained, under the erroneous notion of its being nutritious, has led to the use of many species of sea-weeds and lichens as articles of diet.

One of the plants of this kind, which has been used most extensively and is still largely employed, is the Iceland-Moss (*Cetraria Islandica*). It belongs to the family of Lichens, and is a native of the northern parts of the world. This and other lichens probably contain other dietetical secretions besides starch, as we find they are capable of supporting animal life. The Rein-Deer-Moss (*Cenomyce rangiferina*) is an instance of this. In the northern parts of the world as well as in mountainous districts this lichen grows in great abundance, and during the winter season is the principal support of the rein-deer. In spite of the extreme cold to which it is subjected this plant grows with vigour, and the rein-deer, in order to obtain it as food, is obliged to remove with its nose the snow with which it is sometimes covered for many feet. The Cup-Moss (*Cenomyce pyxidata*) of our own moors belongs to the same genus as the rein-deer-moss, and is also used as an article of diet in the same way as the Iceland-moss. The Tripe de Roche is another of these lichens which has been used as an article of diet. It has a melancholy interest attached to it, as it has so often formed the chief article of diet of our arctic navigators. Two species of lichens, the *Gyrophora proboscidea* and *G. erosa*, afford the Tripe de Roche. Although they are said to be nutritious, they are described as having bitter, nauseous, and purgative properties.

Amongst the sea-weeds which have been used as articles of diet none is better known than the *Chondrus crispus*, which under the name of Carrageen-Moss, Irish Moss, and Pearl-Moss has been for a long time used in Europe. [ALGÆ.] It grows on the rocky sea-shores of Europe; and when washed and dried, and then boiled with water, makes a mucilaginous decoction, which, like the same preparation of the Iceland-moss, has been recommended in consumption, coughs, diarrhœa, and other diseases. It has however no bitter principle, and is probably less tonic than the lichen. This and other sea-weeds have been occasionally had recourse to by the poor inhabitants of the sea-shores of Europe, more especially Ireland, when the ordinary corn or potato crop has failed. They contain however but little nutritious matter, and persons soon famish who live upon nothing else. There are certain forms of sea-weed which are often eaten as an addition to other kinds of food. There is in all of them a certain flavour of the sea, arising probably from the saline matter they contain, which renders them very objectionable to some persons as articles of food, and which will probably always form an objection to their general use. Of those which are eaten in various parts of England we may mention:—

1. Laver, Sloke, Slokam (*Porphyra laciniata*). It is on all our sea-shores; and when employed as food is salted and eaten with pepper, vinegar, and oil.

2. Green Laver, Green Sloke, Oyster-Green (*Ulva latissima*). The *Ulva* is not so good to eat as the *Porphyra*, and is only had recourse to when the latter is not abundant.

3. Tangle, Sea-Ware, Sea-Girdles, Sea-Wand, Red Ware (*Laminaria digitata*). It is cooked by boiling for a long time, and adding pepper, butter, and lemon-juice. Cattle are fed on it when young in some parts of the British Islands.

4. Badderlochs, Hen-Ware, Honey-Ware, Murlins (*Alaria esculenta*). The part of the plant which is eaten is the thick middle rib which runs through the frond. It is sometimes called the Eatable Fucus.

5. The Dulse of the south-west of England is the *Iridea edulis* of botanists. It is eaten by the fishermen of the south-west coasts of England, who before eating it pinch it between red-hot irons. In Scotland it is cooked in the frying-pan. It is said to resemble in its flavour roasted oysters.

6. Dulse of the Scotch, Dellisk, Dellish, Duileisg, Water-Leaf (*Rhodomenia palmata*). The Highlanders and the Irish, before the introduction of tobacco, were in the habit of drying this weed and using it as a masticatory. The Icelanders use it as an article of diet under the name of the Sugar-Fucus. In the islands of the Mediterranean Archipelago it is employed as an ingredient to flavour soups, ragouts, and other dishes.

Several other sea-weeds have been employed as food, but these are the principal that are at present used in this country. In China the people are very fond of sea-weeds, and many kinds are collected and added to soups, or are eaten alone with sauce. One of these, the *Plocaria tenax*, is sometimes brought to this country under the name of Chinese Moss. The decoction it makes is so thick that it is used as glue. The Corsican Moss, which has a reputation in medicine as well as a diet, is the *Plocaria Helminthocortos*, and is found on the coasts of the Mediterranean. Another sea-weed was recently imported into London under the name of Australian Moss; but although affording a very thick jelly, it tastes too strongly of the sea to be rendered pleasant by any kind of cooking.

The next dietetical substance of which we have to speak is Sugar. Sugar is distinguished readily from starch by many properties. Sugar is soluble in water, whilst starch is only diffusible through it. Sugar is susceptible of fermentation, and of being converted into alcohol, which starch is not. Sugar has a peculiar sweet taste, whilst starch is insipid. It is on account of the solubility of sugar that we never, or very seldom, find it in plants in a solid condition. It is always dissolved in the water naturally contained in the plants in which it exists. Sugar is not so frequent a product of vegetable change as starch; but is, nevertheless, very generally found during some period of the growth of the majority of plants. [SUGAR.]

Sugar, like starch, is not nutritious, but is taken into the system with the object of maintaining animal heat. Persons may even get fat on sugar, but the living tissues are not nourished by any of the carbonaceous productions of plants. It is true, that in countries where the sugar-cane is grown, slaves and their children, during the period of its gathering, partake of it in large quantities, and are nourished upon it; but the sap of the sugar-cane, and the cane itself, contain other alimentary principles besides sugar, which assist in the uutrition of the body.

Sugar, being readily soluble in water, is more digestible than starch. Of the substances which maintain animal heat, it is the most easily digested; and hence we may see a reason why it is supplied to the young of the higher forms of animals. For this purpose it is secreted, by the female of all the *Mammalia*, in the milk, which is furnished universally to their young during the first months of their existence. The instinctive love of sugar, so well known as a distinguishing character of the child, seems to point out its adaptation to the wants of the infant system. Readily digestible however as sugar is, it is one of those substances which speedily undergoes decomposition. When taken into the stomach and the system, its elements seem to enter into secondary combinations, which are very injurious. This is why so many persons find it necessary to limit the quantity of sugar which they take in their diet. The changes however which it so frequently undergoes in tho adult system, do not appear to take place in children; hence the child may eat sugar with impunity, although its parents may not.

Although there are various kinds of sugar, having a different compositiou, they seem all to act dietetically in the same way upon the system. The most common form of sugar in plants, and that which is most frequently eaten in diet, is Cane-Sugar, so called from its being yielded by the sugar-cane. It consiste of—

	Atoms.
Carbon	12
Hydrogen	9
Oxygen	9
Water	2

The other kinds of sugar which are eaten, are milk-sugar, $C_{24}H_{19}O_{19}+5HO$; and grape-sugar, $C_{12}H_{12}O_{12}+2HO$. It will be seen that cane-sugar resembles starch in its composition, and it is probably formed in the plant from that body. Although cane-sugar is found in the sugar-cane, the beet, and the maple, it is not so frequent in plants as grape-sugar, which is the form in which sugar is found in the fruits and other parts of plants which may be sweet.

The sources of sugar, as an article of diet, are of course very various; it is only separated however from a limited number of plants. Of these the principal is the sugar-cane (*Saccharum officinarum*).

The sugar eaten by the inhabitants of Franco is principally obtained from the Beet (*Beta vulgaris*). In tropical countries it is obtained from the juice of palms, as from the Jaggary Palm (*Caryota urens*), the Cocoa-Nut Palm (*Cocos nucifera*), and others. It exists in the stems of all grasses, and is prepared in America from Maize (*Zea Mays*). The Birch (*Betula alba*) in this country, and the Sugar-Maple in America (*Acer saccharinum*), also yield it in their sap.

Grape-sugar, also called Glucose, is found in the fruits of most plants. It seems to act on the system in precisely tho samo way as cane-sugar.

The result of the fermentation of grape-sugar is the production of Alcohol, which does not differ much in composition from sugar. The following is the decomposition:—

	C.	H.	O.
2 Atoms of Alcohol	8	12	4
4 Atoms of Carbonic Acid	4	0	8
2 Atoms of Water	0	2	2
One Atom of Grape-Sugar	12	14	14

Alcohol is taken as an article of diet in the form of beers, wines, and spirits. Although resembling sugar in its composition, its effects on the system are very different. It acts on the nervous system as a stimulant and narcotic, and might perhaps be regarded as ono of the medicinal forms of food. A question has arisen amongst physiologists as to the action of this substance on the system. Liebig, and with him many others, maintain that like starch and sugar and oil, the elements of the alcohol unite with oxygen in the system, and thus by combustion assist in maintaining animal heat. On tho other hand Dr. Carpenter, and those who repudiate the use of alcohol in diet, maintain that it is not destroyed during respiration, and consequently does not promote animal heat any further than as it stimulates the heart's action.

Alcohol when taken as an article of diet not only acts upon the nervous system, but on account of its chemical action on albumen exerts an injurious influence when taken in large quantities upon the mucous membrane of the stomach. It is thus that when indulged in, it becomes a source of indigestion, and lays the foundation of serious diseases. Taken in small quantities in the form of wine or beer, it seems to exert a favourable influence on the digestive function, and to belong to that class of foods to which spices and condiments are referred. Taken medicinally it is often capable of exerting powerful effects, on account of its rousing action upon the vascular system. It does not seem to be necessary to health, as there are many nations that never use it, and individuals, in countries where it is habitually taken as an article of diet, find their health not materially injured by debarring themselves from its use.

The quantity of alcohol contained in fermented beverages varies very much.

With regard to wines, when the juice of the grape contains large quantities of sugar in comparison with the water, and the fermentation is complete, then the alcohol is abundant, and strong wines are produced; whilst, when the sugar is in small quantities, or the fermentation is incomplete, weak or thin wines are the result. Ports and sherries are strong wines, whilst those of the Rhine are generally weak.

Sweet wines are those in which all the sugar is not converted into alcohol. This is mostly the case with wines made from other fruits besides grapes. Hence the well-known sweetness of what are called British wines. This does not however arise from an imperfect fermentation, but from the acid contained in other fruits not being tartaric acid. One of the most remarkable properties of tartaric acid is that it forms an insoluble salt (the cream of tartar) with potash, which is generally found in fruits; and in wines made from the grape this salt falls to the bottom of the cask, forming the tartar or lees of the wine. But other acids, as citric, malic, and oxalic acids, are not thus precipitated from their solutions, and they remain in wines, giving them a very acid flavour, which would render them unpleasant, unless sugar was added to cover their acidity. Sweet wines are objectionable as articles of diet, on account of the sugar they contain, which, when held in solution in wine, seems more likely to decompose, and thus prove injurious to tho system, than when taken in its pure form. In wines made from other fruits besides grapes, the acid is also liable to objection.

Effervescing wines are those which are bottled before the fermentation is complete, so that a large quantity of the carbonic acid, which would be otherwise got rid of, is retained in solution in the wine, and escapes when the bottle is uncorked. Such is champagne. Effervescing wines are more liable to disagree with delicate stomachs than others, on account of their imperfect fermentation rendering them liable to further change in the stomach; and this state of change is probably communicated to the substances used as food contained in the stomach.

The skins and stalks of the grapes, if not the juice, contain tannin. This substance is a powerful astringent, and its presence seems to be tho cause of the astringent character of many red wines, as port, claret, and others. There is also a difference in the quantity of free tartaric acid contained in wines; and those which have the largest proportion of this constituent have an acid flavour. Some of the wines made from grapes are so sour as to be very unpalatable: this is more especially the case with the poorer white wines of the Rhine.

The quality in which wines differ from each other most is what is called their bouquet, or flavour. It differs in wines made from different kinds of grapes, and differs in the same grape in different districts and in different seasons. It is well known that the vintage of one year produces a better or worse wine than that of another, and this depends on the development of the peculiar flavour of the wine. Liebig says that the bouquet is dependent on an acid which he calls œnanthic, and which, combining with the alcohol, forms an ether which gives the odour and flavour to wines.

The quantity of alcohol contained in wines differs very much. The ports and sherries consumed in England contain the largest quantity. But then much of this is added. It is added in the form of brandy. Brandied wines keep best, but are not the best to drink. Unless wines are naturally strong, they will not keep without the addition of alcohol. Clarets, hocks, and Moselles, are seldom brandied. Some of the hocks do not contain more than seven per cent. of alcohol, whilst port and sherry contain twenty-five per cent.

Ardent spirits, distilled liquors, differ from wine in their having been submitted to distillation after the fermentation, which produces the alcohol. Brandy is distilled from wine; and peach-kernels, or other vegetable matter containing oil of bitter almonds, are added to give it a flavour. All the parts of the plants belonging to the division of the order *Rosaceæ*, called *Amygdaleæ*, contain oil of bitter almonds. Rum is distilled from molasses or treacle in the West India Islands, and pine-apples are added to give a peculiar flavour. Gin is distilled in Holland, from rye; in this country from wheat, the grains of which are allowed to become saccharine, and then fermented. Juniper berries are employed to give the peculiar flavour to gin. Whiskey is distilled from wheat, barley, or oats, treated in the same manner as for gin. Nothing is added to flavour it; but the smoke of the peat, by the aid of which the distillation is effected in both Ireland and Scotland, gives a characteristic flavour to this liquor. Liqueurs belong to this division; they aro distilled spirits containing large quantities of sugar, and are flavoured with all kinds of substances, as celery, bitter almonds, gentian, wormwood, &c.

Beers, Ales, and Porters, differ from wines in the addition of a bitter principle, most frequently the hop, to the fermented liquor. The saccharine matter for fermentation is obtained through barley. The grain of barley is steeped in water, and allowed to germinate. When the starch of the grain is converted into sugar, it is submitted to heat, and malt is formed. The malt is placed in boiling water, and hops added; when cooled, the process of fermentation is allowed to take place, and the beer is completed. When the malt is slightly charred during the process of drying, it gives a dark colour to the beer. It is then called porter. These fluids vary much in strength and bitterness, according to the quantity of malt and hops employed.

Beer is the safest of these beverages for habitual use; but even this may be indulged in too freely, and disease may be the result. Of the various kinds of beer, that which is to be most commended, is the weak form of bitter ale, which is now so generally employed in the households of London and its neighbourhood. Beer acts as a tonic on account of its bitter principle, as well as a stimulant, and is frequently, on this account, found to be a valuable addition to the ordinary diet.

The Oleaginous Group of foods is somewhat peculiar. They are taken in various forms from both the vegetable and animal kingdoms, and are known under the name of butter, oil, lard, suet, fat, &c. The following formula will express the composition of this class of bodies:—

Carbon	11
Hydrogen	10
Oxygen	1

It will be seen that the oxygen is in considerably less proportion than in the foregoing substances of this group, and we may consequently conclude that the hydrogen as well as the carbon is consumed in the system in maintaining the animal heat. This is an important point, as it frequently happens that the value of the heat-giving group of foods is estimated by the quantity of carbon alone. That oil has more power in maintaining animal heat than sugar or starch, is seen in the fact that it is eaten in larger quantities by men who live in cold regions than by those who live in the warmer parts of the earth. Just as we pass north or south from the tropics, man adds oil to his food according to the degree of cold to which he is exposed.

Oil seems also to be deposited in the tissues of man and other animals as a source of combustible materials when these fail in their natural food. Thus the *Ruminantia* get fat in summer to supply them with their winter's store of fuel. Hybernating animals, which are fat when they commence their sleep, wake up quite thin. Their fat has been exhausted in maintaining their animal heat during hybernation. [ADIPOSE TISSUE.]

Oil performs another function in the system. It is very evident from its general presence in every tissue of the body that it has an action in connection with the development of the proteinaceous tissues. It seems to assist their development, to act as a kind of preparation for their growth. In this way its curative action in certain forms of disease may be explained. There is no doubt of the beneficial action of cod-liver oil in scrofulous diseases, and its action can only be explained on the above supposition. In connection with the use of cod-liver oil it may be stated that animal oils appear to be in a different physical condition of aggregation from vegetable oils, and are certainly more readily digested and appropriated by the system.

The vegetable oils chiefly used as food are those obtained from the Olive (*Olea Europæa*) and the Almond (*Amygdalus dulcis*). Many seeds, as the Cocoa-Nut (*Cocos nucifera*), Almond (*Amygdalus*), Chestnut (*Castanea*), Walnut (*Juglans*), Hazel-Nut (*Corylus*), Brazil-Nut (*Bertholletia*), contain oil.

The fat of animals is the great source of oleaginous food from the animal kingdom.

We now come to speak of the Nutritious, Proteinaceous, or Nitrogenous articles of diet. The substance called Protein [PROTEIN] is the basis of these. It is the first element that appears in the development of the vegetable cell. It is consequently universally present in plants. It also constitutes the chief material of the tissues of animals. It assumes in both kingdoms various forms, and is called albumen, fibrine, and casein, according to its physical and chemical properties.

Some animals derive this constituent of their bodies directly from the vegetable kingdom, as all the herbivorous and graminivorous creatures; others derive it indirectly from the plant through the animal, as the various forms of *Carnivora*. Man obtains his supply of protein from both sources. As a sect has arisen of persons who deny the propriety of man's taking animal food, it may be well to examine the evidence on which his claim to be regarded as a flesh-eating animal rests. We shall dismiss the sentimental objection, that life ought not to be taken as unworthy of serious refutation, as every one must feel that for carnivorous animals to prey upon lower animals is a natural law.

"In the first place, the experience of the races and nations of men who partake of animal food is decidedly in its favour. Amongst the northern and European nations this practice is universal; and it is precisely amongst these people that we see the greatest amount of physical power, and moral and intellectual development existing. Amongst these nations, those individuals and classes who partake most largely or exclusively of a vegetable diet, are alike physically, intellectually, and morally degraded. It is a well-established fact, that amongst those classes who get the least animal food, as also in those public establishments where meat is only sparingly allowed, mortality is greatest, and disease is most rife. One of the most common forms of disease generated by an exclusively vegetable diet is scrofula, and when traceable to this cause, the most speedy remedy is the addition of animal food to the diet. There are also many other forms of disease produced by the want of animal food, which require for their cure but an abundant supply of the needed material. I need not, I am sure, specify facts to verify this statement. The experience of every medical man would confirm it; and there is no surgeon or physician connected with the great medical charities of this country, but has every day, unfortunately, ample opportunities of witnessing the ill-effects of a vegetable diet, and the benefit, in such cases, of the administration of animal food.

"Nor are we at a loss in accounting for the beneficial action of the flesh of animals as food. From what I have before said, it will be recollected that the muscles and other tissues of animals are composed principally of protein; so that they truly constitute the most nutritious kind of diet. It has also been found, not alone as a matter of general personal experience, but by direct experiment, that animal food is more digestible than vegetable food. The experiments to which I allude are those performed by Dr. Beaumont of America, on a man that had received a gun-shot wound in such a position as to form a perforation into his stomach. This wound never healed, and enabled Dr. Beaumont to perform the experiments alluded to. By placing various kinds of food in the stomach of this man, he was enabled to ascertain how long each required to digest; and it was found that the flesh of animals was much more digestible than any of the more nutritious forms of vegetable food, as bread, and the preparations of flour.

"Could we not find reasons for partaking of animal food in its nutritiousness and digestibility, we might find ample justification from the structure of man as compared with some of the lower animals. To the comparative anatomist it is sufficient that he knows the structure of the teeth, jaws, or stomach of an animal, to tell whether it fed on vegetable or animal food; and when he finds the structure that characterises the one or the other combined, he likewise knows that the animal will require both kinds of food. Let us, then, for one moment glance at the structure of the teeth, jaws, and stomach of vegetable-feeding animals, and compare them with creatures feeding entirely on animal food. We may take the ruminant animals, as the sheep and the ox, as specimens of pure vegetable-feeding animals. On examining their teeth it will be found that they have broad surfaces, made rough for the purpose of nibbing on each other, and between those teeth the grass and grain they eat are well ground before they are swallowed. In order that these teeth may be moved with facility over each other, the jaw, in addition to the up and down movement, which is essential to the reception of the food into the mouth, has a lateral movement, by which the trituration of the food between the teeth may be effected. The food thus prepared passes down a long œsophagus, or gullet, into a complicated bag or stomach. In the ruminants, though not in all vegetable-eating animals, a process of digestion or maceration is carried on previous to the final mastication of the food between the teeth, and its ultimate digestion in the stomach.

"If we turn now to the structure of flesh-eating animals, of which the *Carnivora*, embracing such animals as the lion and the tiger, may be taken as the type, we shall find that instead of teeth furnished with broad surfaces, they have teeth with sharp points for holding and cutting their food. Their lower jaw has no lateral movement, but a powerful up and down action, by which their sharp teeth are brought over each other and made to act in dividing their food, something in the way of the blades of a pair of scissors when used in cutting. In passing to the stomach, we find the gullet short, and the stomach small and simple in its form, adapted for food that is readily digested and speedily conveyed into the system.

"On an examination of these organs in man, it will be found that they are a true mixture of these two classes. His teeth are partly adapted for grinding, whilst some of them are supplied with the sharp projections which are characteristic of the *Carnivora*; thus evidently adapting them for the mastication of both vegetable and animal food. A slight lateral movement of the lower jaw with the up and down action is expressive of the subserviency of his structure to a mixed diet. In the stomach also we find indications of the same intermediate position in its structure; and the same conclusion is forced upon us, that it is part of the apparatus of an animal intended for subsisting upon a diet composed of animal and vegetable substances.

"That man can live on food derived entirely from plants, or entirely from animals, is a well-known fact. The natives of many parts of Asia never eat animal food, whilst the Hudson's Bay hunter, some tribes in the northern parts of the world, and the Guachos of the Pampas of America, seldom or never have vegetable food; but neither the physical, moral, nor social condition of either the one or the other would prompt the suggestion that man attains his highest development exclusively on either vegetable or animal diet. In the various positions in which man is placed in the world, there can be no doubt that the relative quantities of flesh to food derived from plants, may vary much with great advantage; but there seems to be no position in which man in health can be pronounced to be the better with abstinence from either the one or the other kind of food. That man does subsist on either exclusively only proves the great range of his adaptation to the varying conditions in which he may be placed on the surface of the earth; but certainly it is no proof of his labouring under a necessity for the supply of one to the exclusion of the other." (Lankester, 'Letters on Diet.')

Of the three forms of protein referred to above, fibrine is found in the flesh and blood of all animals, as gluten in wheat, barley, oats, rye, and the other *Cerealia*. Albumen is found in the juices of many plants, as cabbage, cauliflower, asparagus, &c.; it is also found in the nervous system and blood of animals. Casein is present in milk, also in the seeds of leguminous plants, as peas, beans, and lentils.

In the animal body is found a substance called Gelatin, which appears to be formed out of the proteinaceous tissues. [GELATIN.] This substance is necessary to the existence of the animal body, and what cellulose is in the vegetable kingdom, gelatin appears to be in the animal kingdom. Although often taken into the system with animal food, especially in soups and jellies, there appears to be no evidence that it is even converted into a proteinaceous tissue. Experiments on this subject have been performed both in France and Belgium on an extensive scale, and the conclusion arrived at was the same, that gelatin is not used for forming any of the proteinaceous tissues of the body; at the same time it is not improbable that the gelatin may be appropriated for the purpose of renewing the gelatinous portions of the tissues, which are very extensive in the animal body.

It will be thus seen that although gelatin cannot be said to be nutritious in the sense of nourishing the actively vital parts of the body, it may assist in keeping up certain parts of the fabric. It need not then be rejected from our food; but it cannot be too widely known, that, as the basis of soups and jellies, it may be administered under the supposition of its being nutritious, and thus lead, if used alone in diet, to disastrous results.

Of the forms of protein which occur in food, Casein demands a short notice. Although, as dissolved in milk, it is very digestible, it becomes, when separated and known by the name of cheese, very indigestible. When milk is deprived of its butter, and the pure casein made into cheese, as is the case with some English cheeses, as those from Suffolk, it becomes so hard as scarcely to be digestible. [CHEESE, in ARTS AND SC. DIV.] But in most cases the casein is curdled with the butter, and a large per-centage of this substance is found in all good cheeses. Stilton cheese is made by adding the cream of one milking to that of another, so that this cheese has double the quantity of butter that other cheeses possess. The indigestibility of separated or insoluble casein will perhaps explain the neglect of beans, peas, and lentils, as articles of diet, although they contain a much larger quantity of nutritious ingredients than most seeds.

In concluding these general remarks upon diet, we present our readers with a summary of the conclusions on this subject arrived at by one of our most recent physiological writers. Dr. Carpenter, in his 'Principles of General and Comparative Physiology,' thus concludes this part of his subject:—

"The waste of the tissues, of which gelatin is the basis, may be supplied either by albuminous, proteinaceous, or gelatinous compounds, since there is no doubt that albumen may be converted into gelatin, although the reverse process cannot be performed. As gelatin does not exist in plants, it must be formed in herbivorous animals at the expense of the albuminous elements of their food; whilst in carnivorous animals it is probably derived immediately from the gelatinous components of the bodies on which they prey. The materials of the adipose tissue, and the oleaginous particles which seem requisite in the formative operations of the system, generally are derived in the carnivorous races from the fatty substances which the bodies of their victims may contain; whilst the herbivorous not only find them in the oleaginous state in their food, but have the power of producing them by the conversion of farinaceous and saccharine matters.

"The foregoing statements are applicable to all tribes of animals 'cold-blooded' as well as 'warm-blooded.' We have now to consider the special case of the latter. In the carnivorous tribes the waste of the tissues is so great, in consequence of the restless activity which is habitual to them, that it appears to furnish a large proportion of the combustible material required for the maintenance of their proper temperature. The remainder is made up by the fat of the animals on which they feed; and it is to be observed that the amount of this is much greater in the bodies of animals inhabiting the colder regions of the globe than in the inhabitants of tropical countries. In the herbivorous tribes the case is different: they are for the most part much less active; and the waste of their tissues consequently takes place in a less rapid manner, and is far from supplying an adequate amount of combustible material, especially in cold climates. Their heat is in great part sustained by the combustion of the saccharine and oleaginous elements of their food, which are appropriated to this purpose without having ever formed part of the living tissues; and the demand for these will be larger in proportion to the depression of the external temperature, a greater generation of caloric being then required to keep up the heat of the body to its proper standard. Hence, cold-blooded animals can usually sustain the privation of food longer than warm-blooded, and this more especially when they are kept cool, so that they are made to live slowly, and death when at last it does ensue is consequent upon the general deficiency of nutrition. On the other hand, warm-blooded animals, whose temperature is uniformly high, must always live fast, and deprivation of food is fatal to them, not only by preventing the due renovation of their tissues, but also by destroying their power of sustaining their heat. The duration of life under these circumstances depends upon the amount of fat previously stored up in the body, and upon the retardation of its expenditure by external warmth, or by the inclosure of the body in non-conducting substances; and there is evidence that if this be duly provided for, and all unnecessary waste by nervo-muscular activity be prevented, the life even of a warm-blooded animal may sometimes be prolonged for many weeks without food."

It will be gathered from the foregoing general remarks that food may be divided into two great classes—the heat-giving and the flesh-forming; and we now present a table of some of the more ordinary kinds of food, in which one or the other, or both, of these classes of substances are found mixed:—

Table of Composition of Food in 100 parts.

Food.	Quantity of Nitrogenous Flesh-forming Ingredients.	Quantity of non-Azotised Heat-giving Principles.	Quantity of Mineral Matter.	Quantity of Carbon.
Milk	4·50	7·90	0·60	6·94
Butcher's Meat free from bone	22·30	14·30	·50	21·56
Bacon, Pork	8·36	62·50	0·50	53·92
Fish	14·00	7·00	1·00	9·15
Flour	17·00	66 00	0·70	45·50
Barley Meal	14·00	68·50	2·00	40·50
Oatmeal	13·60	70·30	3·30	44·10
Indian Meal	10·71	72·25	1·04	36·41
Peas	23·40	60·00	2·50	35·70
Rice	5·43	84·65	0·52	36·00
Potatoes	1·41	22·10	1·00	12·20
Carrots	1·48	11·61	0·81	5·40
Turnips	1·64	10·00	1·62	5·20
Parsnips	2·10	17·70	0·80	8·63
Mangel Wurzel	1·60	12·26	1·14	5·50
Cabbage	1·75	4·05	2·20	2·65
Cocoa (nibs)	9·56	85·76	2·70	68·56
Sugar	0·00	100·00	0·00	42·58
Suet, Fat, Butter	0·00	100·00	0·00	79·00
Bread	6·83	48·65	1·51	25·19
Cheese	31·02	25·30	4·90	36·80
Beer	·85	9·17	0·20	4·33
Vinegar				

100 grains of Tea give in an infusion 5 grains of theine and 26·5 grains of non-nitrogenous substances. (Peligot.)

By adding the first three columns of this table together, and deducting the sum from one hundred, it will give the quantity of water contained in each article of food. Thus, taking butcher's meat:—

Nitrogeneous material	22·3
Carbonaceous material	14·3
Mineral Matter	·5
	37·1
Water	62·9
	100·0

The quantity of carbon expresses the relative heat-giving power of the food. With foods containing fat the quantity of hydrogen should also be taken into consideration.

Such a table as this will be found useful in constructing dietaries for large institutions, which are very often erroneously constituted, and a large waste thereby entailed. The table on the next page contains examples of dietaries, drawn up by Dr. Lyon Playfair, from various sources. This table accompanied an abstract of a lecture by Dr. Lyon Playfair on the 'Food of Man,' delivered at the Royal Institution in May 1853. The following extracts from this lecture will explain some of the valuable results obtained by Dr. Playfair:—

"It was now admitted that the heat of the body was due to the combustion of the unazotised ingredients of food. Man inspires annually about 7 cwt. of oxygen, and about 1-5th of this burns some constituent and produces heat. The whole carbon in the blood would thus be burned away in about three days unless new fuel were introduced as food. The amount of food necessary depends upon the number of respirations, the rapidity of the pulsations, and the relative capacity of the lungs. Cold increases the number of respirations and heat diminishes them; and the lecturer cited well-known cases of the voracity of residents in arctic regions, although he admitted, as an anomaly, that the inhabitants of tropical climates often show a predilection for fatty or carbonaceous bodies. He then drew attention to the extraordinary records of arctic dietaries shown in the table, which, admitting that they are extreme cases even in the arctic regions, are nevetheless very surprising.

"Dr. Playfair then alluded to the second great class of food ingredients, namely, those of the same composition as flesh. Beccaria in 1742 pointed to the close resemblance between these ingredients of flesh, and asked, 'Is it not true that we are composed of the same substances which serve as our nourishment?' In fact the simplicity of this view is now generally acknowledged; and albumen, gluten, casein, &c., are now recognized as flesh-formers in the same sense that any animal aliment is.

"The old mode of estimating the value of dietaries, by merely giving the total number of ounces of solid food used daily or weekly, and quite irrespective of its composition, was shown to be quite erroneous; and an instance was given of an agricultural labourer in Gloucestershire, who in the year of the potato famine subsisted chiefly on flour, consuming 163 ounces weekly, which contained 26 ounces of flesh-formers. When potatoes cheapened he returned to a potato diet, and now eats 321 ounces weekly, although his true nutriment in flesh-formers was only about 8 or 10 ounces. He showed this further by calling attention to the six pauper dietaries formerly recommended, to the difference between the salt and fresh meat dietary of the sailor, &c., all of which, relying on absolute weight alone, had in reality no relation in equivalent nutritive value.

"Taking the soldier and sailor as illustrating healthy adult men, they consumed weekly about 35 ounces of flesh-formers, 70 to 74 ounces of carbon, the relation of the carbon in the flesh-formers to that of the heat-givers being 1 : 3. If the dietaries of the aged were contrasted with this it would be found that they consumed less flesh-formers (25—30 ounces), but rather more heat-givers (72—78 ounces); the relation of the carbon in the former to that of the latter being about 1 : 5. The young boy about 10 or 12 years of age consumed about 17 ounces weekly, or about half the flesh-formers of the adult man; the carbon being about 58 ounces weekly, and the relations of the two carbons being nearly 1 : 5½. The circumstances under which persons are placed influence these proportions considerably. In workhouses and prisons the warmth renders less necessary a large amount of food fuel to the body; while the relative amount of labour determines the greater or less amount of flesh-formers. Accordingly it is observed that the latter are increased to the prisoners exposed to hard labour. From the quantity of flesh-formers in food we may estimate approximately the rate of change in the body. Now, a man weighing 140 lbs. has about 4 lbs. of flesh in blood, 27½ lbs. in his muscular substance, &c., and about 5 lbs. of nitrogenous matter in the bones. These 37 lbs. would be received in food in about eighteen weeks; or, in other words, that period might represent the time required for the change of the tissues, if all changed with equal rapidity, which is however not at all probable.

"All the carbon taken as food is not burned in the body, part of it being excreted with the waste matter. Supposing the respirations to be 18 per minute a man expires about 8·59 ounces of carbon daily, the remainder of the carbon appearing in the excreted matter."

Examples of Dietaries.

The substances used as food which we have called medicinal are very numerous. They include acids, volatile oils, and the vegetable alkaloids.

The acids are eaten in fruits, such as the citric, malic, tartaric, and oxalic acids. It is possible they may be decomposed in the system, and furnish the materials of animal heat. They seem however to perform a more important part in dissolving up the mineral ingredients taken into the system as food. This seems one way in which carbonic acid acts beneficially when taken in wines, beers, and effervescing waters. Acetic acid, or vinegar, acts probably in the same manner as the other acids.

The volatile oils are added to other kinds of food, and, as condiments and spices, form a conspicuous feature in diet. We may class these, with alcohol, as stimulants of the mucous membrane of the stomach.

The use of tea, coffee, chocolate, and Paraguay tea [THEA; COFFEE; ILEX; THEOBROMA] in infusion constitutes a curious class of alimentary substances. In tea, coffee, and Paraguay tea, a principle is found identical in every instauce, to which the name Thein or Caffein has been given. A substance very similar, Theobromine, is found in chocolate. It is undoubtedly upon the action of these substances that the dietetical uses of these plants depend.

Two theories have been advanced to explain the action of this principle. Liebig suggested that the taurin found in the bile was formed from the waste tissues of the body carried into the blood; and that this taurin was necessary for the production of carbonic acid gas, or rather to get rid of the carbonaceous matter in the system in the form of carbonic acid gas. The taurin must be constantly formed, otherwise the heat of the body is not maintained, the carbonaceous matter not got rid of, and disease is engendered. If persons have not sufficient food, or if the digestive organs do not enable them to carry a sufficient quantity of nutriment to the system, the tissues of the body are consumed to form taurin. Liebig found that thein had a composition identical with taurin, or so nearly as to render it a sufficient substitute for taurin, and thus by the use of thein he supposed we were actually preventing the waste of the body, and so maintaining health at less expense than we could by taking more solid food.

Persons who cannot consume a sufficient quantity of food to yield the carbon necessary for generating animal heat, have recourse to tea, and find it actually a nutritious article of diet; and it is only, says Liebig, "by such means as this that it can act as a nutritious agent." But another theory has beeu advanced by Dr. Playfair. He says thein has a composition very similar to nervous matter. Now, seeing that every operation of the miud must be attended with a loss of nervous matter, there is a necessity for a supply of that nervous matter to enable the mind to carry on its operations. A large quantity of proteinaceous matter would be required to be supplied to form the nervous matter with proper constituents if taken iu by means of meat or bread. But these alkaloids at once become a constituent of nervous matter; and this accounts for the agreeable stimulus and permanent effect on the mind produced by the use of tea and coffee, particularly by studious persons, as well as those whose nervous systems are exhausted from various causes.

In any just estimate of diet the mineral ingredients should be considered. The forms which they assume in the system are not well-known, but we have a capital instance in the phosphate of lime, which, forming a part of the bones, we know must be supplied through the diet. This substance is fouud in the cereal grasses, and perhaps one reason that man takes these grasses every where for the substantive articles of his diet is the possession of this substauce. Iron is another substance which is frequently deficient in the blood. It is naturally supplied in the food; but this failing, iron is given medicinally. Potash in combination with vegetable acids seems to have the power of preventing scurvy. [SCURVY, in ARTS AND SC. DIV.] Chloride of sodium is another well-known iustance of the necessity of mineral ingredients in the food.

A few plain rules for taking food will properly conclude this article.

In the first place, food should be properly cooked. Many substances which are very iudigestible when in the raw state are rendered perfectly digestible by cooking. Although the stomach is capable of digesting fruits and some kinds of seeds without any exposure to heat, yet, as a general rule, the breaking down of the tissues which occurs in cooking greatly facilitates the digestion of both animal and vegetable food. But whilst that cooking is proper which enables the stomach more easily to reduce the food to the condition of chyle, there are extremes of preparation which however palatable are to be avoided. Food that is much prepared, so as to reduce it to a fluid condition, as soups, stews, and various made dishes, do not present sufficient solid matter for the healthy process of digestion to be carried on. When the object is to prevent the stomach from doing duty such food is proper. It may also be taken occasionally with advantage as a variety in diet, but food taken long together in this form is injurious.

Much indigestible food at a time should be avoided. Many of the articles of our diet are less digestible than others, and when taken in small quantities are not injurious. It is when such substauces are made the principal constituents of a meal that danger is likely to arise. To mention only a few of the less digestible kiuds of foods :—Unfermented bread and biscuits, uncooked vegetables eaten as salad, unripe fruits, cheese, pie-crust, fat meats smoked, as bacon, and the fat of meat, some kinds of fishes, especially the *Crustacea*, crabs, lobsters, &c. Heavy meals of any one of these articles of diet, or mixtures of them, may be very injurious, and produce serious attacks of indigestion, if not other diseases.

Solid food should be well masticated before it is swallowed. The teeth are organs given us on purpose to perform this function, and its accomplishment is atteuded also with the mixture of the saliva with the food, which seems to be au important step in the process of digestion. Although by hasty mastication persons in business hope to save their time, they should know that at least it is a loss of food, if not immediately a loss of health. Much more food is digested when it is well masticated than when it is swallowed very hastily in large masses. Food that is imperfectly masticated is digested with difficulty, and remaius sometimes so long iu the stomach as to produce irritation of the stomach, and remaining uuacted upou it putrifies, producing pain and tainting the breath.

Eveu where mastication is very complete it is always better to swallow slowly, as by this means every part of the food is brought more fully under the influence of the gastric acid of the stomach, by which it is prepared for absorption into the blood.

Full and heavy meals should be avoided. It is better to get up from table with an appetite than to feel that no more food could be taken. It is always difficult to say how much should be with propriety taken. Some systems will bear twice as much food as others, whilst there are those who require twice as much food as others. Scales and weights are dangerous instruments at table, as some men will starve on what others will thrive. There is an iustinct which, if obeyed, constantly cries "Hold, enough;" which if men would listen to would always guide them right. The feelings after eating should be those of refreshment and comfort—feelings that are not ofteu present when too large a meal has been eaten. All food taken into the system and not wanted is likely to be in the way, and the processes adopted by nature for getting rid of the incubus are not unfrequently attended by disease aud death.

Persons who habitually over-eat are frequently obliged to have recourse to medicines to correct the errors of their indulgence. Such an unnatural way of correcting the evils of an unnatural habit is itself likely to produce disease in the system.

Active bodily exertion should not be taken immediately after the principal meal. The stomach requires a supply of blood to perform its functions. If the current is diverted to other organs digestion is prevented. On this account readiug at meals is an objectionable practice. The brain in this process gets the blood which the stomach requires. Long walks and hard study should both be avoided after a full meal.

Long fastiug is bad. It is bad when the body is resting; it is much worse when the body is actively engaged. The stomach, like all other organs, performs its functions iu virtue of the stimulus afforded it by the blood. If the blood is allowed to go a long time without a renewal of its constituents it no louger supplies the nervous system with energy; the stomach, and eveu other organs, flag in the performance of their duty, and as a consequence digestion is imperfectly performed. How often should man eat iu the day? In the morning, at noon, and at night, is the answer given by the instincts of man.

The body can go longer without food whilst resting than when awake; hence persons may with safety go a louger number of hours between the night and morning meal than betwecu the morniug and noon, or the noon and night meals.

There are no rules without exceptions in certaiu cases, and there are many circumstances which must modify the applicatiou of the foregoiug rules, as well as in other ways regulate the taking of food.

Age is a perpetually-modifying influeuce. The uew-born iufant requires the food which nature has provided for its use every hour or two. As it grows older the intervals at which it takes its food become longer; but it should be always recollected, that as a rule children should have more eating times thau adults. Grown-up people are too apt to assume that what is good for themselves is good for children; hence as great an amount of suffering is entailed on children by restricting the quantity and times of taking their diet amongst the rich as come upon them from absolute want amongst the poor. The craving appetite of children is no vice of fallen human nature, but the incessant demands of au ever-wasting yet ever-growing human body. Bread and butter, or treacle, or common cake, should always be allowed if asked for by rapidly growing boys aud girls between the hours which adults find conveuient for their meals. An evil however arising out of the healthy appetite of youth should be guarded against; it is, that whilst growiug a habit is acquired of eating large quantities of food which are no longer required when growth has ceased. If the appetite is not checked by reason at this period of life, the habit of eating more than is necessary may be productive of evil results.

Old age requires a more frequeut recourse to food thau the adult, though not in so large a quantity. "A little aud ofteu" is a maxim that enables many aged persous to continue their influence in the world, whilst an attempt to maintain the habits of youth and middle age has cost many declining ones their lives.

The mode of life influences the diet. The sedentary, the inactive, do not consume so much muscle and nerve in their existence as the active and laborious, and accordingly require less food. The tailor ought not to eat so much as the day-labourer; and the lady all day in her drawing-room or carriage cannot expect the appetite or the enjoyment of food which is bestowed by the laws of nature on her housemaid.

Other things being the same, more food is required in winter than in summer, more in cold climates than in hot ones. This arises from the greater consumption of certain parts of the food in maintaining the animal heat in order to keep off the external cold. Hence, to bring the appetite of Christmas to the Midsummer meal is to run the hazard of a surfeit; whilst the traveller who carries the eating habits of the north to countries under the line frequently perishes of fevers brought on by repletion.

FOOL'S-PARSLEY. [ÆTHUSA.]

FOOT. [SKELETON.]

FOOT-PRINTS, impressions of the feet of Reptiles, as of *Cheirotherium* [AMPHIBIA], and Birds (*Ornithichnites*), are now become recognised evidence of the existence of particular races of organic beings, in certain geological periods, though no other traces of them remain. By this evidence, the air-breathing *Vertebrata* appear to be of higher antiquity than was formerly supposed, and to date from the lower parts of the Silurian system.

FORAMINIFERA (*Foramen*, *fero*), a group of minute Marine Animals of low organisation, consisting of a slimy transparent jelly, invested with a hard, usually calcareous shell; found in sea-sand and amongst marine refuse dredged up from deep water. Owing to many of their shells having a spiral form, these creatures were long thought to be highly organised *Mollusca*, allied to the living *Nautilus* —an error into which most naturalists fell until recently, when these animals became the subject of a more rigorous and searching investigation than they had previously undergone.

Though usually very minute, their elegant forms early attracted the attention of naturalists. They were noticed by Gualtieri, Planchus, and Ledermuller, prior to the appearance of the 'Systema Naturæ' of Linnæus. In the latter work they are included amongst the *Nautili*, the animal, as well as that of the recent *Nautilus pompilius* with which Linnæus associates them, being alike unknown to the Swedish naturalist. In the 12th edition are descriptions of 15 species. In 1780 Soldani, an Italian priest, published two elaborate works, abundantly illustrated, and largely devoted to the recent and fossil forms of Foraminiferous Shells. He divides them into groups (such as *Nautili*, *Hammoniæ*, and *Orthocerata*) in the most arbitrary manner; but the works are monuments of his labour and perseverance. In 1784 some of the British species were figured by Walker in his 'Testacea Minuta Rariora.' The 'British Conchology' of Montague, 1803 (and 'Supplement,' 1808), contained a still larger number of British forms, respecting the majority of which the error of Linnæus was still followed; but some were shown to be so different from the true *Nautili* as to require removing from that genus. In 1803 Fichtel and Moll figured many of the spiral forms, which they included amongst the *Nautili*. In 1808 De Montfort attempted to subdivide the group into a number of separate genera, but still regarded them as *Cephalopoda*, in which view he was followed by Fleming and other more recent writers.

In 1826 the study of the *Foraminifera* received a fresh impulse from the labours of M. D'Orbigny, a French naturalist, who in that year presented his first memoir on the subject to the French Academy. This memoir embraced the classification of the whole of the Cephalopodous *Mollusca*, or animals allied to the Cuttle-Fish; with which group of organisms D'Orbigny, like his predecessors in the study, imagined the *Foraminifera* to have the closest affinities. He divided the latter into five great families, which were again subdivided into a number of genera, most of them new; the various forms being thus thrown into natural groups in a way that had not previously been attempted even by De Montfort. Though D'Orbigny retained the erroneous idea of his predecessors as to the zoological relation of the *Foraminifera*, this error did not affect the value of his subdivisions of the class, which constituted an important step in advance of all that had been done by others. Indeed the value of his classification is shown by its retention in the writings of all who have succeeded him in the study. He distributed the species into 55 genera, introducing into the catalogue an enormous number of new forms, which he discovered in sands brought to him from various parts of the globe. The views of D'Orbigny and his predecessors respecting the Molluscous character of these animals were sanctioned by Cuvier in an edition of the 'Animal Kingdom,' published in 1828.

In 1835 M. Dujardin presented a memoir to the 'Annales des Sciences Naturelles,' based upon an examination of the recent animals of the *Foraminifera*, in which he rejected the idea that they had any affinities with the *Mollusca*. He pointed out the fact that the animal which tenanted the calcareous shell was a mere animated slime, having no visible organisation, and consequently very different from the highly organised *Cephalopoda*, with which they had previously been associated. He considered their true zoological position to be near the *Amœba*, commonly known as the Proteus Animalcule, and that they constitute part of a larger group, to which he assigned the name of *Rhizopoda*. In 1834 and 1839 Professor Ehrenberg presented two memoirs to the Academy of Berlin, in which he advocated the opinion that the *Foraminifera* were polype-bearing animals, allied to the *Flustræ* and other Moss-Corals, by him termed *Bryozoa*, and of which they formed the first order, *Polythalamia*. He also assigned to them internal organs which no other observers have been able to discover: but notwithstanding these errors he did good service by the discovery that the White-Chalk Rocks were principally composed of the aggregated shells of *Foraminifera*, which by their gradual accumulation had thus produced widely-extended masses of calcareous strata, many hundreds of feet in thickness. The existence of numerous Fossil *Foraminifera* in the Chalk had been demonstrated by Mr. Lonsdale in 1835; and still later, the rich harvest of beautiful forms to be obtained from these Cretaceous strata was further demonstrated by M. D'Orbigny in his monograph 'On the Foraminifera of the White Chalk.'

In 1845 Professor Williamson published a memoir in the 'Transactions of the Literary and Philosophical Society of Manchester,' in which he further demonstrated the entire absence of any real resemblance between the *Foraminifera* and the *Cephalopoda*, and the consequent necessity of arranging the former in an inferior portion of the zoological scale. At first he adopted the idea of Ehrenberg, but in a subsequent memoir (1848) he came to the conclusion that they were not polypiferous, but that they approximated to the Sponges on the one hand, and, as had been asserted by M. Dujardin, to the *Amœba* on the other: their true position in any linear arrangement being immediately above the former of these classes of objects. In another memoir, read in 1851, describing the complicated structure of some forms of the genus *Orbiculina*, Professor Williamson says, "Looking at the structure of the shell of the *Orbiculina adunca*, and especially at the large orifices which communicate between its various cavities, we cannot fail to observe that it is a reticulated calcareous skeleton, whose proportionate relation to the size of the soft animal has differed but little from that of the siliceo-keratose network of many sponges to the slimy substance with which they are invested. The attempt to isolate the various portions of *O. adunca*, and raise each portion to the rank of an individual animal, even in the limited sense in which we should admit such a distinction in the polypes of a *Sertularia* or of a *Gorgonia*, appears to me wholly inadmissible. If the soft structures of *Orbiculina* are as devoid of visible organisation as those of our British *Foraminifera*, and I have very little doubt that such will prove to be the case, the whole animal will be very little raised above the *Polypifera*, only possessing a symmetrical calcareous skeleton, which is at once both external and internal." ('Transactions of the Microscopical Society of London.')

In 1846 M. D'Orbigny published his work 'On the Fossil Foraminifera of the Tertiary Basin of Vienna,' in which he abandoned the views advocated in his earlier writings. He now recognised the inferiority of these objects to the Cephalopods, with which he had previously arranged them. He rejected the idea that they were aggregated creatures, as held by Ehrenberg, as also the existence of the intestinal canal and organs of reproduction described by the illustrious Prussian; but he arrived at the conclusion that they held a position intermediate between the *Polypifera* and the *Echinodermata*.

M. D'Orbigny says, "After what has preceded upon the characteristics of the *Foraminifera*, the comparison demonstrates that they cannot be arranged in any of the known Zoological Classes. Much less complex than the *Echinodermata* or the *Polypifera* as to their internal organisation, they have through their filaments (pseudopodia) part of the mode of locomotion of the former, and are by their isolated, non-aggregated, free existence, more advanced in the scale than the latter. This individual existence of the *Foraminifera*, the liberty which they enjoy, and their mode of locomotion, are characters which deserve to be taken into consideration. Although less complex than many *Polypifera*, they have not a common aggregate life. A multitude does not unite to form a regular body as amongst the *Polypifera*. They are locomotive, which the others are not. Their means of locomotion are complex, and the great regularity of the testaceous envelope of their segments places them far above the *Polypifera*. On the other hand, much less perfect than the *Echinodermata*, they are very inferior to them in all respects. We believe also that, because of the radiation of their filaments, the position of the *Foraminifera* is in the interval (embranchement) of the radiating animals of Cuvier, between the *Echinodermata* and the *Polypifera*, as an altogether independent class." ('Sur les Foraminifères Fossiles du Bassin Tertiaire de Vienne,' p. 19.)

There can be no doubt of their great inferiority to the *Echinodermata*, which possess a distinct alimentary canal, a nervous circulating and sexual system; and connecting with the defined digestive cavity of the polype recent discoveries respecting its reproduction by ova, through the agency of medusiform buds, we must conclude that these latter are equally removed from the structureless animals of the *Foraminifera*. In the preceding argument M. D'Orbigny forgets that the freedom, isolation, and independence, upon which he lays so much stress, are the characteristics of the fixed compound *Polypifera*, in their embryonic or larval states. Consequently this feature, which in the *Foraminifera* is normal and persistent, betokens inferiority rather than superiority to the *Polypifera*, in which aggregation and fixation indicate maturity and a higher development. The argument drawn from their symmetry is of no value. Nothing can be more symmetrical than many of the sponge spicula; and in the vegetable kingdom the symmetrical plants (*Desmideæ*) are amongst the lowest forms.

An additional memoir by Professor Williamson, in 1851 ('Quarterly Journal of Microscopical Science,' vol. i.), afforded other and still more striking evidence of the probable correctness of the views previously enunciated, as furnished by the structure of a species of *Faujasina*, and especially showed that the new growths which added to the thickness of the shell were all applied to its exterior and not to its interior, apparently indicating that the gelatinous animal had the power of extending itself over the exterior of the shell, or of retreating to its interior at will, reminding us of the movements of the gelatinous envelope in some of the less highly organised Fungiform Corals. (Rymer Jones, 'Animal Kingdom,' p. 19.) In 1845 Dr. Carpenter laid before the Geological Society of London an elaborate memoir on the structure of some interesting fossil forms belonging to the genera *Orbitoides* and *Nummulina*, which, with the publication of M. D'Orbigny on the *Foraminifera* of Cuba, constitute the chief additional works that have appeared on this subject.

The following is the latest classification of the *Foraminifera* adopted by M. D'Orbigny, and though marked by some serious imperfections, it is the best that has been hitherto published. The five principal divisions are chiefly based on the variations in the arrangement of the successively added segments.

Order 1. *Monostega.*—Animal consisting of a single segment. Shell composed of a single chamber. Genera: *Gromia*, Dujardin; *Orbulina*, D'Orbigny; *Oolina*, D'Orbigny.

Order 2. *Stichostega.*—Animal consisting of segments arranged in a single line. Shell composed of chambers superimposed linearly on a single straight or curved axis. No spiral growths:—

Glandulina, D'Orbigny.	*Rimulina*, D'Orb.
Nodosaria, Lamarck.	*Vaginulina*, D'Orb.
Orthocerina, D'Orb.	*Marginulina*, D'Orb.
Dentalina, D'Orb.	*Conulina*, D'Orb.
Frondiculana, Defrance.	*Pavonina*, D'Orb.
Lingulina, D'Orb.	*Webbina*, D'Orb.

Order. 3. *Helicostega.*—Animal consisting of segments arranged in a spiral. Chambers piled up or superimposed on one axis, forming a spiral volute:—

Cristellaria, D'Orb.	*Alveolina*, D'Orb.
Flabellina, D'Orb.	*Rotalina*, Lamarck.
Robulina, D'Orb.	*Globigerina*, D'Orb.
Fusulina, Fischer.	*Planorbulina*, D'Orb.
Nonionina, D'Orb.	*Truncatulina*, D'Orb.
Nummulina, D'Orb.	*Anomalina*, D'Orb.
Assilina, D'Orb.	*Rosalina*, D'Orb.
Siderolina, Lamarck.	*Valvulina*, D'Orb.
Hanerina, D'Orb.	*Verneuilina*, D'Orb.
Operculina, D'Orb.	*Bulimina*, D'Orb.
Vertebralina, D'Orb.	*Uvigerina*, D'Orb.
Polystomella, Lamarck.	*Pyrulina*, D'Orb.
Peneroplis, Lamarck.	*Faujasina*, D'Orb.
Dendritina, D'Orb.	*Cauderina*, D'Orb.
Spirolina, Lamarck.	*Chrysalidina*, D'Orb.
Cyclolina, D'Orb.	*Clavulina*, D'Orb.
Lituola, Lamarck.	*Gaudryna*, D'Orb.
Orbiculina, Lamarck.	

Order 4. *Entomostega.*—Animal composed of alternating segments forming a spiral. Chambers piled up or superimposed upon two alternating axes, forming a spiral:—

Robertina, D'Orb.	*Heterostegina*, D'Orb.
Asterigerina, D'Orb.	*Cassidulina*, D'Orb.
Amphistegina, D'Orb.	

Order 5. *Enallostega.*—Animal composed of alternately arranged segments without forming a spiral. Chambers disposed alternately along two or three distinct axes, not forming a spiral:—

Dimorphina, D'Orb.	*Textilaria*, Defrance.
Guttulina, D'Orb.	*Vulvulina*, D'Orb.
Polymorphina, D'Orb.	*Bolivina*, D'Orb.
Virgulina D'Orb.	*Sagrina*, D'Orb.
Bigenerina, D'Orb.	*Cuneolina*, D'Orb.
Gemmulina, D'Orb.	

Order 6. *Agathistega.*—Animal composed of segments wound round an axis. Chambers wound round a common axis, each one investing half the entire circumference:—

Uniloculina, D'Orb.	*Cruciloculina*, D'Orb.
Biloculina, D'Orb.	*Articulina*, D'Orb.
Fabularia, D'Orb.	*Sphæroidina*, D'Orb.
Spiroloculina, D'Orb.	*Quinqueloculina*, D'Orb.
Triloculina, D'Orb.	*Adelosina*, D'Orb.

The simplest type of the *Foraminifera* (*Monostega*) presents but a single segment, and is illustrated by the *Orbulina universa* (*fig.* 1), which is a small spherical shell with a lateral aperture, the interior of which has been occupied by the living jelly to which the shell owes its existence. The beautifully symmetrical *Lagenæ*, or Flask Animals (*fig.* 2), the British species of which have been figured by Professor Williamson in the 'Annals of Nat. Hist.,' also belong to this type.

In the order *Stichostega*, as for example the *Nodosaria*, *Dentalina* (*fig.* 3), the shell advances beyond the simple type of the *Monostega* by a process of linear budding. The first cell is usually spherical, as in *Orbulina*, but through the orifice in this primary cell there protrudes as a growth from the contained animal segment, a second segment, usually a little larger than the first, which speedily incases itself in a shelly covering. This new growth is successively followed by others developed in the same way, until the organism attains to its maturity, when it exhibits a series of cells arranged end to end in a straight or but slightly curved line.

In the *Helicostega*, a large and conspicuous group, the gemmation takes place with a spiral bias, producing the nautiloid form of shell which misled the earlier microscopists. Sometimes all the convolutions are visible. (*Operculina*, *fig.* 4.) In others the outer convolution embraces those previously formed, and conceals them (*Cristellaria*, *fig.* 5). In a third type all the spiral convolutions are visible on one truncated half of the shell, whilst they are embracing on the others (*Faujasina*, *fig.* 6), thus combining the other two types. Some genera, like the Stichostegous and Heliostegous orders, develop on the plan of the latter, up to a certain stage of their growth, when the arrangement of the cells ceases to be spiral and becomes straight, (*Spirolina*, *fig.* 7), as in the *Nodosariæ*. The orifices penetrating the septa and connecting the contiguous segments are sometimes single, and at others more numerous.

1 2 3 4

7 5 6

1. *Orbulina universa.* 2. *Lagena striata*, var. *perlucida.* 3. *Dentalina communis*; Chalk. 4. *Operculina.* 5. *Cristellaria Lyonsii*; Chalk. 6. *Faujasina.* 7. *Spirolina.*

In the *Entomostega* the shell is spiral, as in the *Helicostega*, but instead of each chamber being equilateral, it has a larger and a smaller side, the position of which is alternately reversed as the segments are multiplied. (*Cassidulina*, *fig.* 8.)

In the *Enallostega* the new segments are arranged alternately on opposite sides of a central line, so as to form two parallel, non-spiral, alternating series (*Textilaria*, *fig.* 9), the segments being connected by a single orifice.

The *Agathistega* present an entirely different aspect, as well as structure, from the rest of the *Foraminifera.* They are much less transparent than the majority of the other orders, being composed of a material resembling white porcelain, and which presents a rich amber-brown hue when viewed by transmitted light. They are usually more or less oblong, and as each new segment is equal to the entire length of the shell, it follows that the terminal orifice presents itself alternately at its opposite extremities. Sometimes the new segments are spread out in one uniform plane (*Spiroloculina*, *fig.* 10), at other times each new segment instead of being exactly opposite its neighbour, is a little on one side of it; consequently the chain of segments is wound round the primary central one, as the thread is around a ball of worsted. (*Quinqueloculina*, *Triloculina*.)

In the great majority of the species the interior of each chamber is simple and undivided, but there are some forms, especially amongst the *Helicostega*, in which the newer and more external chambers are subdivided either by transverse pillars or by complete partitions perforated by one or more apertures, through which prolongations of the gelatinous substance unite the various segments of the soft animal. (*Orbiculina*, *fig.* 11.) Ordinarily but one such chain of communications exist (animal of *Rosalina*, *fig.* 12); but in the cases just referred to, there is a great increase in the number of such orifices, so that the septa become completely cribriform. The distribution of these apertures affects the gemmation or mode of growth, since it is through them that the new segments are successively formed, the gelatinous substance being extended by a process of budding or sprouting. An increase in the number of such orifices is most common where the consecutive segments present a rapid increase in their size. In the genus *Orbiculina*, this growth is sometimes so remarkable that the new segments soon form concentric circles, embracing all those previously formed. (*Orbiculina complanata*, *fig* 11.) In such examples the connecting apertures are distributed round the entire periphery, and gemmation most probably takes place simultaneously through them all; so that the soft animal, if decalcified by an acid, would present a succession of rings, inclosing one another, and connected together by transverse radiating bars.

The memoirs of Professor Williamson have shown that the shell inclosing each new segment is at first very thin; but as additional calcareous chambers are formed, each such addition not only encases the new gemmation of the soft animal, but extends over all the exterior of the previously-formed shell. The exact way in which this is accomplished is doubtful; but it is probable that the soft animal has the power of diffusing itself over the shell, and depositing upon its surface additional layers of calcareous matter.

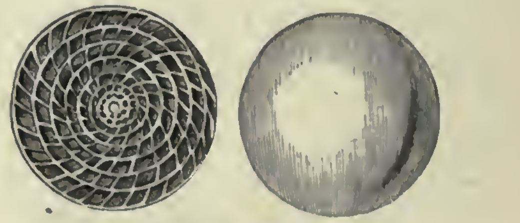
8. *Cassidulina*. 9. *Textilaria*. 10. *Spiroloculina*. 11. *Orbiculina complanata*. 11a. Part of two chambers of an *Orbiculina*. 12. Decalcified animal of a *Rosalina*. 13. *Rosalina globularis*, viewed as a transparent object showing the foramina. 14. Horizontal section of Fig. 6, showing the internal system of tubes. 15. Fossil *Nummulina*. 16. Vertical section of Fig. 15. 17. *Verneuilina tricarinata*; from the Chalk. 18. *Rosalina Lorneraria*; from the Chalk. 19. *Globigerina cretacea*; from the Chalk.

The foramina in the calcareous shell present various appearances. Sometimes they are large and conspicuous (*Rosalina globularis*, fig. 13); at others they are so small that their existence is only to be demonstrated by means of high magnifying powers. Through these foramina, long delicate processes of the soft animal, termed pseudopodia, are protruded. The exact use of these, whether for tactile, prehensile, and locomotive purposes, or for the imbibition of nutritive fluid, is not very clear; but they very probably fulfil in some degree each of these functions. They may be regarded as analogous to the prolongations which the Proteus Animalcule (*Amœba*) extends in various directions; only in the *Foraminifera* these organs are more delicate as well as more uniform in thickness than in the shelless creature referred to.

Professor Williamson has also demonstrated the existence in several species of a curious system of interspaces and branching tubes, which ramify amongst the calcareous layers forming the walls of the shells. (Horizontal section of *Faujasina*, fig. 14.) These are especially obvious in the genera *Faujasina*, *Operculina*, and *Amphistegina*. The tubes open at the exterior of the shell, especially at the peripheral margins, either by a few large or by numerous small apertures. These canals are probably designed to admit water to the interior segments of the animal, with which they communicate through the minute foramina. In some cases the pseudopodia are protruded through such of these canals as are situated in the umbilical region; but these appear to be exceptional instances.

The relations of the *Foraminifera* to Palæontology render them interesting objects to the geologist. Many of the more recent calcareous strata chiefly owe their origin to the accumulation, through successive ages, of these minute atoms. The White Chalk Rocks are mainly composed of them; vast ranges of Tertiary Strata present the same characteristic features; and though the older Limestones have been so altered by pressure and chemical agents that their origin is less clear, there are many indications that they have primarily resembled the rocks of more recent age—an inference that is rendered probable by the great extent to which sediments now accumulating in the bottom of the sea are charged with these little organisms, and in some cases entirely composed of them.

The Fossil *Foraminifera* are chiefly distinguishable from recent ones in the greater prevalence of specimens of comparatively large size. Though one recent species was brought from Borneo by Sir E. Belcher measuring more than 2 inches in diameter, the living forms usually range from the $\frac{1}{4}$th to the $\frac{1}{100}$th of an inch. But the Tertiary Strata of the earth abound in examples of the fossil genus Nummulite (*Nummulina*, *fig.* 15), so called from their resemblance to coins, which vary from the $\frac{1}{8}$th of an inch to the size of half-a-crown. These are often so abundant as to form mountain masses, extending through the Alps, Northern Italy, Greece, Syria, Egypt, and Northern India. The Mokkadam Mountains in Egypt, where the stone used in building the pyramids was obtained, chiefly consist of these Nummulites, which are known to the natives by the name of Pharoah's Pence.



Nummulites lenticularis.

The structure of the Nummulites has been investigated by Messrs. Jolie and Leymeric, and especially by Dr. Carpenter, whilst the specific forms have been studied by M. D'Archiac. The genus belongs to the group of the order *Helicostega*, in which the outer convolutions completely embrace the earlier-formed ones; hence it is only by making microscopic sections, or thin slices, that their structure can be fully seen. When such a section is carried horizontally through the centre of the shell the segments present a spiral arrangement; they as well as the convolutions being remarkable for their small size and consequent great number. In other respects they present few or no essential differences distinguishing them from more recent forms. A still more curious genus, known by the name of *Orbitoides*, occurs in America, Switzerland, and India; in the former of which countries it appears largely to represent the Nummulites of the Old World. The labours of Dr. Carpenter have revealed a remarkable structure in this genus, but one that appears to have some recent representatives.

Forms of *Foraminifera* have been found in every formation from the Silurian to the Tertiary. In most countries the superficial marls and silts which are associated with peat are found to be full of the siliceous shields of *Diatomaceæ*, and with these are found the calcareous shells of *Foraminifera*. They diminish in numbers as we pass below the Chalk; perhaps also they recede more from the forms of existing minute *Polythalamacea*, but this is a point requiring further investigation. The most abundant forms in the Chalk belong to *Rotalia*, *Spirolina*, and *Textilaria*. In the Oolites and Mountain Limestone the forms generally resemble those of *Textilaria*.

The following table exhibits a summary of the distribution of the genera :—

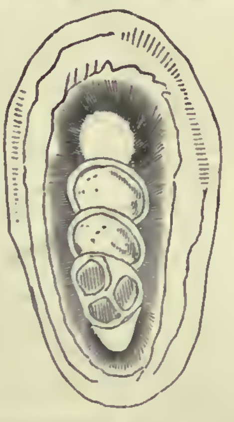
In Cainozoic Strata of Britain, according to Morris's Catalogue.

Anomalina.	*Polymorphina.*
Biloculina.	*Polystomella.*
Cristellaria.	*Quinqueloculina.*
Dentalina.	*Rotulina.*
Glandulina.	*Rosalina.*
Globigerina.	*Rotalia.*
Marginulina.	*Spiroloculina.*
Nodosaria.	*Textilaria.*
Nonionina.	*Triloculina.*
Operculina.	*Truncatulina.*
Planorbulina.	

In the Cainozoic Strata, taken generally, Bronn enumerates 46 genera, and Ehrenberg has augmented the number.

In Mesozoic Strata. Chalk of Maestricht, Meudon, Wilts, &c. (Morris's Catalogue.)	*Bulimilina.*
	Cristellaria.
	Dentalina.
	Gaudryina.
	Globigerina.
	Lituola.
	Marginulina.
	Nummulina.
	Rosalina.
	Rotalia (7 species British).
	Siderolina.
	Spirolina.
	Textilaria.
	Truncatulina.
	Turbinulina.
In Mesozoic Strata. Oolite of Caen. (Bronn.)	*Cristellaria.*
	Planularia.
Oolite of Stonesfield.	*Textilaria* (?).
	Rotalia (?).
Oolite of Yorkshire.	*Rotalia* (?).
	Textilaria (?). frequent.
In Palæozoic Strata. Mountain Limestone of Bristol.	*Textilaria* (?).
Limestone of South Devon.	Genus (?).

In a fossil state the shells of *Rotalia* show the minute perforations through which the pseudopodous tentacula passed, and by a careful examination of the remains of those bodies embalmed in flint Dr. Mantell ('Medals of Geology,' vol. i. p. 232) has shown the general internal arrangement of the shell, and general form, if not the minute



Foraminifer of the Mountain Limestone, forming the centre of an oolitic grain. Power 120. (Original.)

Foraminifera of the Chalk, obtained by brushing it in water. Power 120. (Original.)

organisation, of the animal inhabitant. In a communication to the Geological Society of London this author has expressed his opinion that the soft body of *Rotalia* is actually silicified, and distinguishable by colour from the clearer flint which has replaced the shell.

The relation of the Fossil *Foraminifera* to the recent types is perhaps closer than that of most other tribes. It appears not only that several Tertiary forms are identical with living species, but further, according to Ehrenberg, that no less than nine or ten *Foraminifera* of the Chalk are undistinguishable from existing species. The following is the list of those species and the localities where they occur in real Chalk :—

1. *Globigerina bulloides*	Denmark.
2. *Globigerina helicina*	Cattolica.
3. *Rosalina globularis*	Gravesend.
4. *Rotalia ocellata*	Cattolica.
5. *Rotalia globulosa*	Rügen.
6. *Rotalia perforata*	Cattolica.
7. *Rotalia turgida*	Gravesend.
8. *Textilaria aciculata*	Brighton.
9. *Textilaria globulosa*	Rügen.
10. *Spirolina cylindracea*	Paris.

Even if some doubt must remain as to the exact identity of the specific forms thus declared to occur, both in recent and in cretaceous beds, the analogies are too close and too numerous to allow of hesitation in admitting that the Foraminiferous races of the Mesozoic and Cainozoic periods have more decided affinity than appears in any other group of organic life. As some of the *Polypiaria* of the Silurian series pass upwards into the Devonian era, some of the *Foraminifera* of the Chalk, with *Terebratula vitrea* and *T. Caput Serpentis*, appear to reach our own day ; and thus by feeble, but not to be neglected links, the systems of ancient and modern life are united into one only partially discontinuous series ; the seeming interruptions being in the higher grades of life, the less striking connections being formed by the simpler marine organic structures, which might better survive great physical catastrophes, and better endure successive variations in the condition of the sea.

FORBIDDEN FRUIT. [CITRUS.]

FOREST-FLY. [HIPPOBOSCA.]

FOREST-MARBLE, one of the upper beds of the Bath Oolite series. [OOLITE.]

FORFICU'LIDÆ, a family of Insects belonging to the order *Orthoptera*, and, according to some authors, constituting the order *Dermaptera*.

To this family belong the various species of Earwigs. They are distinguished from the Orthopterous Insects (excepting the *Blattæ* and the *Mantis* tribes, which with the *Forficulæ* constitute Latreille's family *Cursoria*) by having the posterior legs formed for running. Their wings, when folded, are almost always disposed horizontally on the body. The females have no corneous ovipositor. Both sexes however are furnished with two corneous forcep-like appendages at the hinder extremity of the body. The antennæ are slender, filiform, inserted before the eyes, and vary considerably as to the number of their joints; the thorax is generally of a rounded form, and but slightly convex.

The family *Forficulidæ* is divided by Dr. Leach into three genera, the principal characters of which are taken from the number of joints to the antennæ. This first genus, that to which he restricted the name of *Forficula*, is distinguished by having 14 joints to the antennæ. In the next genus (*Labidoura*) the antennæ have 30 joints; and in the last, the genus *Labia*, the antennæ are 12-jointed.

To the first of these genera belongs our common Earwig (*Forficula auricularia*, Linn.), an insect too well known to require a description.

Earwigs appear to prefer damp situations; are found under stones and under the bark of trees, frequently in great abundance. They are also found in flowers, which they destroy by eating the leaves, &c.

A remarkable fact connected with the habits of the Earwig is, that the female sits upon her eggs in the manner of the hen ; and the young (which resemble the parent, except in being of a paler colour and having neither wings nor elytra), as soon as they are hatched, creep under the belly of the mother for protection.

The wings of the Earwig are transparent, of large size, and when expanded are shaded like a fan : the principal nervures radiate from one point near the anterior margin. These organs when not in use are folded beneath two small horny wing-cases, and hence to the common observer the animal appears wingless.

The male and female common Earwig differ considerably in their anal forceps, those of the female being less curved and destitute of a tooth-like process which is observed on the inner side at the base of the forceps of the male.

There is in this country another species of Earwig almost equally common with that we have just noticed, but which is of a much smaller size. It is found about hot-beds and dunghills, and differs from the common Earwig somewhat in its habits as well as in its structure. This belongs to the genus *Labia*.

One species of the genus *Labidoura* is also found in England, but is of rare occurrence. It is of a much larger size than the common Earwig.

FORGET-ME-NOT. [MYOSOTIS.]

ments is wound round the primary central one, as the thread is around a ball of worsted. (*Quinqueloculina*, *Triloculina*.)

In the great majority of the species the interior of each chamber is simple and undivided, but there are some forms, especially amongst the *Helicostega*, in which the newer and more external chambers are subdivided either by transverse pillars or by complete partitions perforated by one or more apertures, through which prolongations of the gelatinous substance unite the various segments of the soft animal. (*Orbiculina*, *fig.* 11.) Ordinarily but one such chain of communications exist (animal of *Rosalina*, *fig.* 12); but in the cases just referred to, there is a great increase in the number of such orifices, so that the septa become completely cribriform. The distribution of these apertures affects the gemmation or mode of growth, since it is through them that the new segments are successively formed, the gelatinous substance being extended by a process of budding or sprouting. An increase in the number of such orifices is most common where the consecutive segments present a rapid increase in their size. In the genus *Orbiculina*, this growth is sometimes so remarkable that the new segments soon form concentric circles, embracing all those previously formed. (*Orbiculina complanata*, *fig* 11.) In such examples the connecting apertures are distributed round the entire periphery, and gemmation most probably takes place simultaneously through them all; so that the soft animal, if decalcified by an acid, would present a succession of rings, inclosing one another, and connected together by transverse radiating bars.

The memoirs of Professor Williamson have shown that the shell inclosing each new segment is at first very thin; but as additional calcareous chambers are formed, each such addition not only encases the new gemmation of the soft animal, but extends over all the exterior of the previously-formed shell. The exact way in which this is accomplished is doubtful; but it is probable that the soft animal has the power of diffusing itself over the shell, and depositing upon its surface additional layers of calcareous matter.

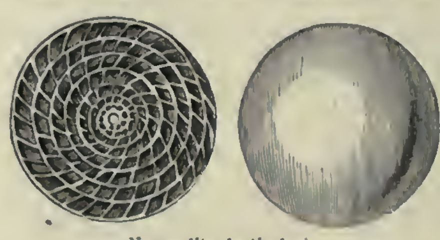
8. *Cassidulina*. 9. *Textilaria*. 10. *Spiroloculina*. 11. *Orbiculina complanata*. 11a. Part of two chambers of an *Orbiculina*. 12. Decalcified animal of a *Rosalina*. 13. *Rosalina globularis*, viewed as a transparent object showing the foramina. 14. Horizontal section of Fig. 6, showing the internal system of tubes. 15. Fossil *Nummulina*. 16. Vertical section of Fig. 15. 17. *Verneuilina tricarinata*; from the Chalk. 18. *Rosalina Lorneraria*; from the Chalk. 19. *Globigerina cretacea*; from the Chalk.

The foramina in the calcareous shell present various appearances. Sometimes they are large and conspicuous (*Rosalina globularis*, fig. 13); at others they are so small that their existence is only to be demonstrated by means of high magnifying powers. Through these foramina, long delicate processes of the soft animal, termed pseudopodia, are protruded. The exact use of these, whether for tactile, prehensile, and locomotive purposes, or for the imbibition of nutritive fluid, is not very clear; but they very probably fulfil in some degree each of these functions. They may be regarded as analogous to the prolongations which the Proteus Animalcule (*Amœba*) extends in various directions; only in the *Foraminifera* these organs are more delicate as well as more uniform in thickness than in the shelless creature referred to.

Professor Williamson has also demonstrated the existence in several species of a curious system of interspaces and branching tubes, which ramify amongst the calcareous layers forming the walls of the shells. (Horizontal section of *Faujasina*, fig. 14.) These are especially obvious in the genera *Faujasina*, *Operculina*, and *Amphistegina*. The tubes open at the exterior of the shell, especially at the peripheral margins, either by a few large or by numerous small apertures. These canals are probably designed to admit water to the interior segments of the animal, with which they communicate through the minute foramina. In some cases the pseudopodia are protruded through such of these canals as are situated in the umbilical region; but these appear to be exceptional instances.

The relations of the *Foraminifera* to Palæontology render them interesting objects to the geologist. Many of the more recent calcareous strata chiefly owe their origin to the accumulation, through successive ages, of these minute atoms. The White Chalk Rocks are mainly composed of them; vast ranges of Tertiary Strata present the same characteristic features; and though the older Limestones have been so altered, by pressure and chemical agents that their origin is less clear, there are many indications that they have primarily resembled the rocks of more recent age—an inference that is rendered probable by the great extent to which sediments now accumulating in the bottom of the sea are charged with these little organisms, and in some cases entirely composed of them.

The Fossil *Foraminifera* are chiefly distinguishable from recent ones in the greater prevalence of specimens of comparatively large size. Though one recent species was brought from Borneo by Sir E. Belcher measuring more than 2 inches in diameter, the living forms usually range from the $\frac{1}{4}$th to the $\frac{1}{100}$th of an inch. But the Tertiary Strata of the earth abound in examples of the fossil genus Nummulite (*Nummulina*, *fig.* 15), so called from their resemblance to coins, which vary from the $\frac{1}{8}$th of an inch to the size of half-a-crown. These are often so abundant as to form mountain masses, extending through the Alps, Northern Italy, Greece, Syria, Egypt, and Northern India. The Mokkadam Mountains in Egypt, where the stone used in building the pyramids was obtained, chiefly consist of these Nummulites, which are known to the natives by the name of Pharoah's Pence.



Nummulites lenticularis.

The structure of the Nummulites has been investigated by Messrs. Jolie and Leymerie, and especially by Dr. Carpenter, whilst the specific forms have been studied by M. D'Archiac. The genus belongs to the group of the order *Helicostega*, in which the outer convolutions completely embrace the earlier-formed ones; hence it is only by making microscopic sections, or thin slices, that their structure can be fully seen. When such a section is carried horizontally through the centre of the shell the segments present a spiral arrangement; they as well as the convolutions being remarkable for their small size and consequent great number. In other respects they present few or no essential differences distinguishing them from more recent forms. A still more curious genus, known by the name of *Orbitoides*, occurs in America, Switzerland, and India; in the former of which countries it appears largely to represent the Nummulites of the Old World. The labours of Dr. Carpenter have revealed a remarkable structure in this genus, but one that appears to have some recent representatives.

Forms of *Foraminifera* have been found in every formation from the Silurian to the Tertiary. In most countries the superficial marls and silts which are associated with peat are found to be full of the siliceous shields of *Diatomaceæ*, and with these are found the calcareous shells of *Foraminifera*. They diminish in numbers as we pass below the Chalk; perhaps also they recede more from the forms of existing minute *Polythalamacea*, but this is a point requiring further investigation. The most abundant forms in the Chalk belong to *Rotalia*, *Spirolina*, and *Textilaria*. In the Oolites and Mountain Limestone the forms generally resemble those of *Textilaria*.

The following table exhibits a summary of the distribution of the genera :—

In Cainozoic Strata of Britain, according to Morris's Catalogue.

Anomalina.	*Polymorphina.*
Biloculina.	*Polystomella.*
Cristellaria.	*Quinqueloculina.*
Dentalina.	*Rotulina.*
Glandulina.	*Rosalina.*
Globigerina.	*Rotalia.*

organisation, of the animal inhabitant. In a communication to the Geological Society of London this author has expressed his opinion that the soft body of *Rotalia* is actually silicified, and distinguishable by colour from the clearer flint which has replaced the shell.

The relation of the Fossil *Foraminifera* to the recent types is perhaps closer than that of most other tribes. It appears not only that several Tertiary forms are identical with living species, but further, according to Ehrenberg, that no less than nine or ten *Foraminifera* of the Chalk are undistinguishable from existing species. The following is the list of those species and the localities where they occur in real Chalk :—

1. *Globigerina bulloides*	Denmark.
2. *Globigerina helicina*	Cattolica.
3. *Rosalina globularis*	Gravesend.
4. *Rotalia ocellata*	Cattolica.
5. *Rotalia globulosa*	Rügen.
6. *Rotalia perforata*	Cattolica.
7. *Rotalia turgida*	Gravesend.
8. *Textilaria aciculata*	Brighton.
9. *Textilaria globulosa*	Rügen.
10. *Spirolina cylindracea*	Paris.

Even if some doubt must remain as to the exact identity of the specific forms thus declared to occur, both in recent and in cretaceous beds, the analogies are too close and too numerous to allow of hesitation in admitting that the Foraminiferous races of the Mesozoic and Cainozoic periods have more decided affinity than appears in any other group of organic life. As some of the *Polypiaria* of the Silurian series pass upwards into the Devonian era, some of the *Foraminifera* of the Chalk, with *Terebratula vitrea* and *T. Caput Serpentis*, appear to reach our own day; and thus by feeble, but not to be neglected links, the systems of ancient and modern life are united into one only partially discontinuous series; the seeming interruptions being in the higher grades of life, the less striking connections being formed by the simpler marine organic structures, which might better survive great physical catastrophes, and better endure successive variations in the condition of the sea.

FORBIDDEN FRUIT. [CITRUS.]

FOREST-FLY. [HIPPOBOSCA.]

FOREST-MARBLE, one of the upper beds of the Bath Oolite series. [OOLITE.]

FORFICU'LIDÆ, a family of Insects belonging to the order *Orthoptera*, and, according to some authors, constituting the order *Dermaptera*.

To this family belong the various species of Earwigs. They are distinguished from the Orthopterous Insects (excepting the *Blattæ* and the *Mantis* tribes, which with the *Forficulæ* constitute Latreille's family *Cursoria*) by having the posterior legs formed for running. Their wings, when folded, are almost always disposed horizontally on the body. The females have no corneous ovipositor. Both sexes however are furnished with two corneous forcep-like appendages at the hinder extremity of the body. The antennæ are slender, filiform, inserted before the eyes, and vary considerably as to the number of their joints; the thorax is generally of a rounded form, and but slightly convex.

The family *Forficulidæ* is divided by Dr. Leach into three genera, the principal characters of which are taken from the number of joints to the antennæ. This first genus, that to which he restricted the name of *Forficula*, is distinguished by having 14 joints to the antennæ. In the next genus (*Labidoura*) the antennæ have 30 joints; and in the last, the genus *Labia*, the antennæ are 12-jointed.

To the first of these genera belongs our common Earwig (*Forficula auricularia*, Linn.), an insect too well known to require a description.

Earwigs appear to prefer damp situations; are found under stones and under the bark of trees, frequently in great abundance. They are also found in flowers, which they destroy by eating the leaves, &c.

A remarkable fact connected with the habits of the Earwig is, that the female sits upon her eggs in the manner of the hen; and the young (which resemble the parent, except in being of a paler colour and having neither wings nor elytra), as soon as they are hatched, creep under the belly of the mother for protection.

The wings of the Earwig are transparent, of large size, and when expanded are shaded like a fan: the principal nervures radiate from one point near the anterior margin. These organs when not in use are folded beneath two small horny wing-cases, and hence to the common observer the animal appears wingless.

The male and female common Earwig differ considerably in their anal forceps, those of the female being less curved and destitute of a tooth-like process which is observed on the inner side at the base of the forceps of the male.

There is in this country another species of Earwig almost equally common with that we have just noticed, but which is of a much smaller size. It is found about hot-beds and dunghills, and differs from the common Earwig somewhat in its habits as well as in its structure. This belongs to the genus *Labia*.

One species of the genus *Labidoura* is also found in England, but is of rare occurrence. It is of a much larger size than the common Earwig.

FORGET-ME-NOT. [MYOSOTIS.]

FORMATION, a geological term subordinate to 'system,' and including special 'groups,' or assemblages of strata; in a looser sense it applies also to pyrogenous rocks and mineral veins.

FORMICA a genus of Insects belonging to the family *Formicidæ*. It is distinguished by having the foot-stalk of the abdomen composed of a single joint, the mandibles triangular, and denticulated at the edge. The females are destitute of a sting. This genus comprises about a dozen British species, the largest of which is the Hill-Ant or Horse-Ant, *F. rufa*. The neuters in this species are about one-third of an inch long, of a black colour, with the thorax, abdominal scale, and a large part of the head, red. It makes its large conical nest in the open ground in woods, &c., amassing together large quantities of sticks, straws, &c. For a description of these nests see ANT.

F. sanguinea is of a blood-red colour, with the eyes and abdomen black, and the wings dusky at the base. The neuter is similarly coloured, except that the head is darker. The male is black, with red legs. This species burrows in wood, and is one of those which steal the young of other species, rearing them to perform the duties of the nest. Two of the species subject to these marauders are *F. cunicularia* and *F. fusca*, both of which are inhabitants of this country. The latter species is of a shining black colour, with a slight ashy tinge; its form is rather long, and it is nearly smooth; the three or four basal joints of the antennæ are of a red colour, as are also the legs; the abdominal scale is large and triangular; and the ocelli are distinct. It establishes its nest under stones, moss, &c., and at the foot of trees, the nest being entirely under ground.

Among the exotic species of this genus are to be found many which are extremely injurious or annoying in their habits. Of these the Sugar-Ant of the West Indies is perhaps the most extensively prejudicial. *F. saccharivora*, as it is called, establishes its nest at the root of sugar-canes, lime-trees and lemon-trees, where it loosens the earth so that the trees are either blown down by the violent gales, or so completely deprived of nourishment at the roots that they soon die. Some years ago the injuries committed by this insect were so great that a reward of 20,000*l*. was offered by the planters to any one who should discover an effectual mode of destroying them, yet nothing could be found to stay their ravages. The aid of fire was even resorted to in vain; the insects rushing into the flames in such myriads as to extinguish it. Heavy torrents of rain at last effected their destruction.

F. indefessa, another exotic species, is described by Colonel Sykes as being an extraordinary instance of the operations of instinct in so low a form of animal life. The fondness of these insects for sweet substances is very great, and their attacks on such things were resisted in every possible manner, yet although the table, on which the confectionary and sweets were, was placed with its legs in water and removed a short distance from the wall, they succeeded in reaching them, to the great astonishment of all, until the mode of access was discovered. Colonel Sykes says, "I observed an ant upon the wall about a foot above the level of the sweets; it fell, and instead of passing between the wall and the table and alighting upon the ground it fell upon the table." Others followed its example with similar success; and it was no longer a matter for doubt as to how they continued to swarm in such numbers about their favourite food, however carefully guarded.

FORMICIDÆ, an extensive family of Hymenopterous Insects, belonging to the section *Aculeata*, and to the sub-section *Heterogyna* of Latreille, comprising the Linnæan genus *Formica*, or the numerous tribes of Ants. The family is distinguished by the wingless state of their abortive females, by the great length of the basal joint of the antennæ in the females and the neuters, in which they are elbowed at the extremity of this joint, and by the first or the first and second joints of the abdomen being knotted; the upper lip of the neuters is large, horny, and perpendicular, falling between the jaws; the eyes are rounded, or oval and entire; the jaws are large in many of the species, the form of these organs varying greatly in many of the species. In their structural character the *Formicidæ* resemble the *Tiphiæ* and *Doryli* belonging to the section of the Sand-Wasps. The neuters are smaller than the males, and these are smaller than the females; the abdomen in the first and last of these sexes is composed of six segments, in the male of seven. The females and neuters are furnished with a sting in many of the species. Those species which have stings emit an irritating fluid into the wounds which they make, while the stingless species discharge a red transparent fluid on to the skin, causing painful blisters.

The various genera of this family, according to Latreille, are:— *Formica*, *Polyergus*, *Ponera*, *Myrmica*, and *Atta*. This last genus differs from *Myrmica* only in having very short palpi; the head of the workers is generally very thick. *Acephalota* is the Visiting Ant of the West Indies. [ANT; FORMICA; POLYERGUS; PONERA; MYRMICA.]

FORSTERITE, a Crystallised Mineral, the primary form of which is a right rhombic prism. The crystals are colourless, translucent, brilliant, and small; they are harder than quartz. This substance occurs at Vesuvius accompanied by pleonaste and pyroxene. It has not been accurately analysed, but contains silica and magnesia.

FOSSIL COPAL was first found in the Blue Clay at Highgate, near London; it occurs also at Wochlow in Moravia.

It occurs in irregular pieces or small nodular masses. Its colour is yellowish or dull brown; nearly opaque. Lustre resinous. Fracture conchoidal. Specific gravity 1·046. When heated it yields an aromatic odour, and melts into a limpid fluid; it burns with a yellow flame and much smoke. When strongly heated in contact with the air, it is totally dissipated.

FOSSILS. The term 'Fossil,' in its general acceptation, signifies that which may be dug out of the earth. In this sense, antiquities, as well as natural metallic and mineral bodies, may be said to be fossils. But the word is generally used among geologists and mineralogists sometimes to designate simple and compound mineral bodies, such as earth, salts, bitumens, and metals, but more generally the petrified forms of plants and animals which occur in the strata that compose the surface of our globe. Most of these fossil species, many of the genera, and some of the families, are extinct; and all of them were considered in the darker ages to owe their origin to the plastic power of the earth. They were named *Lapides idiomorphi*, *L. figurati*, and, as their organic nature began to be suspected, *L. diluviani*. Superstition was, in old times, busy with some of them, the Belemnites and Ammonites for example.

The appellation *Petrifacta*, 'Petrifactions,' soon became common in books and catalogues of cabinets, and then Sir John Hill's proposition to denominate such petrified bodies extraneous or adventitious fossils, was adopted by many naturalists. Parkinson objected to 'Petrifactions' as a general term, and distinguished 'Fossils' by employing the expression 'Primary Fossils' to denote those mineral substances which are supposed to have been native, or, in other words, to have existed primitively in the earth; and by applying the appellation 'Secondary Fossils' to the petrified exuviæ of plants and animals. Though the terms of this last-mentioned writer are now no longer adopted, he must always be considered as one of the fathers of this branch of geology, a branch which William Smith first effectively used as the key to the stratification. In the steps of Smith the first writers on this subject have since trod; and the study of 'Organic Remains,' by which name the animal and vegetable bodies penetrated by or converted into mineral substances are now known as a whole, has become of first-rate importance in deciphering the history of the lithological structure of the earth's crust. The well-known Eocene, Miocene, and Pliocene periods of Lyell, for instance, depend in a great degree upon the proportionate absence or presence of living species among the organic remains which have hitherto been discovered in certain groups of strata of comparatively modern origin.

Some notices of the fossil plants and animals, when such are known, are given in the articles which relate to existing families, genera, or species; and extinct families, genera, and species are treated of under their respective heads.

FOSSORES, a family of the aculeated *Hymenoptera*. [HYMENOPTERA.]

FOUQUIERA'CEÆ, a natural order of Plants belonging to Lindley's syncarpous group of Polypetalous Exogens. The species are trees or shrubs, with entire oblong fleshy clustered leaves, seated in the axil of a spine or a cushion, with scarlet flowers arranged in a terminal spike or panicle. The sepals are 5, imbricated, ovate, or roundish; the petals 5, regular, combined in a long tube, arising from the bottom of the torus or calyx; the stamens 10 or 12, arising from the same line as the petals, but distinct from them, exserted; the anthers 2-celled; the ovary superior, sessile; the style filiform, trifid; the ovules numerous; the capsule 5-cornered, 3-celled, 3-valved; the valves bearing the dissepiments in the middle; the seeds in part abortive, compressed, winged, affixed to the axis; the embryo strait, in the centre of thin fleshy albumen; the cotyledons flat. This order was separated by De Candolle from *Portulaceæ* for the following reasons:—"1, because the petals were in a long tube of the same nature as that of gamopetalous *Crassulaceæ*; 2, because the capsule consists of three loculicidal cells, that is to say, which separate through the middle, forming three septiferous valves; and 3, because the embryo is straight, with flat cotyledons, and stationed in the centre of fleshy albumen." (Lindley, 'Nat. System.') In the structure of their flowers *Fouquieraceæ* resemble *Crassulaceæ*; and in the character of their fruit, *Loasaceæ*, *Turneraceæ*, and *Stackhousiaceæ*.

There are only two genera comprehended in this order: *Fouquiera*, named after Dr. Peter Edward Fouquiere, a professor of medicine at Paris; and *Bronnia*, named in honour of Henry George Broun, who has written on leguminous plants. Each of these genera has a single species: both plants are natives of Mexico. Of their properties little is known.

F. formosa is a showy shrub, and may be grown in a light rich soil, and propagated by means of cuttings, which will root freely in sand under a hand-glass in heat. *Bronnia* has been referred by some botanists to *Tamaricaceæ*.

(Lindley, *Natural System*; Burnett, *Outlines of Botany*; Don, *Dichlamydeous Plants*.)

FOX. [VULPIDÆ.]

FOXGLOVE. [DIGITALIS.]

FOX-GRAPES. [VITIS.]

FOX-TAIL-GRASS. [ALOPECURUS.]

FRACTURE, in Mineralogy, means the irregular surface which appears when a mineral is broken, so that surfaces do not constitute a Cleavage. The kinds of fracture are determined by the aspect and forms of the surface presented by the mineral. Werner divides the varieties of fracture into compact, fibrous, radiated, and foliated. The compact may be splintery, even, conchoidal, uneven, earthy, or hackly. The fibrous may be coarse or delicate, straight or curved, parallel or diverging; and the diverging again is either stellular, scopiform, or promiscuous. The radiated fracture is broad or narrow, straight or curved, diverging or promiscuous; and streaked or smooth.

FRAGILARIA. [DIATOMACEÆ.]

FRANCOA'CEÆ, *Francoads*, a very small natural order of Exogens, consisting of the genera *Francoa* and *Tetilla*. They are South American herbaceous plants, with lyrate radical leaves and a scapose inflorescence. The sepals and petals are four; the stamens four times as numerous and hypogynous, half of them being rudimentary. The pistil consists of four carpels adhering by their interior angles, with a sessile 4-lobed stigma. The seeds are numerous, and contain a minute embryo lying in a mass of fleshy albumen. Great differences of opinion have existed among botanists as to the affinities of this order. Dr. Lindley states that its nearest affinity is with *Dionæa*, which chiefly differs in its unilocular fruit, anisomerous flowers, and the want of sterile stamens. Its seeds are absolutely the same in all essential respects.

A portion of the flower-stem of *Francoa sonchifolia*.

1, the stamens and pistil; 2, a transverse section of the ovary; 3, a seed; 4, the nucleus of the seed taken from within the spongy testa; 5, a longitudinal section of the nucleus showing the minute embryo.

FRANCOLIN. [PERDICIDÆ.]

FRA'NKENIA, a genus of Plants, the type of the natural order *Frankeniaceæ*, and named in honour of John Frankenius, a professor of botany at Upsal, and the first enumerator of the Swedish plants in 'Speculum Botanicon.' It has a 5-cleft style, the lobes oblong, with the stigmas within. Capsules 1-celled, with three or four valves, and many seeded. These plants are small and heath-like, with prostrate stems; the flowers usually rise from the forks of the stem, or are disposed in terminal corymbs.

F. pulverulenta, the Powdery Sea-Heath, has its leaves opposite in whorls, obovate, retuse, glabrous, and the under surface powdery, with ciliated petioles; a slender root, and axillary terminal flowers of a pale red-colour. This plant grows in the sand by the sea-shore in many parts of Europe and Asia; it is occasionally found on the coast of Sussex in England, but is very rare.

F. lævis has clustered, linear, glabrous leaves, with revolute margins, ciliated at the base; prostrate downy stem, and terminal axillary solitary flowers. It is a native of the muddy salt-marshes by the sea-coast, in many parts of Europe and the Canary Isles. In England it is found principally on the eastern coast, and flowers in the months of July and August. The flowers are generally flesh-coloured, but sometimes white, with yellow claws.

Don enumerates 16 species of this genus, besides those already named as being found in Great Britain. Of those not British plants the majority occur in Africa and Australia, and some are found in South America. *F. hispida* grows on the rocks extending from the island of Cyprus to Siberia. The hardy species of this beautiful evergreen genus are well adapted to ornament rock-work, and may be easily cultivated. They may be propagated by cuttings or by dividing the roots, and may also be grown from seed under a hand-glass.

(Don, *Dichlamydeous Plants;* Babington, *Manual of British Botany.*)

FRANKENIA'CEÆ, *Frankeniads*, a small natural order of Exogens, allied to *Violaceæ* and *Sauvagesiaceæ*, with a procumbent habit, small leaves, and very often minute flowers half hidden among the leaves. They are all furnished with a tubular ribbed calyx, and that, together with their having 5 petals, a definite number of hypogynous stamens, and a 1-celled capsule bursting into valves, to whose edges the seeds adhere, gives them a distinctly limited character. The species are chiefly found in the south of Europe and north of Africa; they however occur in various other parts of the world; four species from Australia; two are natives of the Cape of Good Hope; one of South America; and three of temperate Asia. Endlicher says they are mucilaginous and slightly aromatic. The leaves of *Beatsonia portulacifolia* are used in St. Helena as tea. *Frankenia pauciflora*, remarkable for the size of its flowers, is a very pretty greenhouse shrub.

A twig of *Frankenia pulverulenta*, natural size.

1, a flower; 2, the pistil and stamens; 3, a transverse section of the ovary, all magnified.

FRANKINCENSE, a resinous substance, the produce of the *Abies excelsa* (De Candolle), the *Pinus abies* (Linn.), Common Spruce-Fir, from which it either exudes spontaneously or more abundantly from incisions of the bark. When it first flows out it is liquid, but on exposure to the air concretes, and is collected during autumn and winter. It occurs in two states, in tears (*Thus*, or *Olibanum sylvestre*), and in large irregular lumps or compressed cakes. When recent the colour should be white, or only inclining to yellow, subdiaphanous, soft, tenacious, and glutinous: by the action of time it becomes hard, and even friable, the colour having deepened into an orange hue. By the heat of the hand it softens, and by a higher temperature liquifies. It possesses a turpentine-like odour and taste. It is insoluble in water, but completely soluble in alcohol with the aid of heat.

It consists of two kinds of resin mixed with oil of turpentine. By melting it in water, and straining it through strong cloths, it is deprived of much of its oil, when it is termed Pix Arida, or Burgundy Pitch.

For the genuine Thus, or Frankincense of the ancients, see BOSWELLIA; also OLIBANUM, as the substances distinguished by this name (derived from the Arabic Loohan) were of different kinds, and procured probably from Africa and Arabia, as well as from India.

FRANKLINITE, a Mineral which occurs in attached crystals, granular, and massive. The primary form of the crystal is a cube; its colour is deep iron-black. Opaque. Lustre metallic. Specific gravity 4·87 to 4·09. Hardness 6·0 to 6·5. Streak deep red-brown. Cleavage parallel to the planes of the regular octahedron, but very indistinct. Fracture conchoidal. Magnetic, but without polarity.

The massive varieties are amorphous. Structure granular, compact. This mineral is found at Franklin, New Jersey, North America.

According to Berthier it consists of—

Peroxide of Iron	66
Oxide of Zinc	17
Red Oxide of Manganese	16
	— 99

FRATERCULA. [AUK.]

FRAXINELLA, the common name of a Plant belonging to the genus *Dictamnus*, which is referred to the order *Rutaceæ*. *Dictamnus* has a 5-parted, unequal, deciduous calyx; 5 unequal unguiculate petals; 10 declinate stamens with awl-shaped filiform unequal filaments, having glandular tubercles at their apex, and roundish anthers; the style single, diclinate, striated lengthwise, terminated by a blunt papillose stigma; the capsule stipitate, composed of 5 carpels, which are connected on the inside, compressed, 2-seeded.

D. Fraxinella, Bastard or False Dittany, False White Dittany, Fraxinella, has 4-5 pairs of leaflets, cordate at the base, acute at the apex, finely serrulated; the racemes long; the calyx unequal. It is found wild in the south of Europe, especially in Germany, France, Spain, Austria, and Italy.

The leaves, flowers, and stem of this plant, when gently rubbed, emit a strong lemon odour, and when bruised the scent is more powerful. The volatile oil which gives it its peculiar odour is secreted in the largest quantities in the pedicles of the flowers, which are covered with little glands of a rusty red colour, which exude a viscid resinous juice. The volatile oil from this plant is evolved in so large quantities that it will burn when a light is held near it, and, in a dark place, may be seen to take fire. It was formerly used in medicine under the name of ***Dictamnus albus***, and the root was considered stomachic, anthelmintic, and aperient. Stoerck, to whom we are indebted for the re-introduction of so many European plants into modern medicine, recommended it in epilepsy, intermittent fever, and amenorrhœa. The plant used in medicine under the name of ***Dictamnus Creticus***, the Dittany of Crete, is the ***Origanum Dictamnus*** of Linnæus. [ORIGANUM.]

D. angustifolia, has 4-5 pairs of leaflets, alternate, ovate-lanceolate, acuminated, finely serrulated; the racemes long; the calyx nearly equal. It is a native of the Altaï Mountains.

There are several varieties of *Fraxinella* found in gardens, with white, red, and purple flowers. They will grow in any common garden soil, from seeds, which ripen well in this country.

(Don, *Dichlamydeous Plants;* Burnett, *Outlines of Botany;* Lewis, *History of Materia Medica.*)

FRA'XINUS, a genus of Plants belonging to the natural order *Oleaceæ*, under which the Common Ash is comprehended. They inhabit various parts of the more temperate regions of the northern hemisphere, both in the Old and New World, but are unknown in a wild state in the southern. Although, if strictly limited, the species are destitute of corolla, yet the genus does, in fact, belong to the natural order of the olive and lilac, a transition to which is afforded by what are commonly called Flowering Ashes, the *Orni* of modern botanists, in which a corolla exists in the form of four long narrow petals. Both these genera have the kind of fruit called a key, or technically, a 'samara,' that is, a seed-vessel which does not open, which contains one or two cells, and which is prolonged into a thin wing at the apex. As they are all called ashes in the gardens, and are exceedingly nearly related to each other, we notice them both in this place.

Fraxinus, or True Ashes.

Of these the most important is the Common Ash (*F. excelsior*), a tree inhabiting the cooler parts of Europe, from Great Britain to a considerable distance through Asia. It is said to exist in Japan in a wild state, but this requires confirmation; it does not occur in North America, but species similar to it in appearance are common on that continent. The ash is one of the most useful of our British trees, on account of the excellence of its hard tough wood, and the rapidity of its growth. In its appearance too it is singularly graceful for a European tree, often resembling in its slender stems and thin airy foliage the acacias of tropical regions. Every one who has seen the beautiful effect of the ashes mingled with the ruins of Netley Abbey, near Southampton, must have been struck with this peculiarity. The principal objection to the ash is the injury it does to the plants which grow in its neighbourhood, by rapidly exhausting the soil of all its organisable materials. In consequence of this, few plants will thrive, or even grow near it; and hence the impropriety of the common practice of planting the ash in hedgerows; the extent of its roots may always be distinctly traced by the langour and paleness of the crops that stand near it. Many varieties, or supposed varieties of it, are known to cultivators, and many more might easily be collected if it were worth the while; for it sports very much in a wild state. The most striking of the reputed varieties are the following:—

1. *F. pendula*, the Weeping Ash; with all the characters of the common wild tree, except that the branches grow downwards instead of upwards, so that if grafted upon a lofty stem the head will soon reach the ground and form a natural arbour. This is said to have originated accidentally in a field at Gamlingay, in Cambridgeshire.

2. The Entire-Leaved Ash; with all its leaves simple, broad, ovate, coarsely serrated, and puckered. Nothing can well be more unlike the common ash than this, which nevertheless appears upon good authority to be merely a seedling variety. Out of leaf it is hardly distinguishable by its branches from its prototype.

3. *F. crispa*, the Curled-Leafed Ash; with very short stunted branches, and deep green crumpled leaves. If this is, as it is said to be, a mere monstrous variety of *F. excelsior*, it is one of the most remarkable with which we are acquainted. It has a particularly dark aspect; its leaves are so thick, and its shoots so short, that it forms a blackish round-headed tree of the smallest dimensions. Its origin is unknown; it, as well as the *Ornus*, is sometimes called *F. Theophrasti*.

4. *F. verrucosa*, the Warted-Barked Ash. In this the stems are covered over with a great number of little grayish brown tubercles; otherwise the plant has the appearance of the common ash.

Besides this, the only European ash that deserves notice is the *F. parvifolia*, Small-Leaved Ash. Its foliage is much finer and narrower than in *F. excelsior;* the leaflets are narrow and finely serrated, the bark is rugged, the growth slow, and instead of the toughness so characteristic of the latter species, the branches are so brittle as to be liable to constant injury from high winds. It is however a very beautiful tree, and for ornamental purposes where size is no object, it should be planted, especially as a single tree. It is possible that *F. rostrata* may be a variety of it: but nothing can be more erroneous than the idea that it is itself a variety of *F. excelsior*. It is found only in the southern parts of Europe.

In the Levant occurs the *F. lentiscifolia*, Lentisk Ash, a most graceful species, with long narrow leaves, composed of five or six pairs of small, distinct, sharply serrated, shining leaflets. It inhabits the country about Aleppo, and is hardy in this country, where it forms a tree of the most elegant appearance, intermediate, as it were, in appearance between a willow and an ash. The branches are deep rich purple. It is often called *F. Chinensis* in the nurseries.

With regard to the species of American Ash we have, in the first place, to remark that they are not well adapted to this climate, being in general too ill prepared by our short cold summers to bear our winters, and moreover injured by spring frosts: circumstances much to be regretted, because some of the species prove very handsome trees. In the second place, the number of species has no doubt been greatly exaggerated by writers upon garden botany; we cannot however at all agree with a modern writer upon these subjects, who believes all the American ashes to be one and the same species. The following are, we think, undoubtedly distinct:—

F. pubescens, the Black American or Downy Ash, with three or four pairs of leaflets, which are nearly entire, flat, downy beneath, as well as the branches. A swamp tree in the middle states of the American Union.

F. Americana, the White American Ash, with seldom more than three pairs of leaflets, which are smooth, flat, nearly entire, and glaucous on the under side; the branches smooth. A large tree in Canada and the northern states of America.

F. sambucifolia, the Water-Ash, or Elder-Leaved Ash, with three or four pairs of leaflets, which are rugose, constantly serrated, hairy at the axils of the leaves underneath; when bruised smelling a little like elder; buds deep blue. A common tree in forests in the northern parts of North America.

F. quadrangulata, with the shoots distinctly and sharply quadrangular. A tree from Ohio, among the most unsuitable of the American ashes for this climate.

F. epiptera, the Wing-Topped, Seeded, or Two-Coloured Ash, with the keys very broad and wedge-shaped at the upper end and taper at the base. The young branches are green, covered with white dots. A small tree, found all through the American Union.

All the foregoing can be procured in the English nurseries, and they perhaps form the only distinct species of the genus. A great many supposed species were distinguished by the late Mr. Bosc, whose names are current in collections; but they can scarcely be determined with precision. A fine collection of Ashes exists in one of the enclosures in Kensington Gardens.

F. Caroliniana, the Carolina Ash, has 2 or 3 pairs of leaflets, oval, petiolate, serrated, glabrous, and shining above. The flowers are calyculate. The branches glabrous and, like the buds, brownish. The racemes loose, an inch and a half long, often twin from the same bud. The pedicles numerous and umbellate. The calyx small and campanulate. It is a tree from 30 to 50 feet high; native from Pennsylvania to Carolina. It is a very remarkable variety, readily distinguished by the size of its leaflets, which are nearly round. In America it is entirely neglected as a timber-tree, and in Europe it is solely considered as ornamental.

There are a great many varieties of the species *F. excelsior*, some of which undoubtedly deserve to be considered distinct species. Several of them yield the sweet resinous laxative substance known by the name of Manna. *F. excelsior* not only produces it in the warm climate of South Europe, but is reported to have a tonic febrifugal bark and leaves almost as cathartic as those of Senna, producing unequivocal action on the system.

The species of this genus which most extensively produce Manna are now described under the genus

Ornus, or Flowering Ashes.

O. Europæa, or Common Manna-Ash, is a small round-headed tree, with leaves resembling those of the Common Ash, only the leaflets are elliptical, abruptly acuminated, and have a considerable collection of hairs at the base of the midrib underneath. In the summer when the leaves are full grown the trees become ornamented with a profusion of white delicate blossoms, which give them a strikingly beautiful appearance. The species inhabits the southern parts of Europe, especially the woods of Calabria and Apulia, and in those countries flowers in April.

O. rotundifolia is universally distinguished as a second species of this genus; differing in its leaves being much longer, the leaflets roundish, ovate, acute, not cuspidate, coarsely serrated, entire, and rather cuneate at the base, and not at all hairy underneath. In flowers it is much the same. It is a native of Calabria and elsewhere in the south of Europe.

These two plants are interesting as producing the sweet laxative substance known in the apothecaries' shops under the name of Manna. It is a secretion from the leaves and branches; and, according to Fée, is caused either by artificial wounds or by the puncture of an insect. Both species yield the substance, but, according to Tenore, that from *O. rotundifolia* is of better quality than the other.

"In Calabria and Sicily," says this physician, "in the hottest part of the summer months, the Manna oozes out of the leaves, and from the bark of the trunk and larger branches of the *Fraxinus*, or Calabrian Ash. The *Ornus* likewise affords it, but from the trunks and larger branches only, and that chiefly from artificial apertures; whereas it flows from the *Fraxinus* through every little cranny, and bursts through the large spores spontaneously. The different qualities of the Manna are from different parts of the tree."

The sweetness of this substance is not due to the presence of sugar, but to a distinct principle called Mannite, which differs from sugar in not fermenting with water and yeast. Some trees yield the Manna spontaneously; these only grow in the most favourable situations, and the sap runs out during the greatest heat of summer. It begins to ooze out about mid-day, in the form of a clear liquid, which soon thickens, and continues to appear till the cool of the evening, when it begins to harden into granules, which are scraped off the following morning. This kind is called 'Manna in Tears,' and is as pure and white as the finest sugar. Inferior qualities are obtained by making incisions in the trees, which forms the principal part of the Manna sold in our shops.

(Loudon, *Arboretum Britannicum*.)

FRAZE'RA, a genus of Plants belonging to the natural order *Gentianaceæ*, named after John Frazer, a collector of North American plants. It has a 4-cleft deeply-parted calyx. The corolla 4-parted, rotate, deciduous, with a bearded orbicular gland in the middle of each segment. The stamens 4, inclosed; filaments filiform; the capsule compressed, partly margined, 1-celled. The seeds few, imbricated, elliptical, winged, and fixed to the margins of the valves.

F. Carolinensis, the *F. Walteri* of Michaux, is the only species of this genus. It has a biennial root; stem from 3 to 5 feet high, erect, sub-quadrangular, and smooth; leaves opposite and verticillate, oblong, lanceolate, the lower ones a foot long and more than 3 inches broad; flowers in aggregate clusters. This plant is indigenous in the swamps of the Carolinas, and is found on the borders of lakes in Pennsylvania and New York. The whole plant has a very stately appearance, and in character approaches so near to *Swertia* that, without examining the fruit, it might be mistaken for a species of that genus. The root yields a powerful bitter, nearly as pure as that of quassia, and wholly destitute of aroma. It is fully equal in its medicinal effects to gentian, and when fresh is said to be emetic and cathartic. The roots have been imported into Europe as a sort of Calumba, and hence have acquired the name of American Calumba. This plant requires moisture, and flourishes best in a peat soil. It should be protected the winter after being raised from seed or that preceding its flowering.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

FREESTONE. [SANDSTONE.]

FREGILUS. [CORVIDÆ.]

FRENCH BERRIES. [RHAMNUS.]

FRIGATE. [PELECANIDÆ.]

FRINGE-TREE, the English name of the American shrub *Chionanthus Virginica*.

FRINGILLA, a genus of Birds belonging to the order *Fringillidæ* and the division *Insessores*. The beak is straight, longer than deep, conic, and pointed; mandibles nearly equal, cutting edges entire, forming a straight commissure; nostrils basal, lateral, oval, partly hidden by the frontal plumes. Wings with the first quill-feather longer than the fifth, but a little shorter than the second or third, which are equal, and the longest in the wing. Legs with the tarsi of moderate length; toes divided, and adapted for hopping and perching; claws curved and sharp.

F. cœlebs, the Chaffinch. [CHAFFINCH.]

F. montifringilla, the Mountain Finch, Brambling, or Bramble Finch. This bird is a visiter to this country only in winter, coming to us from the north, but at different times, according to the temperature of the country from which it emigrates. They have not been known to breed in any part of this country; those kept in confinement under the most favourable circumstances have never done so. It is not an uncommon bird in Denmark. Mr. Hewitson saw them at one place in the southern part of Norway, where they were breeding. It is described as building in fir-trees; the nest formed of moss, and lined with wool and feathers; the eggs four or five in number, white, tinged with yellow, and spotted with dark red, like those of a chaffinch. The call-note of this bird is a single monotonous chirp.
